Having noticed, from time to time, the methods used by different engineers in keeping plant records, I submit our system. Hourly readings are taken of the load in amperes and marked in the space for the generator or generators that are running; also, the boiler pressures in the same way, checked up with a recording steam gage. The time of starting and stopping and length of run of each engine are recorded, and the time boilers are cut in or out and the fires are cleaned. The temperature of the feed water before and after passing through the rubbish furnace is also recorded.

This furnace is used for burning waste paper, straw and wood collected during the day. The feed water, as it goes to the boiler, is pumped through two coils, one used as a grate and the other over the fire. By this arrangement the feed water is brought up to 260 degrees or over. Exhaust steam is used on the heating system, and space is provided for recording the back pressure on this system.

We have no way of weighing our coal at present, but coal is measured in a box holding 20 cubic feet. This box has no bottom, is placed on the boiler-room floor and filled even with the top. Then it is lifted, leaving the coal in front of the boiler. The number of boxes used during a run is recorded, also the number used between runs. Coal is weighed once a week in a box holding just 1 cubic foot, to check up the weight of the different lots of coal.

All feed water passes through a meter which is read at the beginning and end of a run. With the meter readings, the temperature of the feed water and the weight of the coal by measure, and the amount of water evaporated per pound of coal can be figured, thus giving an approximate test on the boilers every day.

Another meter is provided for any new water that is used for boiler feed, which in the winter months amounts to very little, as the returns from the heating system are used over. On the opposite side of the card are recorded the cost and output for the day. Wattmeters are read at the end of a run; the cost of supply and labor for the day are kept, and fixed charges, such as depreciation, insurance, rent of space occupied by plant, interest on investment, etc., are added. With the output and cost with and without fixed charges the cost per kilowatt-hour is easily ascertained.

The weather report is posted in the space. This has been found very useful in comparing one month with another, as to cloudiness, which would account for a heavier or lighter load; also, the temperature, which would account for more steam for heating purposes.

Ashes are recorded by the cans, and are removed at a fixed cost per can. At the end of each month a typewritten report is made out as to the amount of coal on hand the first of the month, the amount received, the amount used and the balance.

The amount of water used for the month as per meter for new water, the output for each recording wattmeter, the number of hours each engine has run and the number of hours each boiler was under steam are recorded.

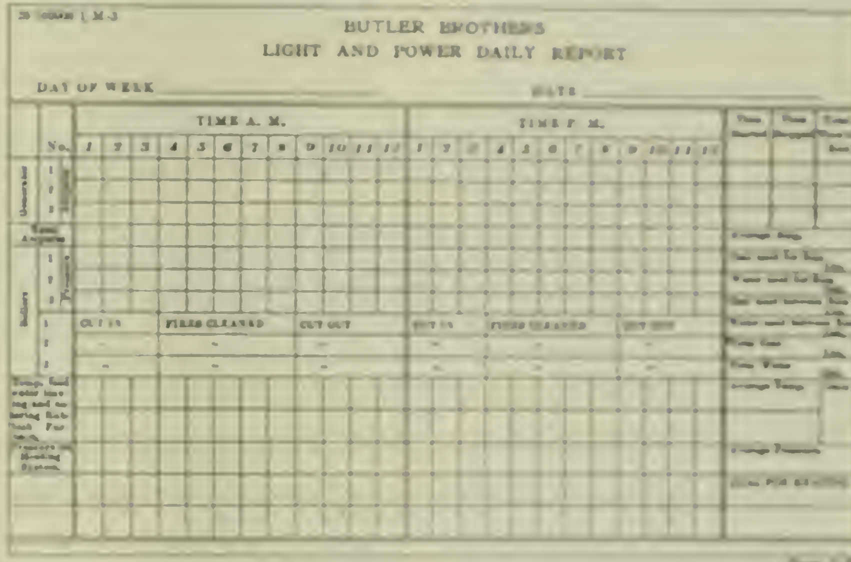
The temperature of the feed water before and after entering the rubbish furnace, showing the gain in degrees and allowing 10 degrees for 1 per cent. saving in coal, and the percentage of coal saved by using rubbish furnace are followed by the cost of coal, water, labor, oil, grease, waste, packing, repairs, etc., to which are added the fixed charges. From this is figured the cost per kilowatt-hour, with and without fixed charges for the month.

During the winter the number of hours the heating system was on and the average pressure are recorded. A monthly report of the weather is attached to the report.

This system has been found very useful in comparing the cost of running the plant from month to month or year to year, and several improvements and changes have been made as the result of these records, which have reduced the cost of operation and cost per kilowatt-hour considerably.

CHARLES W. [illegible]

Jersey City, N. J.



OBVERSE SIDE OF DAILY REPORT

REVERSE SIDE OF DAILY REPORT

The accompanying record is a copy of that of January 1, 1909, and I fill in a blank like this every day. I do not [illegible] it to be as accurate as if I had [illegible] cording instruments, but it is accurate enough for me, and it is very little trouble for one of the men to fill in the reports every hour. Each day I strike an average and put the results in a book, and at the end of the month I do the same again; thus I can look back to any month and know just what was done, and can tell very closely the number of kilowatts generated and the number of hours each machine has run, how much ice it has made, also the supplies used. I weigh all coal as it is brought to the boiler room, and also keep an expense sheet showing the cost and time of purchase of all supplies, and where used.

Remarks:

Safety Valves

Regarding the recent discussion of this subject before the American Society of Mechanical Engineers, in my opinion the proposed rule for areas of safety valves should include a term for a fixed lift rather than a variable one, for the reason that with the latter would result a hopeless confusion of safety-valve openings in boilers of the same size. Thus, under Mr. Darling's rule a boiler of a certain size might be provided with a safety-valve connection varying from 2½ to 4 inches in diameter, depending upon the make of valve specified. It would be far more convenient and satisfactory to standardize the safety-valve connections so that any valve, having the capacity required, could be used. To do this it would be necessary that the valves themselves be standardized within certain set limits and this could be done only by a body of disinterested and capable engineers, properly authorized to investigate the subject from a universal standpoint.

What is the proper lift is a more or less debatable question, but it is reasonable to suppose that the average practice of the leading, reliable manufacturers, disregarding the minimum and maximum extremes, is very nearly correct. Considering the elements of design of the various parts, closeness of adjustment, smooth popping and closing action and rate of discharge, a properly constructed valve will work better at a certain lift than at any other. High-lift valves are certainly no improvement nor are they necessary for general purposes. If they were, the standard designs could be very easily altered with but little expense and manufacturers would not be slow in making the necessary changes.

If the lift is too high the seats and spring bearings are subject to a severe pounding action; there is more danger of chattering; close adjustment is not possible; there is danger of lifting of water and the boiler seams are sometimes strained to the opening point.

On the other hand, with a correctly designed valve having a reasonable lift the wearing effects and the dangers are reduced to a minimum; it is capable of very close and accurate adjustment and its action is smooth and reliable.

Having determined what is the proper lift, it becomes a very simple matter to formulate the rule governing safety-valve discharge areas or seat-opening diameters. The only thing remaining would then be to determine what variation there should be in valve sizes to suit various pressures.

Jerome J. Aull.

Cincinnati, O.

In connection with some special work, it was desirable to have reasonably accurate data on the relieving capacities of pop safety valves of various sizes. Kent's "Pocketbook" was naturally turned to, but the 1900 edition had few accurate data. Next, publications emanating from well known insurance companies were examined, and again the data were incomplete. Finally, the rules and regulations of the United States Board of Supervising Inspectors were searched, and as usual nothing was found but generalities and a long list of approved makes of pop safety valve. This was discouraging, as it would naturally be assumed that a safety appliance as extensively used as a pop safety valve would have been most minutely tested by both the United States Government and insurance interests before approving for general use.

As the writer understands it, the primary function of any safety valve is to open at a predetermined pressure and to have a relieving capacity sufficient to handle the maximum amount of steam that the boiler to which it is attached can generate. The promptness with which these functions are performed is a measure of its value as a safety appliance. The durability of the valve in service is a matter of proper mechanical design and the use of the best materials and workmanship.

That the pop safety valve has not long since been thoroughly investigated is surprising, especially when the large amounts of time and money expended in researches having no other possibilities than small gains in operating economy are considered. Economy merits much attention, but should not safety receive equal consideration? Upon what proper data do the United States Board of Supervising Inspectors and the boiler-insurance companies approve of such a long list of pop safety valves? A careful examination of the construction of the various types shows that there must be wide differences in their relieving capacities, size for size, and yet the most diligent search of the United States rules did not show any suggestion that the officially approved valves were widely different in this respect.

In an official publication like the United States rules, the reader naturally assumes that approval, without qualification or specific classification, indicates that the approved fittings are of equal reliability and of substantially similar merit. That such is not the case will be evident to any experienced engineer examining the various constructions.

It would therefore seem that it is incumbent on the Government and the insurance companies (since approval by these authorities is almost mandatory) either to make or to have made by competent engineers complete qualitative and quantitative tests on all approved pop safety valves, and to insist that all new designs shall be similarly tested before approval. Quantitative tests should be made at specified standard pressures to show the relieving capacity in pounds of steam per hour which a particular valve will have at the specified pressures. The tests must be sufficiently comprehensive to determine the relation between the relieving capacity and pressure for each standard size of the approved types, and the experimental results could be set out in empirical formulas applying to each make of valve.

For such formulas the basis is clearly indicated in Kent's "Pocketbook" and involves the circumference of the opening, the form of the discharge passages, reaction, and other constants peculiar to each design. The diagram of relieving capacities at various pressures should consist practically of a series of straight lines having their origin at the zero of absolute pressure. The main experimental work would consist of actual determinations of the relieving capacities at 100, 150 and 200 pounds, and interpolating for intermediate pressures.

In order that the users of pop safety valves, as well as the insurers and inspectors, shall profit by these researches, it could be made obligatory on the part of every manufacturer of pop safety valves permanently to stamp on every valve the relieving capacity at some standard pressure or at the pressure for which it is set. This would place the user in position to specify the relieving capacity at a particular pressure and select his valves on a basis of mechanical design and construction.

At present, it is apparently the practice of boiler manufacturers to make term contracts for safety valves with some manufacturer of approved reputation. With the generality of manufacturers, this means that strictly commercial considerations determine the make of valve to be furnished on the boiler contracts and unless the purchaser very carefully specifies and vigorously insists on the highest quality of valves, an approved valve of inferior grade is supplied.

In view of the commercialism which largely rules, this subject should be taken up and aggressively handled by the great arbiters of safety appliances, namely, the United States Government and the insurance companies.

Knock in an Engine

In reply to J. W. Bryant regarding the knock in his engine, I had the same experience and found that the trouble was in the bull ring, which had about 1-32 inch play. I turned off the follower head to a better fit and the knock was gone.

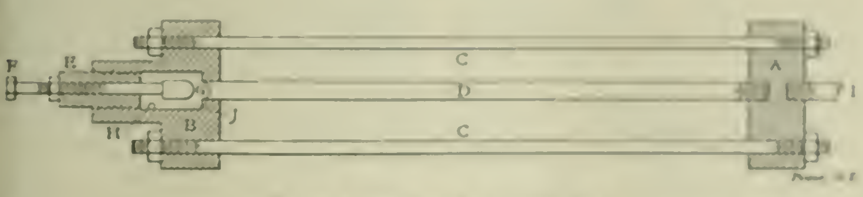
G. W. Gresham

Marietta, Ga.

A Steam Saver

In one of the plants in which I was engineer, several heating coils were connected to the high-pressure steam line and located in such position that it was impossible to connect them to the return line. They were, therefore, allowed to drip outside.

It was decided to make several "steam savers," in the following manner, the expansion and contraction of our iron pipe being the principle involved in the operation:



A "STEAM SAVER" FOR HEATING COILS

The two castings A and B (see sketch) are held at a fixed distance apart by the two 3/4 inch rods C C, which are about 5 feet long and about 8 inches apart. Between these rods is a piece of common iron pipe D, threaded and screwed tight into the casting A. The other end is turned smooth and is a loose fit in the block B, the end being seated at an angle of 45 degrees.

The block B is drilled and threaded to receive the brass plug E, tapped for the valve stem F, which adjusts the valve F to the seat G and is ground to a good fit. A hole at H connecting with the chamber J is threaded for a 1/4 inch pipe to carry away the discharge from the trap. The heater is connected at I and is set with the valve end a little lower than the other end.

To put in operation, screw the valve away from the seat and let steam blow through until the pipe is hot, then set up on the valve until seated, then fasten with the locknut. When the pipe gets full of condensed steam it will contract enough to open the valve and let the water out, but as soon as it begins to warm up it will expand and check the flow.

The valve and seat can be examined without disturbing the adjustment by taking out the plug E, and when once set the valve will not need any attention for a long time.

Hong, O.

Boiler as a Water Supply Tank

Under the above heading recently, A. J. Dixon describes a water system designed for a hotel plant by an inexperienced technical graduate. That he is inexperienced can easily be seen, and that he is woefully shy on technical knowledge is also manifest.

A much more economical plan would be to place an open tank in the attic, if possible, to be supplied by the house pumps. The water level in the tank could be kept nearly constant by a float operating a current switch at the pump motor. By this plan a much more uniform pressure would be maintained on the house service, and unless the building were a high one the head would be much less than 80 pounds. If the water supply from the pumps were shut off for some time the water in the tank would continue the supply for some time, which could not be done with a pressure tank.

Norman Campbell

Detroit, Mich.

Compound Engines

In a recent contribution C. L. Hansen says I produced indicator diagrams to prove that a compound engine develops twice the horsepower that a simple engine does. I may have a wrong idea of compound engines, but neither Mr. Hansen nor anyone else has proved otherwise.

Mr. Hansen says that the data I furnished only showed that I had the work nearly equally divided between the high- and low-pressure cylinders. That is true, but suppose these diagrams show 100 horsepower in the high-pressure cylinder and 100 horsepower, or nearly so, in the low-pressure cylinder; we have a 200-horsepower engine, do we not? Suppose we remove the low-pressure cylinder, do we still have a 200-horsepower engine?

It is certainly cheaper to build a 200-horsepower simple engine than a 100-horsepower compound, but if a compound can be made to do twice the work of a simple engine is it not more economical than a simple engine whether running condensing or noncondensing?

I have learned that in order to increase the power of an engine one should either raise the boiler pressure, speed the engine up, enlarge the cylinder, or compound by adding a low-pressure cylinder.

G. W. Hanson

Lexington, Neb.

Follower Plate and Bolts Broke

When our 20x36-inch Corliss compound engine was started one morning there was an unusual click in the high-pressure cylinder. We did not shut down, however, but on the morning of the third day the click was more noticeable than ever. About 10 o'clock it knocked so hard that we shut down and taking the cylinder head off, found that the follower bolt had broken off and dropped down into the exhaust-valve port. The valve bracket was broken and the valve stem twisted about half a turn. The bracket was patched and the valve stem turned up and replaced.

The engine ran well for a week, when one day, as the chief was shutting down, another bolt broke. Taking off the cover we found that the follower plate and one bolt were broken, the piston rod bent and the cylinder out of true.

Repairs were made, but we never found out what broke the bolts and follower plate.

F. L. Ferguson.

Adams, Mass.

Puzzling Transformer Action

In reply to E. L. Mason's "Puzzling Transformer Action" in a recent number, I think the iron in the transformer must be working at a low value, and when the switch is in the down or bucking position the transformer works in a reverse condition; that is, the secondary or series winding produces enough flux to induce a higher voltage in the primary winding of transformer *C* than is upon the terminals of the constant-current transformer *A*, thereby raising the line voltage as stated.

By having the primary connected on the load side of the line as shown in the diagram, I should think there was enough phase displacement between primary and secondary to disturb the operating of the line. I advise Mr. Mason to try the primary connected to the power or left-hand side shown in his diagram of connections.

L. Earle Brown.

Ensley, Ala.

I think Mr. Mason has not considered the choking action of the secondary winding of his potential transformer when the switch at *D* is open.

I believe his transformer "bucks" all right, but it "bucks" more when one winding is open. If he provides a switch for cutting out the other winding of the transformer *C* when the switch at *D* is open, he will get the results he is after.

F. W. Cerney.

Mesa, Ariz.

I should say that the only thing wrong with the connection is that the primary of the boosting transformer is connected to the boosted side of the line.

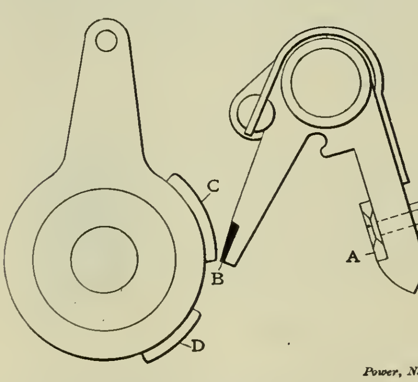
This should not be, as the voltage supplied to the primary has no stability only under certain conditions. I would advise that the primary of the booster transformer be connected to the line between the load transformer and the coil which is in series with the line. Then the voltage supplied to the primary will be practically constant and will not be affected by the lowering or raising of the voltage. Under this condition the results desired can be obtained.

James E. Kilroy.

Lincoln Place, Penn.

Safety Cams

The writer has seen a number of engines on which the steel toe *B* (see sketch) had become worn down as shown. In one instance the engineer shortened the regulator rod to get the desired trip by bringing down the steel *C* nearer to *B*, but throwing the safety trip *D* out of its



ILLUSTRATING SAFETY-CAM WEAR

reach. In case the regulator stop is out and the belt should break under such conditions, away goes the engine at full stroke.

This was once the case in my present plant. To demonstrate the fact, I left the stop out when shutting down one day, with neither steam valve unhooked.

There is also another way of throwing the back trip *D* out of place. In the erecting shop the engine valves are set, and wristplate marked, showing the throw of the eccentric. Then the wristplate is set on its center mark and, according to the diameter of the cylinder, is given the desired lap, which places the eccentric about 135 degrees ahead of the crank when on its dead center. This setting will give a square corner at the closure, and a very late opening for the exhaust.

The engineer will want compression, and the more he rolls the eccentric ahead the more lap he gives the steam valves and the more he throws the safety trip *D* back, making it impossible to unhook should the belt break.

John Tryon.

Lynchburg, Va.

Boiler and Furnace Construction

Those who have made boiler making a separate branch of manufacture have given too much attention to mere relative proportions. One maker places reliance on enlarged grate surface, another on large heating surface, while another demands boiler room enough without, however, explaining what that means.

Among modern treatises on boiler construction this principle of room enough seems to have absorbed all other considerations and the requisites in general terms are summed up as sufficient amount of heating surface, sufficient steam room, sufficient air space between grate bars, sufficient area in tubes and flues and sufficient large grate surface; or, in simple terms, this amounts to saying: "Give sufficient size to all parts and you will not be deficient in any." With reference to the several parts of a furnace, there are two points requiring attention, namely, the superficial area of the grate for retaining the fuel, and the sectional area of the chamber above the fuel for receiving the gaseous portion of the coal.

As to the area of grate bars, seeing that a solid is laid on them requiring no more space than it actually covers at a given depth, it is important that the area be not too large. As to the area of the chamber above the coal, seeing it is occupied by a gaseous body requiring room for its rapidly enlarging volume, it is important that it is not too small.

As to the area of grate bars, seeing grate, this will be easy to adjust, as a little observation will soon enable the engineer to determine the extent to which he may increase or diminish the length or width of the furnace. In this respect the great object consists in confining the length within such limits that at all times it will be uniformly covered. This is the absolute and only way to get economy and efficiency, yet it is the very condition which in practice is most neglected. Indeed, the failure and uncertainty which has attended most anxiously conducted experiments has most frequently arisen from neglect of this one condition. If the grate bars are not properly covered the air will enter in irregular currents through the uncovered parts. Such a state at once bids defiance to all regulation or control.

Now, on the control of the supply of air depends all that human skill can do in effecting perfect combustion and economy, and until the supply of fuel and the quantity on the grates are regulated it will be impossible to control the admission of air. In most boilers the furnace area is invariably made too shallow. The proportions allowed are indeed so limited as to give it rather the character of a large flue or tube, whose only function is to allow the combustible gases to pass through it, rather than that of a chamber in which a series of consecutive chemical processes are to be conducted. Such furnaces, by their diminished areas also have the injurious tendency that they increase the already too great rapidity of the current through them.

Constructing the furnace chamber so shallow and with such small capacity appears to have arisen from the idea that the nearer the body to be heated was brought to the firebed the greater quantity of heat would be imparted. This is, no doubt, true when we present a body to be heated in front of a fire. When, however, the approach of the colder body will have the direct effect of interfering with the process of nature, as in gaseous combustion, absolute contact with flame should be avoided where the object is to obtain all the heat which would be produced by the combustion of the entire constituents of the fuel. So much, however, has the supposed value of the near approach and even impact prevailed that the space behind the bridgewall is frequently made but a few inches deep and called the flame bed. Broader views have shown that it should be made capacious and the impact of the flame avoided. In general, it may be stated that the depth between the top of the grate bars and the shell of the boiler should not be less than 30 inches where the grates are 4 feet long, and increased in the same ratio where the length is greater.

JOHN COOK

Springfield, Ill.

Increase of Salary

As to the engineer being justified in asking for an increase in salary, depends on more than one thing. If his "boss" is the manager or superintendent, and responsible to men higher up, one reason may be that he wants all the credit for the saving due to the paying of a smaller salary, and the saving made by the engineer. In such case the man above the engineer is getting the credit, which will make him that much more solid with his "boss," when it should go to the engineer, who will never get an increase until he asks for it.

Perhaps another reason why he does not get a raise is that the "boss" realizes that he is saving him $30 per week over his former engineer, but in doing so he is letting his plant run down so that when the crash does come the cost of repairs will equal or more than equal that which is being saved at present.

NORMAN S. CAMPBELL.

Detroit, Mich.

If an engineer saves his employer $50 per week and the employer does not offer to raise his salary, it is time they had a heart-to-heart talk about the matter.

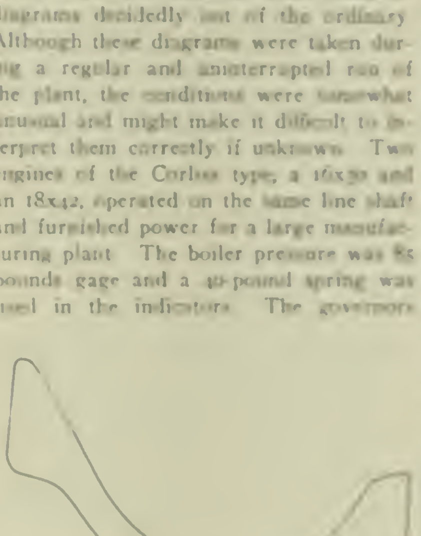
Excessive modesty in this matter of salary is not good for one's purse. It is well, also, to be prepared to tell the "boss" he can get another man for the place if he does not come up with the cash. Have your eye on another job before you bring the matter to a test, however.

F. W. CRAY.

Mesa, Ariz.

Peculiar Indicator Diagrams

The writer was called upon to test a power plant and obtained some indicator diagrams decidedly out of the ordinary. Although these diagrams were taken during a regular and uninterrupted run of the plant, the conditions were somewhat unusual and might make it difficult to interpret them correctly if unknown. Two engines of the Corliss type, a 16x30 and an 18x42, operated on the same line shaft and furnished power for a large manufacturing plant. The boiler pressure was 85 pounds gage and a 40-pound spring was used in the indicators. The governors



EXTRAORDINARY DIAGRAMS

were found to be so adjusted that nearly the whole of the load was carried by the larger engine, which gave fairly good diagrams, cutting off under normal conditions at about 0.4 stroke. The corresponding diagrams from the small engine were similar to and only a trifle smaller than the right-hand or crank-end diagram shown in the illustration. It was only under extremely heavy loads, with the large engines taking steam for practically full stroke, that the small engine began to pick up its load.

A number of diagrams were taken under the normal conditions described and everything was running smoothly when the writer was called away from the engine room. Returning a half hour later he found the small engine giving unmistakable signals of distress. Diagrams were taken with the result shown in the illustration. This led to an investigation of the exhaust valve and it was found that the key had dropped out of the valve stem. After a hurried search the engineer found the key under the cylinder and replaced it with the engine running, to the satisfaction, and all was well, or at least, as well as before.

These diagrams were, of course, only possible on account of the fact that the small engine was driven by the larger during the time of the trouble. It will be noted that the entire area of the head end is negative, representing work done by the piston upon the steam instead of work done by the steam upon the piston, and that this negative area is equal to or slightly greater than the positive area at the crank end. When one notes the pressure in the cylinder during compression it is not surprising that an engine that was generally run down should, to the best of its ability, express its resentment of such treatment.

Perhaps the most peculiar feature of the diagrams is the fact that the compression line is above the admission and expansion lines for the entire length. A very serious amount of leakage by the admission valve seems to be the only way of accounting for this.

H. M. PHILLIPS.

Pittsburg, Penn.

Architects and Heating Systems

While modern practice calls for the mechanical equipment of large office buildings and hotels, especially where independent lighting plants are included, to be designed and supervised by a firm of consulting engineers, or architects having engineers in their employ, many small installations, principally heating systems, are looked after by the architects themselves.

Many architects issue specifications of machinery which has long been standardized, without troubling to ascertain if the particular parts required conform to the manufacturer's standard. For instance, a case which came to the writer's notice a few days ago, and which was primarily responsible for this letter, was that of a firm of architects who were required to provide two boilers for a low-pressure heating system, in which the maximum pressure should never exceed 15 pounds per square inch. The specifications, besides calling for an odd-size boiler, called for a certain thickness of shell plate, which exceeded by 1/8 of an inch the thickness of the shell of a standard power boiler designed with a safety factor of 5 for a working pressure of 100 pounds per square inch.

It is not enough to know theoretically what amount of heating surface or evaporative power a boiler should have, or the amount of water a pump must deliver and the head it must deliver against, and then specify any size to fit the work, whether it be standard or not. Ought not architects who are drawing up specifications for the machinery acquaint themselves with the common standard to which these machines are manufactured, and specify one which would permit of a manufacturer quoting on his standard article, and on which he could be of assistance after quicker delivery and lower price?

Of course there are cases where, owing to conditions beyond the architect's control, a standard pump, boiler or whatever machinery is wanted cannot be installed; but then, and only then, should the architect depart from standard lines and specify special machinery.

N. H. Ballow.

Toronto, Ont.

Burning Slack Coal

The following facts were brought out in recent tests of water-tube boilers with Arkansas slack, which has a calorific value in the neighborhood of 12,000 B.t.u., and for the most part contains no lumps, although occasionally about 5 per cent. of a carload will consist of lumps the size of nut coal.

The grates used in the boilers under test are of the shaking type. The teeth grip the clinkers formed on the bottom of the fire bed, tearing them off piece by piece and working them through the grates. The air space amounts to about 40 per cent., which may seem excessive for slack, yet was not.

Before starting the tests it had been suggested that firing by coking be tried. It was found, however, that the coal would not coke, but would burn into a condition somewhat like a "quick-lunch" Hamburger steak, well done outside but raw in the center.

On the first test the damper was left wide open and a fire from 12 to 14 inches thick was carried. Every 30 minutes the grates were shaken, thus keeping the fire at the same hight without cleaning. The slice bar was used to lift the fire off the grates, being careful not to bar the clinkers up into the live coals. Every 15 minutes the rake was run over the top of the fire to break up the caked coal.

After a twelve-hour run the fire was cleaned and a number of large clinkers were found. They were quite porous, however, and had not cut down the draft to an appreciable extent. The results justify the conclusion that with the same load, 320 horsepower on a rating of 300 horsepower, more frequent shaking, or cleaning every six hours, would prevent the formation of such large clinkers. Another way to prevent large clinkers was tried later and proved even more effective.

A subsequent test on light load, about 170 horsepower, showed that a fire 8 inches thick with the damper half closed would give the best results. It had been the habit of the fireman to leave the damper wide open, carry a heavy fire and regulate the draft with the ashpit doors. This latter practice is all two common, as it is much easier to kick an ashpit door shut than to close the damper. The saving in fuel by operating with a half-closed damper and a lighter fire was shown by the fact that in twenty-four hours from 2½ to 3 tons less coal was burned than with the damper open wide with a heavy fire.

Another point brought out in the tests was the value of a steam jet in preventing the formation of clinker. At one time the clinkers formed in the fire seemed to lack their usual porous quality and the draft dropped. With the introduction of a steam jet through one of the ashpit doors, however, the draft was bettered in a short time, and the test was continued for several hours without cleaning the fire.

In slicing the fire, it had been the practice of the fireman to break up the fire, thus mixing the clinkers with the live coal. Better results were obtained, however, by lifting the slice bar only enough to separate the clinkers from the grate, making a freer path for the air without spoiling the fire.

Reversing Polarity of Machine

I am running a 300-kilowatt direct-current machine in parallel with a 500-kilowatt direct-current machine, both generating current for electric-railway work, at 600 volts. Once in awhile one of the machines reverses.

One man gave as his idea that a heavy load coming on one machine will slow it down and so reduce the voltage below 600.

Does it not pull the other machine down in the same way? If it does not, will someone state why?

Central Valve Engines

Mr. Barnett has criticized my letter on "Central Valve Engines." My object in sending that letter was to give a previous correspondent the information which he could not get.

My sketch was intended to show, not so much the correct relative position of the valve to the pistons as the distribution of the steam through the various ports, etc. In trying to show this clearly I committed the mistake as pointed out by Mr. Barnett. With the pistons as shown the valve in these particular engines should have been open to the low-pressure cylinder at the top 3/64 inch, which is the lead for that end, and the bottom high-pressure port should be open 7/32 inch, the lead for that end. The small sketch which I made, to have shown to scale, would have shown the valve practically closed, and it would have been difficult to see how the steam was distributed.

With reference to Mr. Barnett's remark "that I am not conversant with the most elementary principles of valve setting as covering the simplest slide-valve engine," I have up to the present been able to set the valves of not only this particular type of engine, but of various other types, including simple slide-valve, riding-cutoff, Corliss and that interesting central-valve, single-acting engine referred to by Mr. Barnett, having had nearly twenty years' practical experience in running, overhauling and general repair work.

Do Crank Pins Wear Flat?

The assertion is often made that the crank pins of steam engines wear flat, but I find that they do not, but they do wear out of center with the bell. Only a few weeks ago, at the plant where I am employed, the shaft and crank of an old 18x36 Corliss engine was replaced by a new one and on calipering the old pin I found it to be badly worn. I was told that the crank had been in use more than sixteen years.

A Machine Shop Blunder

A friend who owns and runs a wood-working shop sent for me to come to his place and see if I could find out what was the matter with his 12x16-inch throttling slide-valve engine. He had always had trouble in keeping up steam with a 60-horsepower boiler.

When the throttle was opened and before the engine started, steam could be heard blowing through and it did not seem to make any difference on which stroke we tried it. The valve and piston were removed, but everything seemed all right. While engaged in measuring the lap and the spacing of the ports, I chanced to look above the valve seat and saw a ⅜-inch hole leading from the steam chest to the exhaust port.

In drilling the holes for the cap screws holding the governor to the top of the steam chest, one of the holes came directly over the exhaust port, and the drill had been run through into the port. The valve seat being raised from the cylinder side of the chest, a ⅝-inch drill came through just back of the seat and one side had cut through into the chest about ⅜ inch. A short cap screw had been used which did not reach down far enough to stop the hole.

I took the old cap screw out and after tapping out the hole made a new screw that would reach down into the port, thus stopping this leak.

Some Useful Lessons of Limewater

Interesting Simple Experiments Showing the Relation of Electricity and Chemistry; A Valuable Lesson on the Carbon Compounds

BY CHARLES S. PALMER

There are so many sides to the study of chemistry that it is sometimes difficult to select the best order of attack; but one subject which naturally comes in at this time is the study of the simple primary electric battery. The main points of this primary battery can be easily mastered by anyone, and with the simplest of apparatus. We will first construct the simple battery, and in another lesson we will study some of the most important properties of the electric current, both from the physical and the chemical standpoint. It is true that we do not know much about the nature of the force which is called "chemical affinity;" but, whatever it is, it is certainly very closely connected with electrical action; and you can easily study some of the main points of this marvelous thing, the electric current, both as to the way in which it is started, and also as to what it can do chemically. It is all the easier to do this, now that we have studied the two fundamental elements, oxygen and hydrogen, the typical oxidizer and the typical reducer.

To Construct a Simple Battery

The apparatus which you will need is about as follows: A tumbler of dilute sulphuric acid, a strip of zinc and another of copper, about 1 inch wide and 3 or 4 inches long, and a short piece of common insulated copper wire, say about 1/16 inch in diameter without the insulation, that is, coarse copper wire. The reason for using coarse rather than fine wire is that the laws regulating the flow of electricity through wires are something like the laws of the pressure and the flowing of liquids through tubes; and just as a large tube will carry more liquid, so a coarse wire will carry more electricity. You want to clean and scrape the insulated wire for an inch or two at each end so as to free the wire from all fabric, tar, rubber, wax, or whatever material is used for a cover. If you have worked any with electricity these directions will seem gratuitous and unnecessary, but in any event you must remember that good results can always be obtained, but only at a little expense of careful attention in having the connections clean so that the metallic surfaces will come directly together without having any dirt, grease or foreign substance in between. You will connect one end of the well-cleaned copper wire to the zinc strip, by boring a hole through the zinc, hooking the wire through, and pressing or hammering it flat so that the hooked wire will touch both surfaces of the zinc, as shown in Fig. 1. The other end of the wire is attached exactly the same way to the copper strip, and the connecting wire is twisted into a loose coil or spring which can be easily adjusted to the distance of the two strips apart as they are placed in the tumbler. It may also be convenient to have a bit of some non-conducting substance, like a short piece of rubber, resting in the bottom of the tumbler to keep the two metal strips apart. The arrangement of the two strips of copper and zinc with the short coil of connecting wire is shown in Fig. 2. Now fill the tumbler about three-quarters full of dilute sulphuric acid, say about one part of acid to six or seven parts of water.

The first thing to do is to dip the zinc strip alone in one side of the tumbler of dilute acid, and you will note a rapid effervescence of bubbles, which, of course, you know to be hydrogen, from your experience of the last two lessons in making hydrogen by the action of dilute sulphuric acid upon zinc; or, to put it another way, by the action of zinc upon dilute sulphuric acid. Now there is nothing very remarkable in this, but it is the preparatory step to the next experiment which completes the making of your simple electric battery. As long as the zinc alone is in the dilute sulphuric acid, bubbles of hydrogen come off from the surface of the zinc, Fig. 3, but keeping the zinc in the tumbler and dipping the copper into the other side (the ends of the copper and zinc plates being connected by the insulated wire), you will note that the hydrogen ceases to come off from the zinc plate, and comes off from the copper plate, Fig. 4. There may be slight effervescence from the zinc plate, when both the zinc and copper are dipped in the dilute acid, but this gas from the zinc plate also is mainly oxygen, something which we will try to prove later on. The point that you want to notice is that if you dip the zinc plate alone into the dilute sulphuric acid, you get a brisk evolution of hydrogen gas from the zinc plate; but if you dip both the zinc and the copper plates (connected by the insulated wire) into the dilute sulphuric acid, the principal evolution of hydrogen gas is from the copper plate. We will neglect for a moment the slight evolution of oxygen gas from the zinc plate, when both the plates are

FIG. 1

FIG. 2

FIG. 3

dipped into dilute acid, to study the main evolution of hydrogen gas which comes off of the copper plate.

"Action at a Distance"

Evidently something very remarkable is happening here because, as shown in Figs. 3 and 4, the hydrogen, which would come off from the zinc alone, seems to be thrown off at the copper plate. This is not the same hydrogen as that which would come off at the zinc plate alone, but it is the same kind of hydrogen in quality and quantity; and its appearance on the copper plate an inch or two away from the zinc plate in the tumbler is what is called "action at a distance," and this action at a distance is characteristic of the electric battery. This action of copper in throwing off hydrogen, when the zinc-copper couple are connected by a wire and dipped into dilute acid, this action of the giving off of hydrogen from the copper plate, is all the more remarkable because *copper alone does not* give off hydrogen in such quantity and with such readiness in dilute sulphuric acid. You want to prove this point, namely, the action of dilute sulphuric acid and copper on each other alone, because it is the whole point of experiment. Indeed if you stop here and take both the zinc and copper out of the dilute acid and then dip the copper only into the acid you will note almost no action, because dilute sulphuric acid has hardly any effect on copper, at least for a few moments. The following points, then, you have established:

First, that the zinc alone in the dilute sulphuric acid gives off a rapid bubbling of hydrogen.

Second, that the copper plate alone when dipped into dilute sulphuric acid does not give off any hydrogen to speak of.

Third, that when the zinc and copper (connected by the insulated wire) are both dipped into the dilute sulphuric acid at the same time there is a rapid evolution of hydrogen gas, but from the copper plate.

As stated, something remarkable is happening here, and you can see that it is the action of the so-called electric current between the metals, through the dilute acid and through the conducting wire, which seems to transfer the evolution of the hydrogen from the zinc plate to the copper plate. It is just this action of the electric current which you want to note. There are a great many sides to this experiment, some of which we can take up now, and some of which will come up from time to time later on. This zinc-copper couple in dilute sulphuric acid, the zinc and copper being connected by the insulated wire, forms the typical simple galvanic or voltaic electric cell. There is an electric current flowing around, from metal to metal, through the liquid and through the connecting wire; indeed, there are probably two currents flowing around, one the so-called positive current, flowing in the liquid from the zinc to the copper and carrying hydrogen from the zinc to the copper in the tumbler (and then going on around through the wire back through the zinc again), and the so-called negative current, which carries oxygen from the copper to the zinc in the tumbler, and which goes on around the wire back to the copper. These two currents, the positive flowing in one direction carrying hydrogen and the negative current flowing in the opposite direction and carrying oxygen, are always equal in quantity and in intensity, and exactly balance each other. Indeed, we cannot have a positive current without having exactly the same amount of the opposite kind, namely, the negative; and, similarly, we cannot have the negative current without having exactly the same amount of the positive current.

While we cannot go very far into the explanation of this at present, yet it should be said here that we probably have and use what are essentially the same thing as these positive and negative currents in every chemical action; but they are so mixed up with each other and they balance each other so evenly and quickly that one does not realize this until he separates them very much in the same way that you are doing in your simple primary battery made of the zinc-copper couple. Indeed, this simple primary battery is nothing more than a simple but elegant and marvelously ingenious scheme for separating the results of the two currents so that one can take them apart, as it were, and study each one separately.

Defects in the Zinc-Copper Battery

There are several defects in this simple zinc-copper battery, which you will note if you let it work for a few moments. One of these defects is that the hydrogen bubbles will soon begin to stick to the copper plate, and your battery will soon become tired and "polarized," as the expression is; therefore, later on you will try to get some way to overcome this difficulty of the accumulation of the hydrogen at the copper plate. This is done by surrounding the copper plate (or what may take the place of the copper plate) by some "de-polarizing" or oxidizing substance. Another defect of this battery is that the zinc is altogether too active in the dilute sulphuric acid and is quickly corroded and eaten up; whereas it may be preserved against needless waste by rubbing the zinc plates with a few drops of metallic mercury carefully applied with an old rag. This amalgamating of zinc plates in primary batteries used to be a very important point in the old days before the modern power generator or dynamo was used to develop electricity, and when they had to depend on such primary batteries as a source of electricity.

There is another side of this, also, which we may study right here. While there are always both the positive, the hydrogen-carrying or the metal-carrying, current and the negative, or the oxygen-carrying, current in every battery, yet for convenience and simplicity we purposely neglect the negative current and speak in terms of the positive current, as though

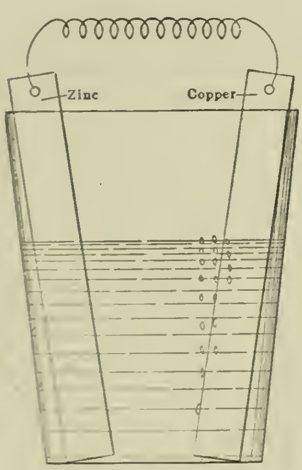

FIG. 4

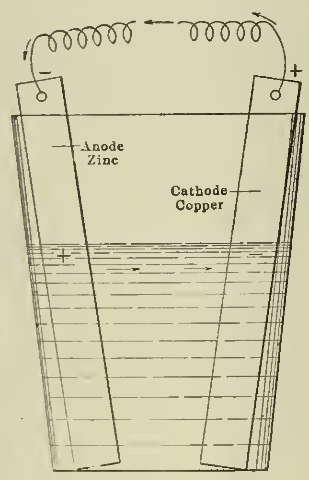

FIG. 5

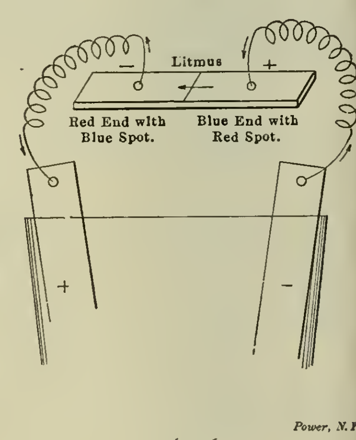

FIG. 6

that were the only kind of current. One reason for this is that the carrying of the metals, as hydrogen, is usually more easily noted and measured than the carrying of the nonmetals, as oxygen, by the electric current. Another reason is that when the double electric current gives off hydrogen at one plate or "pole" and oxygen at the other plate or "pole," there are two volumes of hydrogen to one of oxygen, these being the proportions in which oxygen and hydrogen unite to form water (H_2O).

The "Anode" and the "Cathode"

In studying this positive electric current in this simple primary battery it is plain that the action *seems* to start at the surface of the zinc plate in the dilute acid. We will therefore think and speak of this zinc plate as being the starting point for the positive electric current. We will also call the zinc plate or "pole" the "anode" (the "road up" or the "up road"); and we will call the copper plate in the battery the "cathode" (that is, the "down road" or the "road down"). Thus, we will speak of the zinc plate or the metal-exciting plate *in* the battery as the anode, and the copper plate or the metal-receiving plate or "pole" *in* the battery, as the cathode. That is, *in* the battery the current goes "up" into and through the zinc plate, across through the dilute acid, "down and out" through the cathode or copper plate, and so on through the insulated conducting wire to the zinc plate again. We have taken the greatest liberties with both fact and language in talking about this electric current in its passage through the anode and cathode; but on the whole perhaps it is justifiable, if you remember that we are still in the infancy of our ignorance regarding the nature of chemical affinity and the electric current.

It will do you no harm to think about this positive electric current as though it were an invisible current of fluid force or energy; but we must always be careful to name the facts in the right order and contrast. This is the more necessary because if we cut the connecting wire in the middle, as we are going to do in a moment, the end of the wire leading from the cathode will itself become an anode or "road up," and the other cut end of the wire, leading up to the zinc anode of the battery, will itself become a cathode or "road down or out," considering only the cut ends of the wire.

There is also another way of looking at this flow of the positive current in the circuit, from anode to cathode in the battery and from anode to cathode at the cut ends of the conducting wire *outside* the battery, and that is by the use of the signs + (plus) and − (minus). Just as we think of the temperature as falling from plus (+) above zero, on the thermometer, to minus (−) below zero (say from 10 degrees above zero to 10 degrees below zero), so we can think of the electric current, that is, the positive electric current, as always going in the direction in which it falls from plus (+) to minus (−). You will notice that we have indicated these signs carefully and exactly in Fig. 5 and you will want to study this figure and memorize the relative positions of these signs; for they stand for the governing direction of the flow of the positive electric current.

Now, to show you that we are talking about real chemistry and not about a mere dream, take the two ends of the cut wire as shown in Fig. 5 and put one on the upper and the other on the under side of your tongue, when you can easily *taste* the electric current. Indeed, if you take a strip of plain clean zinc about 1 inch square and lay it on the under side of your moist tongue, and then place a clean copper cent on the upper side of your tongue and let the projecting ends of the zinc and copper touch each other, you will have a little electric battery and you can taste the electric current every time that you make the zinc touch the copper cent. Of course, in this simple battery in the mouth, the saliva represents the dilute acid, and what you are tasting is a strange mixture of the reducing effect of the positive or metallic current and the negative or nonmetallic current; and you cannot fail to note the strong metallic taste of this simple tongue battery.

To find out just what it is that you are tasting in the tongue battery, and just what it is that you have produced in the zinc-copper couple in the tumbler battery, try the experiment indicated in Fig. 6. Take a piece of common litmus paper and dip it into a little dilute soda or acid so that one-half will be colored blue and the other half red. The strip of litmus paper should be about ½ inch wide and 2 inches long. Then neutralize a little sulphuric acid, say a teaspoonful of dilute acid, with a few drops of caustic soda, until it is exactly neutral, so that it will leave red litmus paper red and blue litmus paper blue. You can get this point of exact neutrality by a little fussing and by adding a drop of dilute acid from one tumbler and a drop of dilute caustic soda from another tumbler until the sodium sulphate produced is exactly neutral.

Then dip the strip of litmus paper into this neutralized solution of sodium sulphate. Lay the red and blue litmus paper, which is saturated with the sodium sulphate, on a clean glass or saucer and put the end of the cut conducting wire from the copper pole on the blue end and the end of the conducting wire from the zinc pole of the tumbler on the red end of the litmus paper, having both the zinc and the copper plates immersed in the tumbler battery. At once you will notice that where the wires touch the sensitive strip of litmus paper, on the blue end around the wire from the copper pole will come a fine red spot, and on the red end of the litmus paper around the end of the wire from the zinc pole will come a blue spot.

This experiment will teach you everything that you need to know about the fundamentals of the chemical action of the electric current. You will see that the current is flowing, that is, the positive current, in the direction of the step arrows, as marked in Fig. 6; you will note, also, that where the current from the battery goes into the litmus paper, the end of the wire from the copper being an anode shows the oxidizing or acid action of the negative current and turns the blue litmus red, while the end of the wire leading to the zinc, on the litmus paper, shows the metallic or basic action and turns the litmus paper blue. The actual reactions which are happening (in the sodium-sulphate solution in the litmus paper) are quite complicated, and we will not stop to analyze them completely at this time; but you can see that the electric current can be broken up anywhere in the circuit into its two parts, the one part at the pole where the current goes in always showing an oxidizing or acid effect, and the other part where the current goes out always showing a basic or reducing effect. You will have to be patient with yourself, and you will have to read and re-read this chapter several times; but you can easily memorize the main points in one very simple and easy way—by doing the experiments. Indeed one hour of experiment is worth many hours of reading and study. One wants to read and study just enough to see how to perform the experiment; then the experiment itself becomes the teacher, takes charge of all of us as students and teaches us how to see and how to remember.

Two Main Points to be Noted

There are many other and many applications to this fundamental experiment of the simple primary electric battery; but there are two main points for each of us to note at this time: one is the way in which the hydrogen is driven off from the copper rather than the zinc pole in the tumbler battery, and the other is the way in which the cut ends of the conducting wire, carrying the electric current, show very clearly the opposite chemical action of oxidation or acids at one pole and bases or reduction at the other. If we will stop here and let our imaginations work a little, we can easily see something of the almost unlimited possibilities of the chemical action of the electric current.

In this experiment we have produced a very feeble electric current from a primary battery; but the chemical effects of the electric current are the same whether the electric current is produced by a primary chemical battery, or by a mechanical generator or dynamo, provided the current is what is called a "direct current." The chemistry of the alternating current is a different matter and cannot be considered here; but the action of enormously powerful direct currents, such as those produced at Niagara falls and used in the manufacture of aluminum, the clay metal, and many other equally interesting substances, all this shows a little of just what you have begun to block out in this lesson.

There is another word of explanation which should be offered here. I refer to the difference between the so-called "primary" and "secondary" batteries. There is really very little difference in theory between the primary and secondary battery; both have their anodes and cathodes, and in both the positive current flows in the way indicated in noting the course of the current in our simple tumbler battery. But, *practically*, there is a great difference between the primary and secondary battery; for the electric current represents a form of power or energy, and the electric current can be produced either by the mechanical dynamo or generator, or by the primary battery (though at present the primary battery is not used as an economical source of large currents). Now in the saving up or storing of the energy of electric currents use is made of the secondary battery, which is frequently made of two lead plates (one in the form of metallic lead, the other in the form of the brown oxide of lead, PbO_2); these "secondary" or "storage" batteries make a large subject, and they represent a problem which is only half worked out at present. This word of explanation is simply given to show the meaning of the word primary as we have used it for our tumbler battery in a simple form for originating an electric current.

In the next lesson we will consider some of the other chemical and physical aspects of the electric current; and incidentally it will be a good thing for you to get another piece of insulated copper wire, 4 or 5 feet long, and also a small pocket compass, even one as small as the common watch-charm compass; for anything of this sort will come in very handy. You will also want to get a short piece of good steel, 4 or 5 inches long, and magnetize it by holding it close to a certain part of any direct-current generator; any friendly operator will help you to magnetize it. But do not forget to go over and over the material presented in this lesson, and to clinch it by experiment, so that you will learn it as though you were going to remember it forever; it is worth knowing.

The principal producing countries of lignite are Germany, Austria and Hungary, which in 1906 produced 55,513,000 tons, 23,779,000 tons and 6,263,000 tons, respectively, while the provisional figures available for Germany in 1907 show a production of 61,542,000 tons, and in Austria 25,840,000 tons. In the United Kingdom the production has for some years been *nil*.

The Inception of the "Van Stone" Joint

In a group at the Engineers' Club the other evening, the conversation turned upon loose-flange joints, suggested by W. F. Fischer's article upon the subject which had just appeared in POWER, and George I. Rockwood, who was of the number, related the story of the inception of this type of joint by himself, as follows:

"In 1903 I had occasion to put some 8-inch high-pressure steam pipes into the

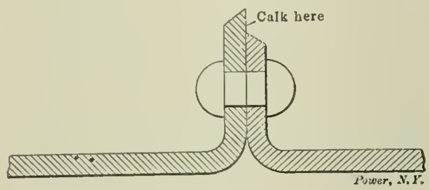

FIG. 1

plant of the Samuel Winslow Skate Manufacturing Company, Worcester. Casting about for the best form of pipe joint, I investigated the work which had been put up in Providence, about that time, in the Narragansett Electric Light Company's station, where the ends of the pipe were flared out and riveted directly together in much the same way that the flanges on the ends of the abutting sections of Lancashire-boiler furnaces are riveted together (Fig. 1).

"I was informed that considerable trouble had been experienced with this form of joint and that most of the piping had to be replaced after a short time, owing to the impossibility of contending successfully with the strains produced by the expansion and contraction of the line. It then occurred to me to make use of the heavy cast-iron flange (Fig. 2). The flange was bored a rather close fit to the pipe, its face was turned to the section shown, and the flange was then slipped over the pipe and temporarily left some distance on it from the end. The blacksmith then heated and flanged over the end of the pipe, after which he moved the cast flange up to the heated end, secured it there and molded the two flanges together.

"The fundamental object I had in view was to secure together the abutting flanged ends of two pieces of pipe in such manner that the expansion strains of the line could not affect the relative positions of the contacting faces. By making the flanges with deep skirts and by flaring the outer faces of the flanges to admit a calking tool, I was able to correct any tendency of the pipe to leak when first put up, by simply calking the steel up against the heavy anvil-like faces of the flanges.

"A year or two later, after I had watched the behavior of the pipe joints in this factory, I contracted with the Walworth Manufacturing Company, in Boston, for a long line of pipe varying from 16 to 6 inches in diameter, and provided with this same style of pipe joint. Before letting the contract to the Walworth Manufacturing Company, I attempted to get figures from several other pipe contractors, but entirely without success, as no one else wished to attempt the flanging-over process for fear of lack of success due to splitting of the ends of the pipe when subjected to such a treatment. The Walworth Manufacturing Company evidently did not realize the difficulty of the job, for after it had had the contract for some days, its salesman called at my office and asked to be allowed to provide screwed flanges, as they found it almost impossible to prevent the splitting of the pipe when they attempted to flange it. However, after some persuasion and further experimenting on the part of their superintendent, Mr. Van Stone, with an oil furnace, and after some practice on the part of their men in hammering over the edge of the heated pipe with long-handled wooden mallets, they were able to finish the job and erect it in position.

"It was an entire success, and during the following summer, after a long absence from home, I called at the office of

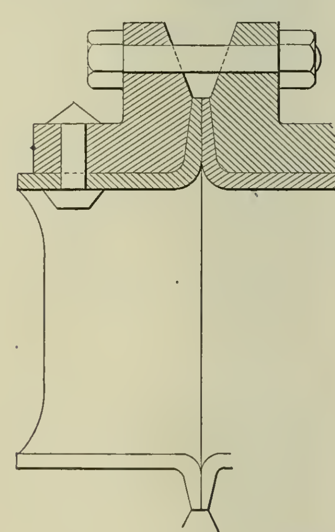

FIG. 2

the Walworth Manufacturing Company and asked them what they thought of the joint. Their answer was that they thought it an excellent joint in principle, but too expensive to build for the market. I, however, had my suspicions aroused and went over to see what they were doing with it in their factory, where I found their shop literally full of orders for piping with this style of pipe joint. I also found they were advertising it as the 'Van Stone Pipe Joint'. Meantime, I had had a patent issued to me—No. 580,058, April 6, 1897. This patent was for a pipe joint (Fig. 3) in which the flanges have divergent opposite sides to admit a calking tool. The Walworth Manufacturing

Company has continued to make its so-called 'Walmanco' pipe joint (the name which they switched over to after Mr. Van Stone left their employ and formed the company of Lumsden & Van Stone, Boston), which is practically a Chinese copy of my patent.

"I talked with the Walworth Manufacturing Company for a good while about their buying this patent; but, owing to a defect in the way the claim had been drawn, I found it was necessary to secure evidence that pipe joints which had been erected and subjected to steam pressure and had leaked, owing to defective workmanship, had actually been tightened by the use of a calking tool introduced between the divergent opposing sides of the flanges. Owing to the difficulty of securing this testimony, and to a certain reluctance to engage in a legal struggle with the Walworth Manufacturing Company, I never did anything further to enforce my rights.

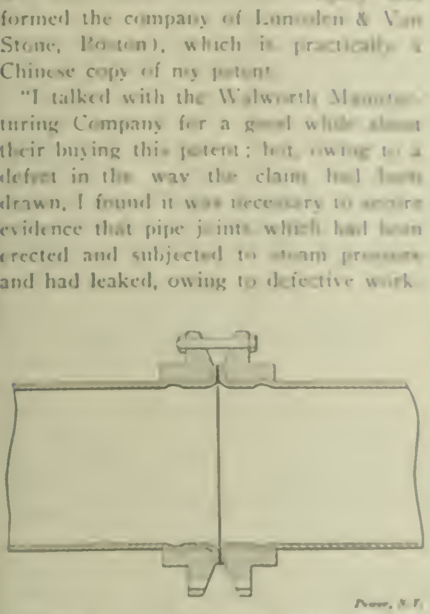

FIG. 3. ROCKWOOD PIPE COUPLING

"In the original pipe joints made by me, I thought it safe, after discussing the matter with my friend, Capt. Charles H. Manning, and in view also of an experience with a pipe line of somewhat similar construction in Natick, R. I., where an engineer was killed while calking a line, due to the pulling of the pipe out of the flange, to introduce a few rivets into the skirt of the flange to take the strains off of the corner where the pipe is bent over. The rivets had the additional advantage of holding the flange in position while the blacksmith flanged the end of the pipe over against it. But, whether the rivets were provided or not was immaterial to the main fundamental advantages of this type of flange.

"I have had it alleged to me that I got the idea of making this type of joint from previous practice in coppersmith's work, where the slatting ends of copper tubes are spun over and are pinched between two light flanges. No one who had ever seen the drawing of such a flange would be likely to have made a steel pipe joint in the way shown in my patent. No suggestion of the advantages of such flanges as anvils against which to calk the joint tight is suggested by their shape. Furthermore, the fact that the flange was original with me is shown by the further fact that it was not until after I had made and used this so-called 'Van Stone' joint that modern practice shifted quickly over to it, practically to the abandonment of all other kinds of joint for use in high-pressure pipe lines."

License Law for Colorado

A bill has been introduced into the legislature of Colorado providing for the examination and license of persons operating steam engines, boilers, etc. Two persons who have had not less than ten years' practical experience each in the care and management of steam boilers and steam engines are appointed by the governor for a term of two years, and these, together with the State inspector of steam boilers, constitute a board of examining engineers.

"It shall be the duty of the board of examining engineers to meet from time to time and at least as often as once in four weeks in the city of Denver, or elsewhere in the State of Colorado, for the purpose of examining the qualifications of applicants for license to operate steam power."

The fee for upon application is $5. If one fails and tries again, the fee is $2.50, and the license must be renewed yearly, the fee for which is $2. The examiners may accept licenses granted by other lawfully constituted bodies in lieu of an examination. Any rejected applicant may apply for a re-examination by an engineer of his own choosing, who shall act in conjunction with a member of the board and a third engineer to be satisfactory to both. Each member of the board shall be paid $5 for each day's actual service and seven cents per mile for each mile actually traveled in the performance of his duties. Railroad locomotives and steam fire engines owned by an incorporated town or city are exempt.

There are also bills before the legislatures of the States of Oregon and New Hampshire providing for the establishment of an inspector of steam boilers but not for the examination and license of stationary engineers. That in New Hampshire has been reported unfavorably by the committee to which it was referred.

License Act for California

There is a bill before the legislature of California to regulate the operation and supervision of stationary steam machinery, which prohibits the employment of any person to operate, supervise or control any stationary engine, steam boiler or other stationary apparatus for generating steam, except persons licensed in accordance with this act. It exempts only apparatus in connection with private dwellings.

The law is to be administered by a board appointed by the governor and consisting of three members, one of whom shall have been employed as a stationary engineer for five years before the ten years preceding his appointment, one shall have had the active management for a like period of some factory or workshop in which steam-generating apparatus is used, and one shall be a graduate of some reputable college of engineering. They are expected to serve without compensation but are to receive their actual and necessary traveling expenses while engaged in the business of their office.

The board appoints an examiner and makes rules and regulations for the conduct of examinations, for which and for the granting of licenses a reasonable fee may be exacted. The examiner is to travel about the State and is allowed a salary and his actual traveling expenses, but no provision is made for deputy examiners.

A New N. A. S. E. Association

On Wednesday evening, March 31, a new branch of the National Association of Stationary Engineers was formed at Fort Smith, Ark. The new association is known as "Border City No. 5" and was instituted with twenty-four members. Although the inclemency of the weather kept many from attending, a most enjoyable night was spent. The following officers were elected: A. T. Hubbard, president; Frank Harris, vice-president; S. B. Robertson, secretary; B. C. Culpepper, corresponding secretary; S. T. Rowe, conductor.

The Largest Steam Turbine in Sweden

The De Laval Steam Turbine Company, in Stockholm, has recently supplied the largest steam turbine to be installed in Sweden to the [illegible] Power Company's electrical central station at [illegible]. It is of the De Laval multiple type, has a capacity of [illegible] horsepower and is direct-connected to a three-phase alternating-current [illegible] generator. The turbine company has supplied the whole of the plant, including two boilers, etc.

The "Laurentic" of the White Star line, will come under her own steam to the Montreal-Liverpool service. She has a tonnage of [illegible] and is fitted with reciprocating engines working in conjunction with steam turbines. Her sister ship, the "Megantic," has the reciprocating engines only.

In the test of a plant by the [illegible] Society for the Suppression of Smoke the thermal efficiency with the [illegible] was [illegible] per cent, and with [illegible] per cent.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for March, 1909, was (weekly and monthly) 190,000.

April 6	42,000
April 13	37,000
April 20	37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Producer Gas Power in Small Units

When one stops to think of the possibilities of small gas producers and engines, it seems strange that the use of that class of apparatus is not vastly more widespread than it is. A suction anthracite producer of any size up to 25 horsepower is no larger and no more troublesome to operate than the hard-coal stove commonly found in country stores, and not nearly as intractable as the average kitchen range. We are vigorously opposed to underestimating the degree of care required by machinery of any kind, and we do not ignore the fact that a small producer and engine plant do require intelligent attention; nevertheless, it is undeniably true that the *amount* of such attention needed by the type of plant under consideration is astonishingly small.

There is an enormous field for such small plants throughout the country, and the builder who has the foresight to develop it and get in first ought to reap a prodigal harvest. A good deal of missionary work along Missourian lines will be necessary, however, in order to convince the prospective customer that the monstrosities which were sent out by some builders in previous years have had their day and that "real" producer-gas engines and anthracite producers are as easily obtained now as abortions were five years ago.

The Presentation of Engineering Papers

Most engineers enjoy a good lecture, or a paper on some uptodate subject. That is one reason why engineering societies have adopted the practice of having papers presented by men of distinction in their lines. If the members who attend organizations did not feel an interest in such matters they would not be there. Without attendance, an engineering society must fail; therefore, it devolves upon any such body so to conduct its meetings that they will attract, not repel. Getting men into a lecture room and boring them to death is not conducive to success.

Most engineering societies publish in advance the papers that are to be read at any particular meeting, in order that the members may have an opportunity of discussing them intelligently at the meeting. This is a good idea, but what is the use of wasting the time of several hundred men by forcing or allowing the author to read in full a paper which every interested member has previously read for himself? If an author is thoroughly conversant with his subject (and he is foolish to attempt a paper if he is not), he should find no trouble in giving concise expression of the ideas presented in his paper without reading it, or even lengthy parts of it, and the audience would undoubtedly find more interest in listening to the speaker than to the reader.

The time usually taken up in reading papers which have been previously distributed in printed form could much more profitably be spent in discussion, and if the members once understand that papers will not be read in full, they will form the habit of reading them carefully beforehand and, consequently, be much better prepared for discussion at the meeting.

The Three Phase Circuit

The three-phase alternating-current circuit is still a good deal of a puzzle to the operating engineer whose early training was obtained in connection with the simple two-wire direct-current circuit. The attempt at simplification by advising that one wire be considered as a common return for the other two does not usually help matters and vector diagrams merely emphasize the confusion. The easiest way for beginners to approach the subject is to consider the three-phase circuit as a consolidation of three simple two-wire circuits, as outlined in a recent article* on the subject. On this basis each wire of the three-phase circuit is the combination of two wires of two of the imaginary two-wire circuits, one wire of each circuit being combined with one wire of one other circuit to form the single resultant wire of the three-phase circuit. Each wire of the three two-wire circuits must be assumed to have a cross-sectionel area equal to 0.577 of the cross section of each wire in the actual three-phase circuit, if the questions of "drop" and energy loss are to be considered.

When one is concerned only with the loss in the line, however, the simplest method is to assume that the requisite power is to be transmitted by a four-wire two-phase circuit. The size of wire required to transmit a given power at a given loss is exactly the same in a three-phase circuit as in a four-wire two-phase circuit, and by working (on paper) with two phases instead of three, all of the confusion as to interlinking of phases is avoided. For example, if a twenty-horsepower three-phase motor is to be connected up for two per cent. loss in the line at full load, assume that it is a two-phase motor of the same horsepower, efficiency and power factor, and figure the line as a two-phase line; then throw out one wire of the four and the remaining three will be correct for the three-phase motor actually to be installed.

It must be remembered, however, in checking the size of wire by the insurance requirements, that the current per wire

*Page 108, POWER AND THE ENGINEER for December 22, 1908.

is greater for a three-phase than for a two-phase motor of the same size and characteristics; what has been said above refers only to voltage drop and energy loss in the line. For example, if the twenty-horsepower motor be of ninety per cent. efficiency and eighty-eight per cent. power factor, and the circuit voltage be 220, the current per wire would be fifty amperes for the three-phase motor and forty-three for an equivalent two-phase machine. The drop and energy loss in the circuit would be the same for both kinds, with a given size of wire, but the underwriters would not allow smaller than No. 4 rubber-covered wire for the three-phase circuit, while No. 5 would be permitted for the other.

To Improve the Load Conditions of a Power Station

When the load on an electric-power station is such that another generating unit must be put in parallel with those already running, it is common practice to readjust the division of load amongst the machines so that the one just "cut in" will take its share. There is no alternative to this practice where direct-current generators are operated, but if the machines are alternators and the load is inductive, it will frequently be found preferable to operate the incoming machine as a synchronous motor in order to improve the power factor of the system and enable the other generators to load their prime movers fully. The condition under which this method is advantageous is the combination of a low power factor and either equality of capacity between each generator and its prime mover or a preponderance in favor of the prime mover.

For example, suppose that each prime mover is just able, at maximum economy, to drive its generator at full rated load when the power factor is ninety per cent. If the power factor should happen to be seventy-two per cent. the normal heating limit of the generators would be reached when the prime movers were doing only eighty per cent. of their maximum-economy output. Under these conditions cutting in another alternator and dividing up the load between all of them would not only reduce the load on each prime mover still farther below the economical point but would farther impair the power factor of the system. On the contrary, if the additional alternator were synchronized, cut in and then allowed to run as a synchronous motor, driving its prime mover idle (with steam cut off), its field excitation could be increased so as to improve the power factor and enable the other prime movers to carry full load without overheating their generators.

This raises an interesting question: For power stations carrying highly inductive loads would it not be worth while to equip one or more of the alternators with a simple dental clutch by means of which its prime mover could be disconnected from it when the machine was needed as a synchronous motor for raising the power factor?

Another "Smoke Consumer" Has Made Its Appearance

In the Dayton (Ohio) *Daily News* of March 22 there appears a reading notice heralding the discovery of a compound which, mixed with coal to the extent of twenty cents' worth of compound per ton of coal, will eliminate all of the gases which cause soot and smoke, and in addition will clean the flues of the boiler, the inside of the chimney, or stack, and add "forty per cent. energy to the coal."

It is said that a satisfactory demonstration was made in the presence of the smoke inspector, who remarked: "These men have the goods."

It has long been known that with a properly designed furnace, operated by intelligent attendants, smokeless combustion of the most smoky grades of bituminous coal can be accomplished, and it has still longer been suspected that human brains had more influence in producing smokeless fires under boilers than mixtures of salt, lime, calcium carbide, oxalic acid, water, etc.

A manufacturing chemist who was burning with his coal a lot of damaged salt said: "There is nothing in salt, oxalic acid or water that can add anything to the heat value of the coal in the furnace, but we use lots of these things. Do you see this ring? There is and can be no connection between this ring and rheumatism, but if you have rheumatism put on this ring and you forget all about rheumatism."

It may be the same with the users of the new smoke-destroying compound. It has no relation in any way to combustion, it may even be detrimental, but put it on the coal and straightway everybody concerned forgets all about smoke. There is nothing known to the industrial chemist "twenty cents'" worth of which mixed with a ton of coal will add to its fuel value in proportion to its cost and at the same time produce smokeless combustion. [illegible] has repeatedly warned its readers against the use of these compounds, and it is thought in some quarters that the United States postal authorities have been negligent in allowing the mails to be prostituted in the carrying of fraudulent solicitations of worthless nostrums.

The John Fritz Medal Presentation

The steam engineer, whether he follows that vocation professionally or in an operative capacity, will find a fund of inspiration and interest in the addresses which accompanied the presentation of the John Fritz Medal to Charles Talbot Porter on Tuesday evening of last week, at the Engineering Societies building in New York. The steam engine has had a greater part in making possible the highly developed civilization in which we live than any one other factor, and so accustomed have we become to its benefits and advantages that the fact that its application to industry and transportation upon any considerable scale covers hardly a century, comes almost as a revelation when it is recalled. The statement of Professor Goss of the conditions existing at the time of Watt and during the early development of the factory engine, the steamboat and the locomotive, and by Professor Hutton of the influence of Mr. Porter's work upon the engine as he found it at the middle of the last century, will throw a new light upon the relations of steam engineering to the world for the layman and quicken the interest of the engineer in his life's work.

The previous awards of the medal have been made informally. The institution of the simple but impressive ceremonial, so much in keeping with the character of the man whose imprint the medal bears, is to be commended and it is hoped that the annual presentation of this medal will become one of the notable functions in American engineering society.

We congratulate Mr. Charles Talbot Porter upon this recognition of his work, conferred in the eighty-third year of his life, and bearing, as he said in brief and dignified acceptance, the expressed approval of time.

Obituary

John McKay, chief engineer and superintendent of the City Investing building, New York City, died Saturday, April 10.

Producer gas, as the term is commonly applied, is intermediate between air gas and water gas. Air gas is made by passing air alone through a bed of incandescent carbon and water gas by passing steam alone through such a bed. Producer gas is made by passing air and steam together through the bed of incandescent fuel. Air gas is almost entirely carbon monoxide; water gas is largely carbon monoxide but carries also hydrogen obtained by the decomposition of the steam. Producer gas is chiefly carbon monoxide with 10 to 20 per cent. of hydrogen.

Charles T. Porter Awarded Fritz Medal

Mr. Porter's Pioneer Work on the High Speed Steam Engine Fittingly Recognized. The Benefits to Modern Industries Pointed Out

With simple but impressive ceremonies the John Fritz medal was awarded, on Tuesday evening, April 13, to Charles Talbot Porter, the father of the high-speed engine. The audience arose as Mr. Porter was escorted to the front of the stage by Jesse M. Smith, president of the American Society of Mechanical Engineers, who addressed the chairman, Henry R. Towne:

President Smith's Introduction

The John Fritz medal was established in 1902 by the profession of engineering as a meed of recognition for notable scientific or industrial achievement. By direction of the Board of Award I present to you and to this company the chosen recipient of the medal for 1908-1909, to whom

it has been awarded for his work in advancing the knowledge of steam engineering and in improvements in engine construction. We thus honor him because he was the first to see the possibilities of the high-speed steam engine; for his mechanical genius in the design of parts and details to embody these principles, and for his insight in recognizing the necessity of the very best mechanical construction in realizing these ideals. He introduced into the development of the power plant an idea and an influence which was so revolutionary as to mark an epoch in the history of the art of engine building, and which has been as world-wide in its effects as has been the use of the reciprocating steam engine as a prime mover. Many of the present generation have inherited without effort the knowledge which it cost Mr. Porter many years of painstaking study and experiment to establish; many, perhaps, use this heritage without a thought of or recognition to the pioneer who won it for them.

That he may now receive the John Fritz medal, I have the honor to present Charles Talbot Porter.

Presentation and Acceptance

E. Gybbon Spilsbury, chairman of the Board of Award, in presenting the medal, said:

Charles Talbot Porter, veteran engineer, assiduous student of science and of the mechanical arts of construction, skilled expert in design of engine details and the application of physical laws to the solution of problems in the field of prime movers which you made peculiarly your own, in the name of the profession of engineering, and on behalf of the John Fritz Medal Board, I do now present you this medal, together with an engraved certificate of the award, in the presence of this distinguished company, and confer upon you all the rights, honors and distinctions which attach to this emblem. May you live long and happily to enjoy the appreciation which is your due at the hands of those whom you have so benefited by your work.

Mr. Porter, in accepting the medal, said:

Mr. Chairman and Gentlemen of the Board of Award of the John Fritz Medal: I thank you most sincerely for this token of appreciation of my work, which is all the more grateful to me that it expresses the approval of time.

"The Debt of Modern Civilization to the Steam Engine"

was the title of Prof. W. F. M. Goss' address, which was as follows:

The progress of the human race has been marked by the implements it has employed. The creation of each new utensil, tool or machine has given mankind greater freedom of choice, and has augmented his power. With the employment of mechanical means for driving machinery came great influence in manufactured products; when better means of communication followed, the range of man's activities was extended, and when labor-saving processes were introduced they brought opportunities for intellectual exercise and development. Thus from the beginning, invention and the development of the useful arts have given new life to the activities of man, have created new procedures, have led to the establishment of new standards of living, have stimulated speculation and have even directed the tendencies of thought.

Among the factors which have played their part in these civilizing processes none is more important than steam, a statement which becomes the more significant when we reflect that at the time its use as a source of power began, the world was already old and very many potent forces were having their effect upon society. The mass of the great common people were making themselves felt and heard. They were reading books and were showing an interest in science, and they were not afraid to undertake new enterprises. Dreams of the possibilities of steam belong to the day of Addison, Steel, Swift and De Foe, when the public was instructed and amused by the "Spectator," the "de Coverley Papers" and the stories of those famous adventurers, Gulliver and Robinson Crusoe. The day of triumphs in English architecture had reached its meridian, for Sir Christopher Wren had already directed the rebuilding of London after its great fire, and was finishing its masterpiece by the completion of St. Paul's cathedral. It was a day when the American colonies, occupying a fringe of territory along the Atlantic seaboard, were exercising themselves as became a stirring people in a new land, fighting their wars and gathering their strength for a greater war which was to come.

Such a period was worthy to usher in the era of steam, was in fact waiting for it, for though it boasted of brilliant men of letters and of great statesmen, there was work waiting which it had no means of doing. There were no large factories in England, because there was no way by which their machinery could be driven. Many English mines had been abandoned because they were flooded with water which could not be removed. For lack of cheaper and more effective means, women and girls were employed in many coal mines to convey coal to the surface. Where galleries resulted from the working of thin veins and head room was lacking, women nearly naked crawled on their hands and feet and pulled loads of coal in cars behind them. Again, at the shafts, women and girls, early misshaped by the severity and monotony of their task, toiled up inclines or climbed a succession of ladders, each carrying to the surface a burden of a hundred pounds or more of coal. Suffering and degradation was the common lot of the women in the mines, and fatalities through accidents were frequent. The traveler desiring to journey from Edinburgh to London was obliged to intrust his trunk to the skipper of some sailing vessel and himself to proceed on foot or horse, usually in company with other travelers as protection against outlaws.

In America, many years after the period of which I now speak, even within the memory of some who live today, the pioneer settler, finding it necessary to pay a bill or collect an amount in Philadelphia or Baltimore, not infrequently journeyed thither on foot from his home in Indiana or Illinois, preferring walking to riding because he could make more rapid progress. The movement of merchandise by land was equally laborious, and as a result there could be little interchange of trade between the people of different communities. Men restricted their requirements to those things which they could themselves produce, and in every country at least, the primitive life, while not devoid of dignity and pleasure, offered many hardships and even [illegible]. Travel by sea was even more hazardous than by land and was attended by far greater misery. A traveler from England to America in 17[illegible] has recorded the following incidents of his trip:

On January 1, the vessel drifted down the Thames. On the third she was aground, and after some damage had been done she was floated again. On the fourth anchor was cast off Deal, where the pilot was given up. Starting again on the [illegible], the vessel soon encountered a storm lasting for several days, was driven off its course, and finally was allowed to drift about until a [illegible] pilot had given the captain his course for Portsmouth harbor, where anchor was cast, the passenger feeling, as he said, "like one risen from the dead." The passengers [illegible] their spirits by visiting the English [illegible] whence they had started, and on the twenty-ninth, practically a month after leaving London, they again set sail. Soon they encountered a period of light winds and calms followed by gales so heavy that they were obliged to lie four days in a trough. Then head winds blew, and supplies ran so low that they were all put on short rations, until 99 days from London, when they had reached the vicinity of the Azores, they fell in with an East Indiaman, four years out, homeward bound to Boston. The larger ship was well manned, well equipped and well provisioned, and the [illegible] had the good fortune to get [illegible] [illegible]

Charles Talbot Porter

taken by one which was known to be very slow. By way of experiment, the captain collected his passengers and crew at the stern, with the result that the speed at once quickened. A subsequent change in the location of a few water casks served permanently to make the vessel the fastest of the fleet.

Into the midst of such conditions came the steam engine. It first freed the mines of England from water, thus reviving industries long dormant, giving employment to the idle, and increasing the fuel resources of a nation. It soon began to hoist the output of mines, to the relief of thousands of toiling women who had suffered without redress for generations. It turned the wheels of factories with a power unprecedented, making possible the introduction of new systems in manufacture by which raw materials might be converted into products serviceable to mankind, and by so doing became the foundation upon which has been reared the industrial prosperity of nations. It supplied pure water and effective means of sanitation to cities, and, supplemented by electric transmission, it furnished light, power and heat to offices and homes.

The steam engine is no longer merely a center of motion for factories, but is a necessary adjunct to the modern home. It usurped the place of the wind in the propulsion of ships, and they now proceed steadily through any sea. Steam also serves in the orderly administration of ships, in hoisting and handling the cargo, working capstans, weighing anchors, supplying water for sanitation and for fire protection, generating electricity for light, and transforming the slightest movement of the quartermaster's hand into the strong, steadily applied force needed to work the helm; it has, in fact, by the performance of numerous functions transformed a slow, uncertain and most uncomfortable process of navigation into one of the speediest, most certain and most delightful means of travel. It has supplied means for the safe and speedy transportation of people and merchandise by land, correlating the activities of cities and uniting different communities into a single people.

Steam, through the agency of the locomotive, has carried order and civilization into Africa, and has made possible the execution of great schemes for internal improvement on that continent; it has carried bread to the hungry in India, and has served in our country almost as a creature of fancy in pointing out to multitudes of settlers the way to new lands and new homes. It has given shape to the frontier, it has carried forward the settlers, and it has made it possible gradually to convert unsettled territory into populous country and untilled lands into productive gardens and farms of a continent' breadth.

All these achievements wrought through the agency of steam are direct contributions to the upbuilding of our modern civilization, the keynote of which is service. The service of the steam engine has not only enlarged the resources of all countries and increased the power of man, but by creating facility in communication is a tremendous force in modifying social life. The ease of present-day travel is a characteristic of our modern civilization. People of all nations may freely intermingle. Through opportunities thus afforded State lines are of less significance, and the prejudices and limitations of communities are lost and forgotten. Business and social interests which are made possible between nations are weaving a bond of common friendship which is world-wide in extent, and which grows stronger with every passing year. The power of navies and artillery, which has so long served to emphasize boundaries and separate nations, is gradually being supplanted by the power of the steam engine which promotes communication, makes possible introductions, and stimulates acquaintanceships, the effect of which is to draw people together and to encourage them in an acknowledgment of their mutual dependence. Through intercommunication the dwellers on the earth are beginning to see that if one nation suffers severely all nations are likely to suffer in some degree, and they are learning respect and sympathy for their fellow-men, and this is a long step toward world-wide international peace.

"The Debt of the Modern Steam Engine to Charles T. Porter"

was the title of Prof. F. R. Hutton's address, which was as follows:

We have just heard that the John Fritz Medal for the current year has been awarded to Charles T. Porter for scientific or industrial achievement under the terms of the deed of gift, and that his achievement has been to advance the knowledge of steam engineering and effect improvements in engine construction.

I am to speak in detail of the character of these achievements and improvements; and of the debt that the reciprocating type of steam engine at the beginning of the twentieth century owes to the pioneer work of Mr. Porter in the latter middle of the nineteenth.

This debt may be grouped under four heads:

First, we owe to him the first vision of the advantages to spring from the plan of making the crank shaft of a steam engine turn at a high number of revolutions; or to have the piston make a large number of traverses per minute in the bore of the cylinder.

It must be remembered that in 1860, when this inspiration came to Mr. Porter, the United States was scarcely as yet an industrial community in the sense in which it became one after the Civil War, and after the engineering schools began their service following the Morrill Land Grant Act of 1862. Great personalities had arisen, such as Haswell and Copeland, Horatio Allen and Ericsson, Stevens and Latrobe, Baldwin and Winans; and their successes were in evidence. But the great mills of New England were run by water power, as was the armory at Springfield; the great producing plants, which grew up subsequent to the war of '61-'65 were unthought of. The boy in kilts, who like myself had a hankering to see the railway locomotive, was escorted by a patient maid to the extreme limit of the city among the market gardens and ruralities of the northern end of the Fourth avenue tunnel at Forty-second street, and a successful blast furnace was in full operation at One hundred and Thirtieth street and the Hudson river, where the Edgewater ferry houses now stand. Sickels, Worthington and Corliss were in the first or second decades of their productive activity, but had made little widespread impress on the manufacturing centers. The locomotive and the marine type of engine had felt the influence of master creative minds, but the stationary power plant of small size was still under the headway of Watt and the standards received from England. English practice grew from the early requirement of the pumping engine for its mines and water works, and the slow rotation favorable to pumping, to paddle propulsion and to the beam type of transmission was the heritage of all designers.

The electrical age had not yet been born, for the Faraday discovery of the mechanical generation of electric current was still only embodied in a piece of laboratory apparatus exhibited with respectful awe to students of the natural sciences, because as yet there was no commercial solution to the problem of the electric arc and lamp, no filament for the incandescent globe and no practicable motor for the reconversion of electric into mechanical energy. No engine designer of stationary engines for mill or factory work cared to speed up the line shafting, for the millwright of the day was perforce using partly balanced pulleys and cast gears with hand-profiled teeth. The factory power unit was comparatively small because the mill was, also. The piston speed was standardized between 200 to 300 feet per minute, or an engine with 2-foot stroke turned from 50 to 75 revolutions per minute.

It should not be necessary in this presence to do more than to refer to the conditions in the reciprocating-piston pressure motor that the work per minute is the pressure P in pounds per square inch over an area A in square inches as the force; and that this force moves over a space in feet which is the length L of the piston traverse in one stroke multiplied by the number N of such traverses. Nor to the fact that the factors which give weight and bulk to the motor are the length L and the area A. To increase N adds little to the weight and inappreciably to the bulk; and to increase *P* necessitates increased strength of parts, but adds nothing to cylinder diameter or length, but may enable both to be reduced. By his recognition and advocacy of the sectional boiler with tubes inclined from the vertical as made by his associate, John F. Allen, Mr. Porter helped to raise initial steam pressures; by increasing the rotative speed from 50 or 75 turns per minute to 150 per minute, he initiated the era of the high-speed steam engine.

From this seed thought of reducing the weight of the motor per horsepower have grown many stately plants of modern day, in the sight of whose blossoms we sometimes forget the hidden roots. Or, to change the figure, there are many structures which rest upon this idea as their foundation, whose appeal to our instant recognitions makes us forget that they are upheld by this early vision of our honored guest. The direct-connected dynamo to be later referred to; the high-speed steam launch, the motor vehicle, the aëroplane, all rest upon the concept of diminished weight per horsepower capacity. Someone may say that this is so obvious that engineers could not help seeing the principle. Granted. But it was given to Mr. Porter to see it *first* as far back as 1860, and to make the hard fight necessary to secure its recognition. All honor to the man who sees a truth for the first time, and before it has been revealed to all!

The second debt we owe Charles Talbot Porter is for recognition of the truth that the problem of mass-accelerations for the reciprocating parts was a vital one, and success was bound up in solving it aright. When the pumping-engine piston or that of the paddle-wheel boat making 30 revolutions a minute, with 8-foot stroke, starts from rest, the moving masses have the time of one-half stroke to reach the velocity of the uniformly revolving crank. This is approximately one-half second. The force necessary to impart this stored energy is the product of the mass accelerated into the half square of the velocity per second. When the time of one revolution is changed from the speed of 30 per minute to 150 per minute, the time for acceleration becomes one-fifth of what it was before, or it must be effected in one-tenth second; and the force to store this greater energy increases as the squares of the velocities if the masses are the same. Hence the fact first observed and worked out by Mr. Porter, that the push of the steam in the cylinder only reaches the crank pin after the work of acceleration has been completed. This also has become a commonplace of the textbooks, and a platitude of the computing designer. Mr. Porter's graphical method of solution by superposing the steam effort *P A* upon the acceleration resistance diagram is everywhere now in use. But he used it first, and we owe him this debt.

The third debt which we owe to Mr. Porter is his recognition of the fact that the high rotative speed and the problem of mass acceleration compelled a standard of mechanical construction for the steam engine which was far ahead of the standards and practice of his time. This is perhaps the greatest unshared obligation of all. It would not do for the crank pin to be oval, or with axis inclined to the plane of connecting-rod effort. It would not do for the shaft to bear only upon a group of segregated points in the bearing. The crank pin must not fit or bring pressure upon an area much less than that computed as necessary for effective lubrication and consistent with long life and cool running. The crosshead must not bump along in contact only with high places upon the guides; the latter must not be warped surfaces, flexing and twisting the connecting rod in its work. Valve-rod pins must bear over their whole length and projected areas; joints in the governor must be drilled in parallel planes so that the pins shall not twist and bind and retard the governor action. Platitudes and commonplaces of engine construction, do I hear anyone say? Indeed, yes, for the twentieth century, but they are so because Mr. Porter first made them obvious. These were not recognized in 1860; that they are now is because of painful uphill effort against shop inertia and the conceit of the craftsman of that date. All honor to Mr. Porter for making these visible to us for the first time.

In this same class are his recognition of the advantages of the double crank unused before for stationary practice, and now so usual in the high-speed center-crank engine; his initiative in the matter of automatic lubrication of bearings both stationary and moving; the utilization of centrifugal force to compel oil to go where desired and needed and to prevent its creeping where it was not wanted. These are universal now; their design was a creation by Mr. Porter in 1860. The design of bed plate with a sweeping curve from the plane of the guides forward to the plane of the path of the crank pin, [illegible] as the "Tangye" bed by British writers, is Mr. Porter's idea, and the overhanging cylinder attached to the bed at its crank end and free to expand toward the head end without deformation is a Porter form as is the collarless crank pin with a [illegible] held in place by a [illegible] bolt. It is given to few to have their creations so completely [illegible] for the first time.

Our fourth obligation to Mr. Porter is for his creation of a form of steam-engine condenser with an air pump capable of being directly driven at high speed of piston traverse from the piston rod of a high rotative-speed engine. This design eliminated the [illegible] plunger moving in and out of a mass of water within the chamber [illegible] the upper portion of the [illegible] and [illegible], acting as a water piston to create and maintain a vacuum above it, without dependence on piston packing. The jet condenser was above the plunger, and the hot-well was beside the injection chamber. The bottom of the latter, or of the condenser proper, had an inclined bottom, so that the water would be drawn out first through the foot valve, and the air following it later in the stroke. The water passing with that of the water piston in the lower part of the pump chamber would pass out into the hotwell through the discharge valve last, the air going first from the upper part of the chamber, so that the tendency for the water to [illegible] was greatly lessened. Mr. Porter considers this pump one of his most notable triumphs of that day; and it is a commonplace of the pumping practice of today.

And, finally, we owe to Mr. Porter the origination of the earliest form of loaded-weight governor. Historically, this was one of his earliest ideas. It was to modify the conical pendulum as applied to regulate an engine, so that the force [illegible] bringing down the balls of the revolving pendulum should be greater than that due to gravity upon the mass of the balls themselves, and to eliminate the friction which had been caused in the joints of a governor by the inertia of the mass required to give necessary power, when such mass was placed in the revolving balls. This change in governor design made it possible to speed up the spindle and revolving balls, and both speed and diminished friction added enormously to the sensitiveness of the spindle type. But not alone do we owe to Mr. Porter the central-weight design; we owe to him further the idea of using a spring having an initial tension to force the revolving balls inward against the tendency they manifest to follow the tangent and fly outward. While first designed for a marine engine governor, to be independent of position of the spindle, it is the basic idea used later by [illegible], by [illegible], and all designers of shaft governors as their underlying scientific principle, with the loading [illegible] appearing in the designs of [illegible] & [illegible] and others. It underlies also the [illegible] spring designs of [illegible] and Pickering.

What, therefore, are we tonight and here doing [illegible] to [illegible] the debt of our age to Mr. Porter:

(1) For his vision of the high-speed steam engine.

(2) For his grasp of the principles of mechanics which [illegible]

(3) For his setting a standard of mechanical work and construction [illegible]

(4) For his creation of two types of mechanism in [illegible] engine [illegible] with [illegible]

I [illegible] debt [illegible] Charles T. Porter [illegible] ingenious mechanic, skilled designer and originator of the Richards form of the steam-engine indicator, present with us tonight as an honored guest. He created this at the urgence of Mr. Porter, to meet the demand for a steam-engine indicator capable of giving a reliable record of pressures in the cylinder of a high-speed steam engine. His concept of a multiplying parallel motion whereby a stiff spring and small piston motion with light masses should be used has underlain the derivatives which have replaced his early design. I am reminded by Mr. Porter that Mr. Richards also designed the first Allen engine bed, and the engines of the Colt armory, now running after more than 40 years, a most bold and successful achievement. May he live long to enjoy the esteem of his associates and fellow workers.

The other reference is to John F. Allen, who has gone to his reward, so that the tribute of this gathering must be only as a wreath upon his tomb. I do this the more gladly since it has been requested of me by Mr. Porter himself.

To Mr. Allen we owe the elegant invention of the single-eccentric link and four-opening valve, with pressure plates, to secure elimination of friction pressure. He gave to the slotted eccentric strap an adjustment which equalized the pressure diagrams taken from the opposite ends of the cylinder, at every point of cutoff, and retained, with a simpler and positive mechanism the features of constant release and compression with variable point of cutoff, which up to then were the exclusive prerogatives of the liberating system. These are today features of every high-speed engine gear. He gave to the locomotive the double-port opening property by the use of the hollow channel over the back of the shell; he designed a sectional water-tube boiler, in which how tumultuous soever might be the circulation of water and steam gas, the tube could never go empty. He invented a riveting machine using either pressure or percussion to upset the metal, and a high-speed air compressor to be its adjunct. I am glad to connect up to Mr. Allen these factors of his ability, which meant so much when the engine of the seventies and eighties became known as the Porter-Allen engine.

"The Debt of the Era of Steel to the High-speed Steam Engine"

was the title of Robert W. Hunt's address:

Naturally, I feel honored by having this opportunity to represent the American Society of Civil Engineers and the American Institute of Mining Engineers, in this first ceremonial presentation of the John Fritz medal. Aside from any personal equation, I am glad that such a manner for the bestowal of the medal has been inaugurated, and I sincerely hope the custom will be maintained for all future presentations. I regard the receipt of that medal as one of the highest honors which can be paid an engineer, and it is fitting that its presentation should be attended with an impressive but simple dignity, typical of the men in whose honor the medal was established. As you will recall, this was done, and the necessary fund secured, as one of the surprises given Mr. Fritz by his uncountable friends upon the celebration of his eightieth birthday. All who know him appreciate that his modesty would have prevented his having taken such action of his own volition. That he may live to participate in the bestowal of the medal for many years to come, is our earnest prayer.

I suppose if a man will only live long enough, his life will certainly cover some more or less eventful periods. It seems to me that my life must have been a very long one, or else the world has been more than busy during its continuance. It has been my fate to have been in touch with the happening of a lot of things, and some of them have been connected with the solutions of iron and steel problems. I have witnessed the development of bessemer steel from its struggling birth through its tremendous, almost unbelievable, growth up to its now suggested decadence. Practically all of those accomplishments were made possible by a more rapid application of power.

Perhaps because the smelting of iron and its subsequent manipulations were titanic in character, and because man was habituated to slow movements, it was imperative that the early processes should have been deliberate; at all events, the original ones were so. The first power applied in the industry beyond that of man, came from the slow-turning water wheel; later, from the slow-speed steam engine. As developments required faster movements, it was obtained through accelerating gears and belts.

Among the first, if not the first, engineers to make direct attachment of a rolling-mill engine to its train of rolls, were John and George Fritz. They thus avoided the expensive and frequently breaking intermediate gears; but the practical speed of their comparatively short-stroke engines was limited, and, so far as I know, Charles Talbot Porter was the first one to give the rolling-mill engineer a controllable, direct-connected, economical high-speed engine.

In 1876, I was general superintendent of the Albany & Rensselaer Iron and Steel Company, of Troy, N. Y., to which organization Alexander L. Holley was consulting engineer. One of the company's buildings had been used as a puddle and top-and-bottom mill, with its necessary puddle and heating furnaces, rolls, etc. The substitution of the manufacture of steel in place of iron rails threw this plan out of commission, and it was determined to convert it into a bessemer merchant-steel mill. The puddle and top-and-bottom mill had been driven by a walking-beam low-pressure engine which had been removed years before from the steamboat "Swallow," following its historic wreck on the Hudson river. The engine stood between the two trains and ran at from 35 to 40 revolutions per minute, the speed of the rolls being increased through heavy gears.

The possibilities of the adaptability of bessemer steel for uses other than rails had been so fully demonstrated by the European exhibits, notably those from Sweden, at the Philadelphia Centennial exposition, that our company decided, as has been stated, to take up its manufacture, and, acting under Mr. Holley's advice, put in two three-high mills, driven by Porter-Allen engines; a 22x36-inch one for the 16-inch train, and an 18x30-inch one for the 9-inch train of rolls. I believe those were the first of Mr. Porter's engines applied to the driving of iron or steel rolling-mill rolls. These new mills were located in the south end of the old puddle-mill building; the old "Swallow" engine and trains were in its north end, and we subsequently remodeled the trains and used them for rolling steel. To see the "Swallow" engine performing its duties with so great seeming deliberation at one end of the building, while in the other end Mr. Porter's two little engines were humming away and accomplishing much greater results, was an educational sight.

We frequently rolled light-section steel rails on the 16-inch train, and were so doing when Mr. Porter made us the visit mentioned in his "Engineering Reminiscences." He relates that our president, Erastus Corning, while standing with him watching the operation, asked a boy, probably a "water boy," "why they were not feeding the billets to the rolls faster." The boy replied: "Because the gentlemen at the hooks could not catch them, sir." The fact that the "gentlemen" of not only that mill, but also at our regular steel-rail mill rolls, could not work faster led me to put in the power-driven tables, which have since in their development done so much to make possible the tremendous output of American rail mills.

This first use of Porter-Allen engines was followed rapidly by other parties, until direct-acting high-speed engines became the typical American rolling-mill type, and I take this occasion to put on record the great debt which iron and steel engineering owes to Charles T. Porter. It has been my good fortune to claim him as a friend for many years, and from the first I have known him and esteemed him as I do now, as a high- and simple-minded, clean-living man, and a profound student. The heavy hand of time has perhaps taken from him a former additional appellation, which was truly his, that of a hard worker, but if ever a man earned the right to rest, it is he!

"THE DEBT OF THE ERA OF ELECTRICITY TO THE HIGH-SPEED STEAM ENGINE"

was the title of Frank J. Sprague's address:

Mr. Chairman, guests of the evening, ladies and gentlemen. It is a trite saying, but often true, that expectation is better than realization, and hence due consideration for the comfort and pleasure of an audience sometimes, and in this instance surely, warrants a late speaker in first acknowledging the truth of the obligation declared in the subject set for his remarks, and then as promptly as permissible dismissing consideration of it. This is a liberty accorded at a time of general rejoicing, when pessimism may be thrown to the winds, and dry statistics consigned to temporary oblivion.

It has been said that every stable government should have, and is benefited by a sizable national debt; and with that happy disregard of the fact that like business fundamentals should govern private and public business, our political sponsors, representatives and executors cheerfully pile obligation on obligation for the stability and happiness of posterity.

So tonight, in interested humility, we have listened to many tales of the debts of our industrial development to the high speed engine, until they have piled up so high as to awaken the envy of a national treasurer complacently facing a $100,000,000 deficit. I am sure that our esteemed confrere, the honored guest of the evening, must at times have felt as did our patron Crœsus when he first securely established his prior lien on a great industry, and perhaps, in an ecstatic impulse of generosity he would be inclined, if only these debts could be cashed in, to establish a Porter Foundation for the Benefit of Indigent and Superannuated Engineers.

The connection of Charles Talbot Porter, individual, with the electrical industry, has not been directly a wide one. It is nearly fifty years since he, an American engineer, sought for his hunting ground, not Mombasa, or the country of the blue Nile, but the home of Watt, in the very fastnesses of insular prejudice and complacent engineering authority. His experience in combating for six years certain preconceived notions and practices has already been most eloquently told, but I may recall the fact that in 1867, at the French exhibition, he installed with British and two Porter-Allen engines, the only high-speed machines, I believe, there exhibited, to drive generators for supplying current for lighthouse apparatus. While these engines were not directly coupled, it is a curious fact that the piston speeds and revolutions were what is common today in isolated direct-coupled plants. At that same exhibition a 300-revolution engine was also installed, and this was sometimes operated without load at over three times this speed. In the dozen years succeeding his return to the United States, Mr. Porter built many engines for various purposes, most of them having certain common characteristics, high piston speed and revolutions, solid engine bed, overhung cylinder and babbitted bearings, but in all this time there was no electric driving until a contract was made for engines for this purpose in Philadelphia.

About this time appeared a "wizard." It was once said that engineers constituted "the best educated set of damn fools in the world," and I suppose among us we must include that class known specifically as inventors. Now there is a very narrow margin between the wizard and failure, on one hand, and eminent success on the other. Happily, in this case the middleman was Thomas A. Edison, for whom, about 1880, Mr. Porter installed a high-speed engine in the laboratory at Menlo park. Shortly after, when planning the installation of the Edison station, first district, at Pearl street, New York, Mr. Edison decided upon an equipment of so-called steam dynamos, later familiarly known as "jumbos," each to be independently driven by a direct-coupled engine. As a consequence, Mr. Porter was invited to construct the first of these engines, and it is a curious commentary that in this particular combination he, in a general way, reversed the ratio of weights for engines and dynamos, the proportion being about 7 to 1 in favor of the engines. It is needless to dwell upon the vicissitudes of that first installation, or the changes which were necessary; both apparatus and plant have passed into history. But I may remark in passing that high engine revolutions is simply a function of high piston speed and length of cylinder, and that in some of our greatest installations, that of the Fifty-ninth street Interborough station, which marks the acme of this type of installation, high piston speed has been accomplished by a comparatively low speed of revolution, but with direct-coupling because of the great size of the electric generators. For this class of service the reciprocating engine is now on a fast descending scale of use for all new work, and the more modern turbine, the outcome of the work of Parsons, Curtis and others, will reign supreme.

Debt there has been, and a large one, of electric development to the high-speed engine, but I am sure that our friend will agree with me that all sound bookkeeping must show a credit entry for every debit one, and in that generosity of heart characteristic of all engineers imbued with catholicity of spirit he will admit that whatever that debt, it is being repaid in royal fashion. Let us think, then, not of debtor and creditor, but of a most interesting fact, an industrial marriage, one of the most important in the engineering world, that of the prime mover and the electric generator.

The world traveler, sailing into the harbor of Kobe, on the southern coast of Japan, and forgetting for a moment the spectre of war so [illegible] improvable and [illegible] will, if favored by happy circumstances, find himself in the presence of an impressive sight, for there, as it were [illegible] apparently floating on a bed of fleecy clouds, he will see the truncated summit of a great volcano, once a terror but now extinct, Fujiyama, the sacred mountain of Japan, famous alike in history and in art.

It is many years since, on a summer's day, while I lay exhausted half way up its rugged slopes, I saw far below me a man and woman, attended by native guides, laboriously working their way over the sand and scoria which deeply covered the mountain sides. Curiosity as well as fatigue impelled me to await the coming of, naturally, two Americans, a professor at the Imperial College at Tokio and his wife, the first white woman, I believe, who made the difficult ascent. This chance meeting ripened soon into a friendship which afforded me an early opportunity to learn of a graceful, courteous characteristic of the inner life of a remarkable people, for shortly after, on the occasion of a marriage anniversary of my friends there was presented to them by a Japanese servant a beautiful picture of the great volcano, and a poem congratulatory of their married state. This likened the man to the majestic mountain in all its dominant strength and overpowering grandeur, and the wife to the beautiful Lake Biwa, resting in happy security beneath the protecting shadow of her consort, fed from his melting snows, and mirroring and reflecting from her pure and placid bosom with unchanged truth, [illegible] the changing moods of her mate, each a complement of the other, both necessary for a harmonious unity.

It is a far cry from the sacred [illegible] the Atlantic coast, from a [illegible] home in the Hermit Kingdom to the [illegible] meeting place of the engineers in Manhattan, but [illegible] heart a [illegible] tion, and the thought of perfect union and [illegible] Japanese [illegible] with us, and [illegible] tion of the elements of every great engineering work.

Our engineering fraternity is a "[illegible] [illegible] there shall be no complaining? And in all our clientele is there any more perfect example of an industrial marriage than the modern high-speed direct-connected electric generator, any more beautiful, enduring and graceful monument of engineering skill?

Let the busy cynic come away from bank and mart, from press and ticker, from club and sport; and woman, too, from household cares and the social whirl, from matinee and bridge, from astrology and the suffragette; and learn a lesson from our humble friends in a great central station, at the starting of their career in housekeeping. The courtship has been a long one, and the marriage ceremony perhaps a little tedious. The groom, forsaking the early tenets of his slow-moving ancestors, and impelled by an innate consciousness of virility vital to meet his coming burdens, has awakened to the necessity of a quickened life, while the bride, in early life a little flighty and nervous, has sobered down to a realizing sense of her new responsibilities. Like the ostriches, they are mated for life; there may be grief and disaster, but there will be no divorce.

How is it these two machines have come together, economizing space, increasing economy, augmenting capacity, reducing investment and increasing dividends? Is this final result the work of any one man? Would the electric art have stood still were there no high-speed engines? To both questions we must answer, No. The truth is that here were two machines destined to be joined in some fashion. One was, in its early development, when used for stationary purposes, normally a slow-speed machine, the other a high-speed one; and so constructed that the only connection was through countershafts, gearing and belts. Every practical consideration, especially when considering central-station operation, pointed to the necessity of eliminating all extraneous devices between the two, and hence augmenting the speed of one and reducing the speed of the other until they could be physically united. And in this development every advantage had to be taken of the possibilities of each, and likewise due heed paid to their individual limitations. Primarily and largely due to Porter, the high-speed possibilities of the former were commercially demonstrated before the necessity arose for reducing dynamo speeds to coincide with engine requirements, although in the great commercial and mechanical development each machine has been indebted to the other, but all honor must be paid and credit given to the men who first blazed the way for the present possibilities.

In every industrial development there appears at some time an engineer with imagination, courage and foresight, who defies chance, courts failure, and embraces opportunity. He may not clearly see the goal to which he is aiming, he may be unconscious of the full measure of the influence of his work, but somehow he is impelled by certain primal convictions which in the face of every discouragement lead him onward. It is to the man and the men, then, not to the machine, that the modern industrial development is indebted. It may be true in this case that the machines which bore the brunt of early development, and the men who staked their all upon it, may have disappeared as practical factors in the present status of the art. Newer makes of machines, improved and widely different governing apparatus, entire abolition of the reciprocating engine for great central-station units, may be the verdict of history. The spirit, however, which blazed the way never dies, and the names of Porter and Allen, Armington and Sims, Sweet, and a host of others, will be linked in industrial history with those of Parsons and Curtis. .

It is precisely such occasions as this, and such honorary tribute as mark tonight's gathering, which happily commemorate the early sacrifices and influence of the pioneer. And so on behalf of the electrical profession, I extend hearty congratulation to Charles Talbot Porter for the honor which has, by the verdict of his brother engineers, so deservedly come to him.

Distinguished Guests Present

Seated upon the platform were Henry R. Towne, who presided; E. Gybbon Spilsbury, chairman of the Board of Award; Prof. Charles B. Richards, who was associated with Mr. Porter in his earlier work, and who invented the Richards indicator to make it possible to indicate his high-speed engine; Jesse M. Smith, president of the American Society of Mechanical Engineers; Sir Charles Algernon Parsons, inventor of the steam turbine; John E. Sweet, Rear Admiral George W. Melville, James C. Brooks, president of the Southwark Foundry and Machine Company, present builder of the Porter-Allen engine; Rear Admiral George W. Noble, Former Chief Engineer Wallace, of the Panama canal; James Douglass, past president of the Mining Engineers; George G. Ward, representing the Institution of Electrical Engineers of Great Britain; Charles L. Clarke, of the Mining Institute; George H. Pegram, of the Interborough, who installed the first dynamos in this country having connected engines; M. Pickler, a Hungarian engineer and old friend of Mr. Porter; Charles Warren Hunt, secretary of the American Society of Civil Engineers; Schuyler Skaats Wheeler, ex-president of the American Institute of Electrical Engineers; and Prof. F. R. Hutton, Prof. W. F. M. Goss, Robert W. Hunt and F. J. Sprague, the orators of the evening.

Telegrams from John Fritz and E. D. Leavitt, letters from William H. Maw, editor of *Engineering*, from "All Hoyle," and a former apprentice at the Southwark Foundry and Machine Works during Mr. Porter's time, together with cablegrams from the Iron and Steel Institute, Institute of Mechanical Engineers, and the Institute of Civil Engineers were read.

Power Plant of West Point Military Academy

A Gilt-edge Lighting and Heating Plant. Test Record Shows Remarkable Thermal Efficiencies for Noncondensing Engines

Since March, 1802, West Point has been the seat of the U. S. Military Academy, which is located on the west bank of the Hudson river about 50 miles above New York. The reservation extends for about three miles in a north and south direction with the principal buildings located in the immediate vicinity of the parade ground, which is located upon a broad plateau about 150 feet above the river level. During the past few years Congress has appropriated a total of 7½ millions of dollars for the enlargement and improvement of the academy, this being made necessary by an increase in the corps of cadets from which most of the commissioned officers for the army are appointed. With this large appropriation it was proposed to build a new cadet headquarters, cadet barracks, hotel, academic building, administration building, chapel, bachelor officers' quarters, cavalry and artillery stables and barracks, quartermaster's storehouse, riding hall, power house and other buildings of less importance.

Extending to the north and south from the parade ground the main roads afford means of reaching the officers' quarters, while at the extreme south end of the post are grouped the stables and barracks for cavalry and artillery companies stationed at West Point. At the extreme north end of the post is the hospital and site of the proposed [illegible]. North of the parade and alongside of the river is a flat low-lying plain level with the railroad tracks and on the gradual slope from the parade above to the plain are located the quartermaster's buildings, shops and barracks for some service detachment and barracks for the band.

As first proposed the power plant was to supply steam as well as electricity to all of the buildings, but as the buildings at the extreme north and south ends of the post were separated by a distance of over two miles, steam distribution through tunnels was out of the question, so that it was decided to restrict the distribution of steam to the buildings bordering upon the parade, the only large buildings not reached being the cavalry and artillery stables and barracks at the south part of the post, and the quartermaster's stores and other similar buildings at the north. These are to be taken care of by separate plants, either by hot water or by steam arranged on a gravity system. Consequently, the proposition was to design a plant sufficient to supply steam and [illegible] the large buildings of the central group then proposed and to be

FIG. 1. THE WEST POINT POWER HOUSE, [illegible]

nish electricity for lighting and for power purposes for the entire post, the plant to be of sufficient size to permit of future installations should the corps of cadets increase to 1200. Provision must also be made for the storage of 4500 tons of anthracite coal in the plant.

A study of the plans for the various buildings seemed to indicate that about 3000 horsepower would be required for warming and ventilating the buildings and supplying hot water for bathing purposes, with a possible increase of 600 horsepower required by the increase in the corps mentioned. The estimated electrical load appeared to be about 1200 kilowatts for the buildings immediately contemplated, and about 200 kilowatts additional for the increase.

Several locations for the power plant were considered, but the logical site from an engineering standpoint seemed to be on the low-lying land between the railroad and the river. Here the underlying rock sloped off so quickly that proper foundations could not be secured, but it was finally decided to blast out a pocket in the rock over the southern entrance to the railroad tunnel and there locate the power house. Under the circumstances, this was undoubtedly the best thing to do, although it must be admitted that the cost of such construction would undoubtedly be prohibitive for an ordinary power plant. The unusual arrangement of the building will be noted in Figs. 1, 2 and 3. It will be seen in Fig. 4 that the chimney is to be concealed in the tower of the riding hall which is soon to be built, and in Fig. 2 that a tunnel has been provided for the mechanical handling of coal either from rail or water delivery, and for the disposal of ashes in the tower noted at the entrance. The elevation of the railway track at this point is about + 10 and that of the road leading from the railway depot up to the parade ground about + 95 opposite the plant.

The boiler house extends north and south and contains a boiler room on the main floor with a basement extending under the front of the boiler room only. The coal bunker above is a large flat-bottomed structure 148 feet long, 57 feet wide between column centers and about 21 feet 6 inches deep on the clear. A tower at one corner of the boiler room contains the elevator for raising coal, and this tower is connected to the ash tower by the tunnel previously referred to; the tunnel incloses the belt conveying the coal from the cars up a steep incline to the base of the elevator. Beneath the engine room is also a basement, and a tower at the corner of the room provides the principal means of access between the engine and boiler rooms, also space for the chief engineer's office and toilet, and lockers and bathrooms for the operating force.

FIG. 2. VIEW OF POWER PLANT FROM THE ROAD

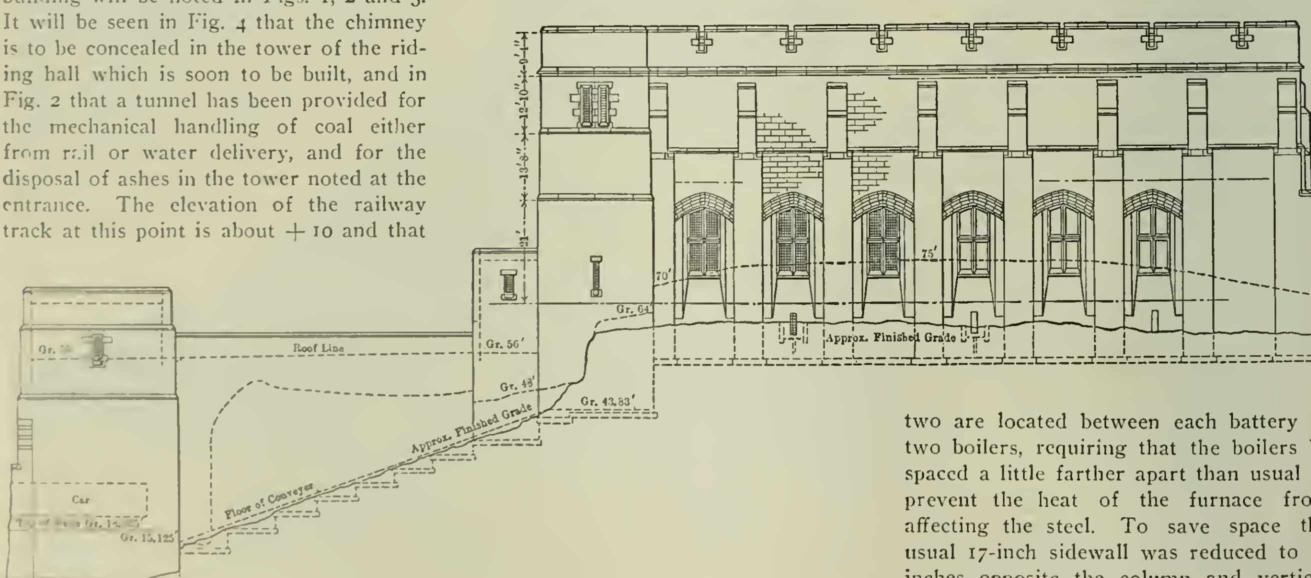

FIG. 3. POWER PLANT ON RIVER SIDE, SHOWING ELEVATIONS OF COAL TUNNEL AND BUILDING

Boiler Installation

At the present writing four Babcock & Wilcox boilers are installed in the plant, each containing about 4400 feet of heating surface and 210 tubes arranged 21 wide and 10 high. The boilers are equipped with Treadkill grates which are proportioned to give 87 square feet of surface under each boiler and a ratio of heating to grate surface of 50 to 1—an unusual ratio for small-size anthracite coal, but permissible in this case as mechanical draft is available when needed.

The boilers are suspended by straps around the drum from horizontal channels carried by the building columns, and the spacing of the columns is such that two are located between each battery of two boilers, requiring that the boilers be spaced a little farther apart than usual to prevent the heat of the furnace from affecting the steel. To save space the usual 17-inch sidewall was reduced to 13 inches opposite the column and vertical cast-iron channels were bolted to the walls to secure an air space. In front of the columns the spaces between the settings were closed by iron plates secured to the flanges of the channel, and bull-nosed brick were laid to finish against the plate.

A Custodis radial-brick chimney has been erected, and this, as previously mentioned, is to be later inclosed by the tower of the riding hall. The inner core of the chimney has an inside diameter at the top of 10 feet, and the stack rises 145 feet above the grate. A ladder on the interior has been provided and also lightning rods

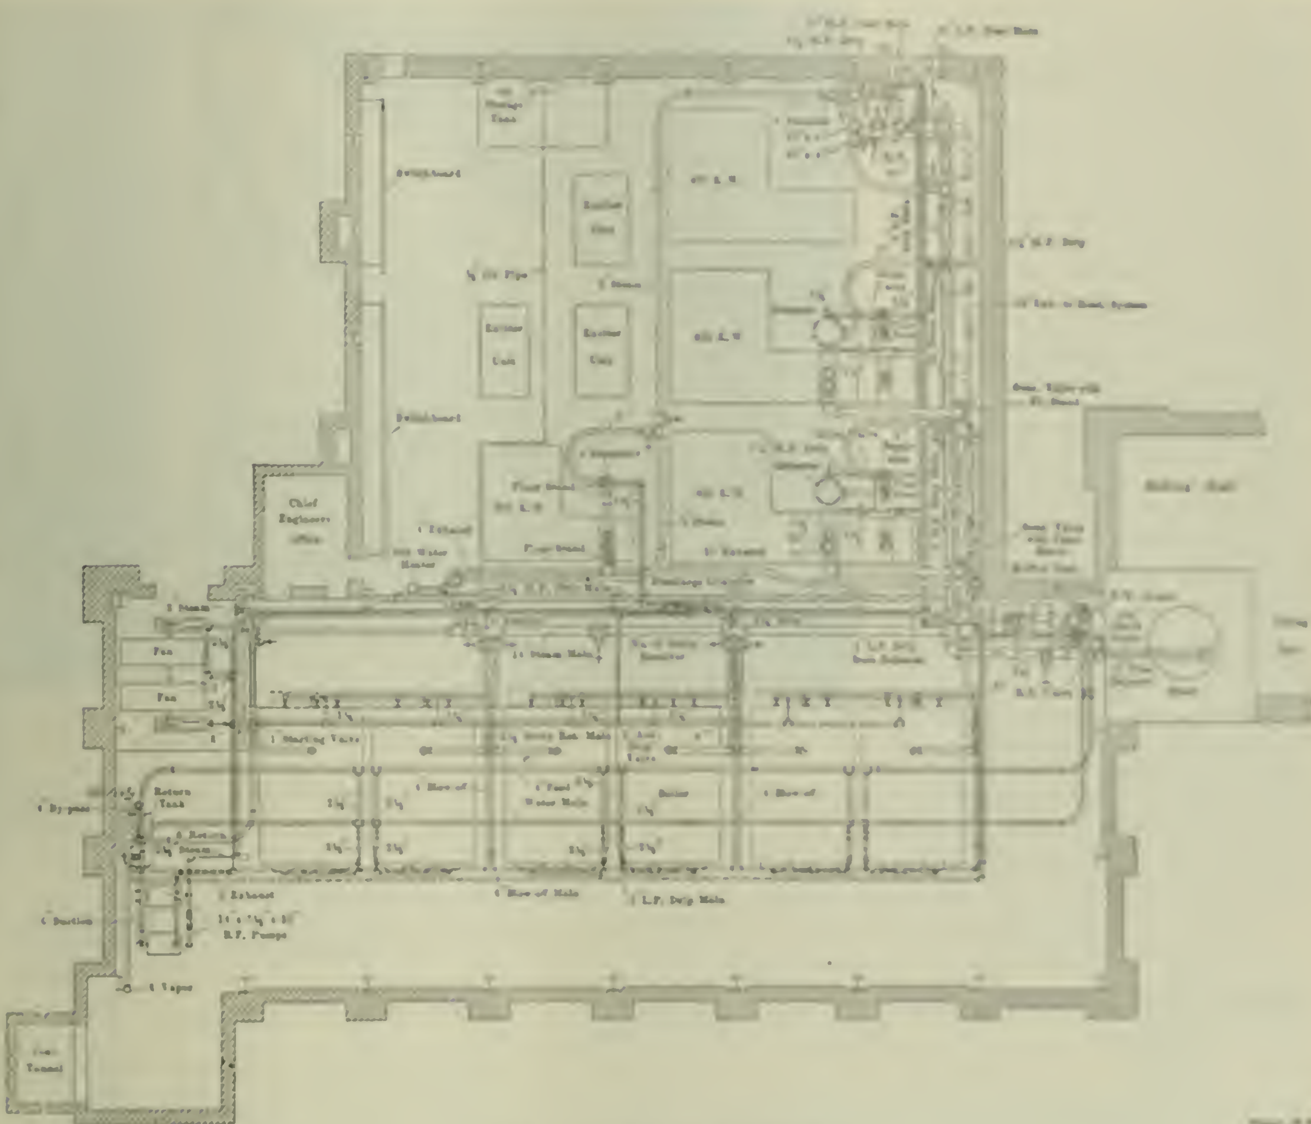

FIG. 4. PIPING PLAN OF STATION

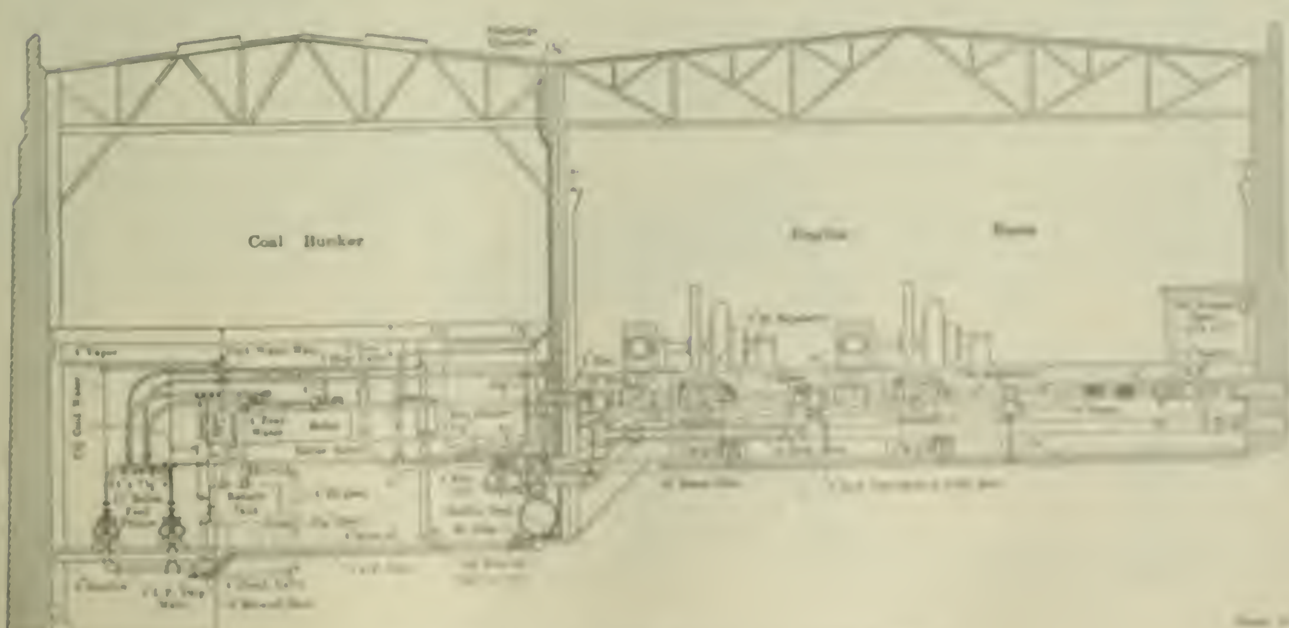

FIG. 5. ELEVATION THROUGH ENGINE AND BOILER ROOMS

connected by a copper cable with an extension run down to the river and there soldered to a submerged copper plate. Within its internal area the chimney also contains a 16-inch cast-iron flanged pipe which was provided to discharge the free exhaust from the engines at the top of the stack, as the escape of this exhaust above the engine-room roof would be objectionable. For architectural considerations the chimney was limited in hight, so that in order to obtain sufficient draft to burn the low-grade coal and run the boilers at their rating, a mechanical-draft plant was installed to help out the chimney in emergency. This plant consists of two Sturtevant fans 8 feet in diameter and 4 feet wide, with engines of sufficient size to drive the fans at 250 revolutions a minute, at which speed each fan is supposed to furnish 55,000 cubic feet of air per minute at a pressure of 2½ inches of water. The installation is located on a mezzanine floor, and each blower discharges downward through an iron duct into a masonry duct running below the boiler-room floor level and extending across the boilers at the rear of the bridgewall, as shown in Fig. 7. Entrance to the ashpit is made through a cast-iron blast box and is controlled by the usual dampers operated by levers extending through the fronts of the boilers. The fans are controlled by a Foster regulator actuated by the boiler pressure.

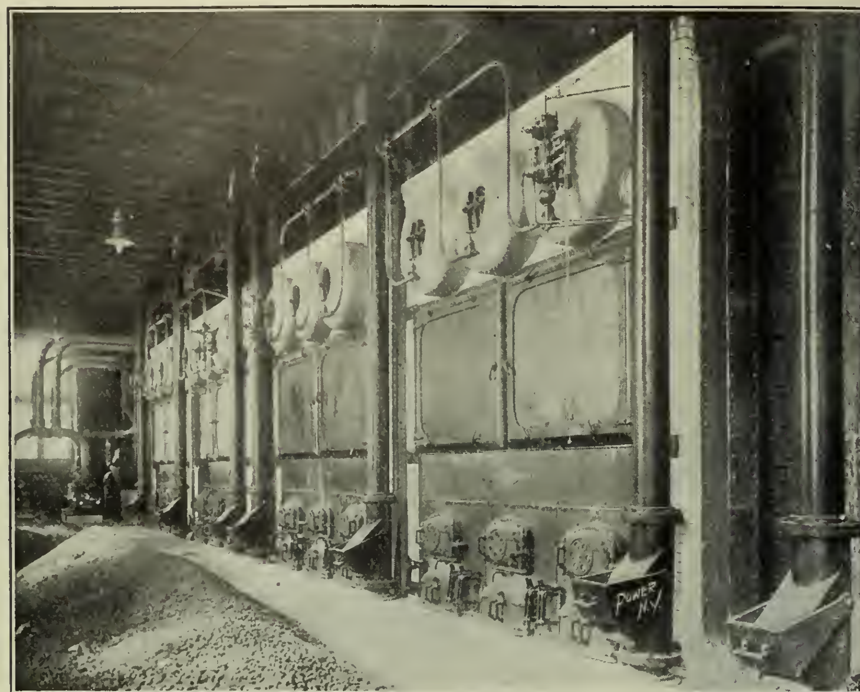

FIG. 6. THE BOILERS AND COAL CHUTES FROM THE BUNKER

From each boiler the smoke connection to the flue is also shown in Fig. 7. The flue has a concrete floor, brick sidewalls and double rowlock brick arches sprung between transverse I-beams for a top. The flue is provided with a pair of dampers close to the chimney. These dampers are illustrated in Fig. 8 and are made of cast iron, heavily ribbed and suspended from the steel floor beams of the coal bunker by a chain of several links with a turnbuckle for vertical adjustment. A Locke damper regulator controls the posi-

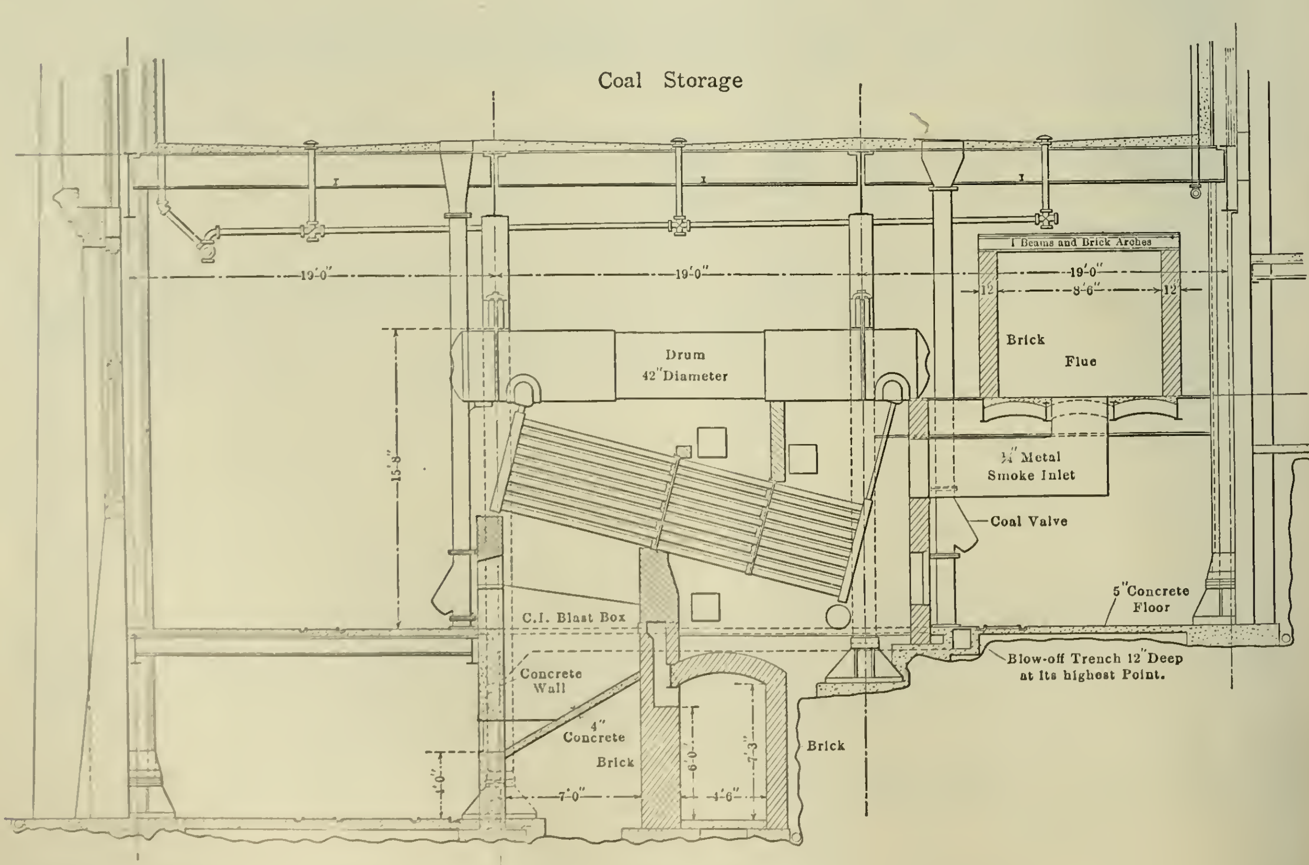

FIG. 7. SECTION THROUGH BOILER ROOM

tion of the damper, but this is not used when the fans are in operation.

Coal and Ash Handling

Figs. 9 to 12 give a fair idea of the coal- and ash-handling equipment. At the present, means are provided only for the mechanical handling of coal delivered by rail, but the system is designed with the idea of taking care of coal by water at any time that it might be desired to so receive it. As the facilities for switching cars at West Point were somewhat limited, it was decided to arrange for the unloading of four 50-ton hopper-bottom cars without shifting. To meet these requirements two tracks were arranged so that two cars could be run in on each side of a belt conveyer and slightly above it, so that a gravity discharge could be obtained through chutes onto the belt.

From beneath the unloading platform the belt runs upward at an angle of about 23 degrees to the base of the boiler-room tower and there discharges into the boot of an elevator which raises the coal to a point above the top of the bunker. From here the coal is spouted onto a transverse belt conveyer extending across the south end of the boiler house, and this discharges into the bunker or onto either one of two longitudinal belts which deliver through automatic trippers to any part of the bunker (except those. In Fig. 9 the conveyer A and the transverse conveyer B are equipped with belts each 18 inches in width, and the longitudinal conveyers C and D are 16 inches wide. The elevator E has buckets 24 inches long, 16 inches wide and 8 inches deep made of No. 12 steel. The system was designed to handle 60 tons of 2240 pounds per hour, but upon test it has considerably exceeded this requirement.

Three Westinghouse motors operate the system, one driving the lower conveyer A, one driving the elevator E and the transverse conveyer B, and one driving the two longitudinal conveyers C and D. The motors are of the inclosed type, and the starting boxes are inclosed in dust-proof iron boxes. An electrical connection is run from each starting box inside of the switch to a pilot lamp on a board in the boiler room. This board also contains an automatic circuit breaker in the main lead supplying all of the motors. The solenoid of the breaker is connected by wires to push buttons at various parts of the conveying system, so that an attendant can by pushing a button stop the operation of the entire plant when necessary. Swinging chutes are provided to deliver the coal from each car to the lower belt, and the

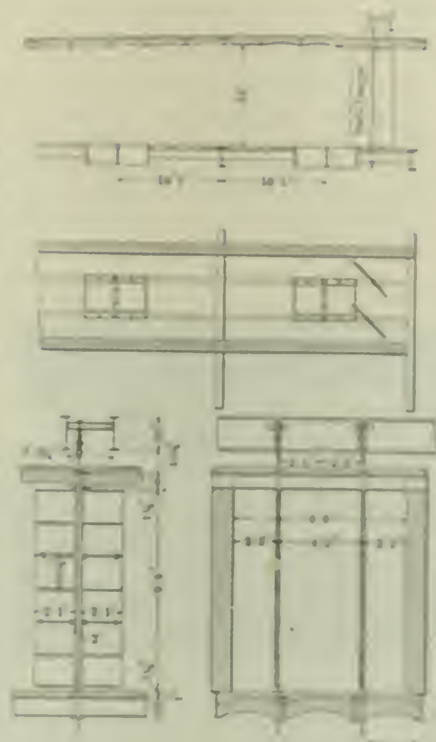

FIG. 8. FLUE DAMPER NEAR STACK

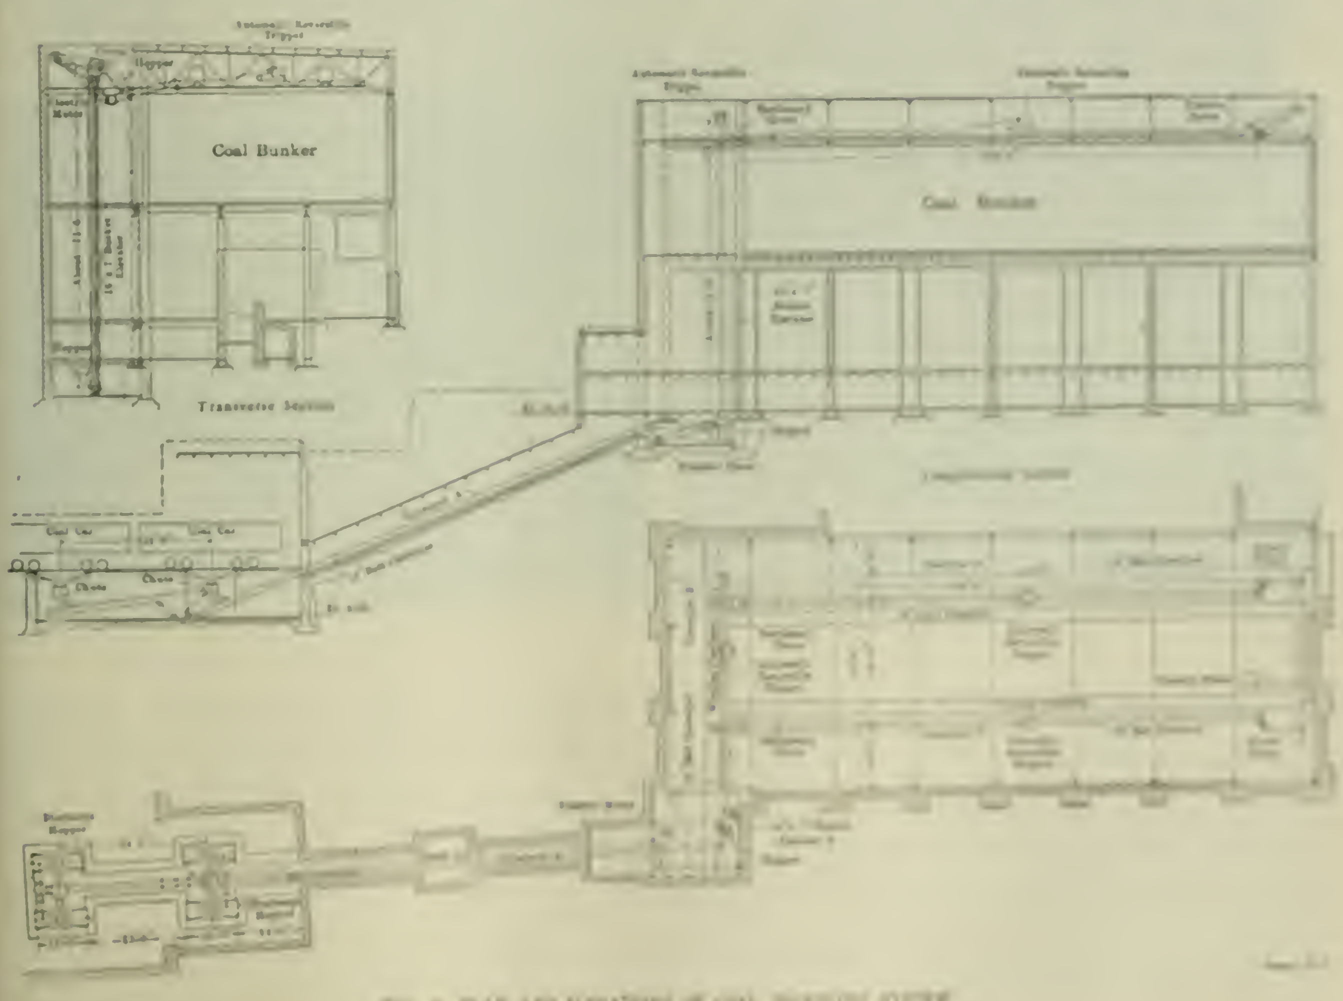

FIG. 9. PLAN AND ELEVATIONS OF COAL HANDLING SYSTEM

motion of this chute is controlled by a wheel on a shaft extending up through the platform on which the cars are located. The Robins Conveying Belt Company supplied the entire conveying system.

From the bunker coal is discharged to the boiler-room floor through a number of chutes located at the corners of the settings, as indicated in Fig. 6. As the bottom of the bunker is flat, similar chutes are provided at the rear of the boilers and are arranged to dump into

FIG. 10. COAL-CONVEYING SYSTEM ABOVE BUNKER

Hunt standard charging cars, so that the coal may be carried on tracks to the front of the boilers. The valves at the bottom of each chute will be noted, and just below the bunker-floor level there is also provided a sliding gate.

Ashes drop from the grate into a deep

FIG. 11. PROVISION FOR REMOVAL OF ASH

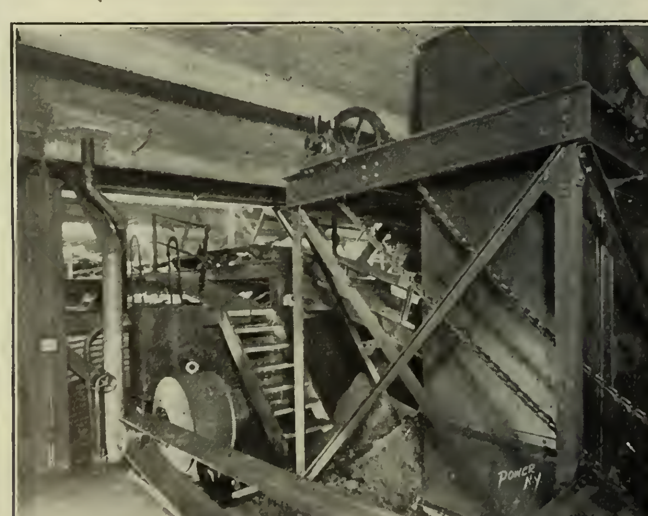

FIG. 12. FROM ELEVATOR TO BELT CONVEYER

hopper provided with the chutes shown in Fig. 11, from which the ashes may be drawn out into industrial cars and run through the boiler-room basement and onto the roof of the conveyer incline to an ash hopper which will be constructed in the near future in the upper part of the tower. From this location the ashes may be discharged into railroad cars for removal, but at present they are used for filling in and are being discharged through a temporary opening through the side wall of the power house by means of wheelbarrows.

Engines

In this department it was decided to install two 400-kilowatt and one 200-kilowatt direct-current generators, each of the larger machines being driven by a tandem-compound Corliss engine and the latter by a simple Corliss engine. These machines, Fig. 13, develop direct current at 240 volts for both light and power, and motor generators are used to obtain alternating current at 2200 volts for the extreme north and south ends of the post. Due to the large amount of steam required for heating during the winter months, and also to the fact that the river was 60 feet below the engine-room level, it was decided to run the engines noncondensing.

A careful selection of the bids of various builders resulted in the selection of Rice & Sargent engines made by the Providence Engineering Works. These units were to operate on a normal working pressure of 130 pounds at the throttle, which might be increased to 150 pounds when considerable back pressure was placed upon the engines during the heating season. The speed was limited to 100 revolutions per minute and the engines were to be capable of running at 50 per cent. overload for short intervals. The tandem compounds were 24x36x36 inches, and the simple Corliss had a cylinder 22x30 inches. Each compound engine was provided with a large reheating receiver containing 0.6 square foot of reheating surface in brass pipes per rated horsepower of the engine. The simple engine has a cylinder steam jacketed in both heads only, and the compound engines have both cylinders jacketed in a similar manner. As apparent in Fig. 13, the engine piping is below the engine-room floor and the main throttle valves and the valves in the exhaust pipes are operated by floor stands.

Trial Tests of Engines

When the time for the trial tests of the engines arrived George H. Barrus was retained to conduct the tests. The guarantees were expressed in the following terms:

"The steam consumption of each compound engine will not exceed 19 pounds of steam per indicated horsepower with a steam pressure of not less than 130 pounds at the throttle and one pound back pressure in the exhaust pipe.

"The friction load of each compound engine will not exceed 4½ per cent. of the rated load which is to be taken at 600 horsepower.

"The steam consumption of the simple engines will not exceed 23 pounds per indicated horsepower per hour when the engine is developing from 275 to 325 horsepower with a steam pressure not less than 130 pounds at the throttle valve and one pound back pressure at the exhaust valve.

"The friction load of the simple engine will not exceed 4½ per cent. of the rated load which shall be taken at 300 horsepower.

"The friction load is to be obtained by

running the engine at its rated speed with a steam pressure of not less than 150 pounds, with the brushes of the generators not in contact with the commutator and the field unexcited.

"A separator will be placed in the steam pipe to each engine and unless there is evidence to the contrary the steam will be assumed to be dry."

The simple engine was designated as engine No. 1 and the two tandem compounds as engines Nos. 2 and 3. It was decided that a test of one of the compound engines would suffice and No. 2 was selected. This engine had been in operation under a load less than three days when the tests were made, and the simple engine had been running under varying loads every night for about twelve weeks. The main steam line, both in the boiler room and in the engine room basement is so arranged with valves and connections to the boilers that No. 1 engine could be run independently from No. 1 boiler, while the other engines and the auxiliary apparatus and other work of the plant are supplied from the remaining boilers. Likewise Nos. 2 and 3 engines can be run independently from Nos. 2, 3 and 4 boilers, while No. 1 boiler is used for supplying the simple engine and all the remaining work of the plant.

Drainage of the steam lines is effected by separators, one for each engine, and by drips located at various low points on the line, all of which discharge into the Holly system installed in the plant. The drainage from the two reheaters of the compound engines, each having 300 square feet of surface, and that from the jackets of the various engines also discharged into the Holly system. Two feed pumps are provided, each discharging into two independent feed lines, either of which can be used for the supply of any boiler. The water is ordinarily drawn from a feed tank in the boiler room, which collects the hot-water returns from the various buildings. The simple engine, which is 22x36 inches, has a piston rod 3.75 inches in diameter and a clearance of 6.1 per cent. The compound engine, 14x26x36 inches, has the following dimensions: Diameter of high-pressure piston rod, 4 inches; diameter of low-pressure piston rod, head end, 4 inches; crank end, 4½ inches; clearance of high-pressure cylinder, 5.1 per cent.; clearance of low-pressure cylinder, 7 per cent.

In conducting the test the method followed was in substantial accord with that recommended by the engine-test committee of the American Society of Mechanical Engineers. For the purpose of securing constant-load conditions an artificial resistance was provided consisting of a water rheostat having about 1000 feet of iron wire, No. 12 Birmingham gage, placed in a tank of running water and divided into five equal sections, each section being controlled by a switch.

Steam consumption was determined by feed-water measurement, corrected for leakage and condensation in engines and mains. No. 1 boiler supplied the steam on the test of the simple engine and Nos. 2 and 3 boilers on that of the compound engines. The same feed pump was used on both tests, and the water was drawn from a temporary weighing apparatus erected for the purpose. The drainage from the separator and drip pockets in the steam main connected with the engine under test was cut off from the Holly system and carried through a temporary pipe to the feed reservoir mentioned. Each of these drips was provided with a water column and gage glass with a regulating valve beneath to keep the pipe clear without loss of steam. The reheater and jacket drips were also disconnected from the Holly system and drained through water columns. The drainage from these points was discharged separately on the boiler-room floor and thrown away. The leakage of the boilers and mains was determined as soon as possible after the conclusion of the principal run of each engine by the water-glass test, the consumption being based on the rise and fall of the level. During the progress of the main tests a set of indicator diagrams, one from each end of each cylinder was taken every twenty minutes, together with the usual observations of

FIG. 13. THE ENGINE ROOM

gages and revolutions per minute. Every half hour records were made of the hight of water in the gage glasses of the boilers and the quantity of water fed from the weighing apparatus. At equal intervals put of the generator were observed. The the instruments showing the electrical out-accuracy of the indicator springs, gages, weighing scales and electrical meters were all verified.

Immediately after the economy runs the friction tests were made. the engines being first shut down in order to raise the brushes from the commutator. In the simple-engine test the pressure in the steam pipe was 97 pounds and in the compound-engine test, 76 pounds. these being the highest pressures which could be carried without undue slamming of the valves, and without introducing conditions unduly affecting the reliability of the indicator diagrams. For these reasons the guarantee requirement of 130 pounds steam pressure for friction tests was waived. The data and results of the economy tests are given in Table 1 and those of the friction tests in Table 2.

In conclusion, Mr. Barrus states that the steam consumption of the compound engines was 18.33 pounds per indicated horsepower per hour, which is 3.5 per cent. better than the guaranteed performance of 19 pounds. The simple engine consumed 20.98 pounds of steam per indicated horsepower per hour, which is 8.8 per cent. better than the guaranteed performance of 23 pounds. The percentage of friction of the compound engine was 3.8 per cent. and that of the simple engines 3.6 per cent., both of which are within the 4½ per cent. guarantee.

Computing the efficiency ratios from the above data gives some remarkable results —an efficiency of 69.6 for the simple engine and 79.2 for the compound engines. These efficiencies are much better than what is usually obtained in engines of this character, even of much larger capacities, and exceed considerably the efficiency ratios of steam turbines. It will be of interest to note how near these efficiencies will be maintained in everyday operation.

Tunnel System and Piping

In the larger buildings near the power house pipes are distributed through a system of underground tunnels shown in outline in Fig. 14. The gymnasium is the most distant building supplied with steam and this is at a distance of 2160 feet from the power house. The work on the tunnels has not yet been completed, as some of the buildings have not been built. To the gymnasium the main tunnel varies in size, depending upon the number of pipes that it contains. It is of rectangular cross-section and from the power house to the point *K* is 7 feet high and 6 feet wide, the side walls being 12 inches and the roof 10 inches thick. From points *K* to *M* the tunnel is 6 feet 6 inches high. 5 feet wide, with side walls and roof 10 inches thick. From point *M* on the tunnel is 6 feet 3 inches high and 4 feet wide, with walls and roof 10 inches thick. The floor is 8 inches thick throughout. The roof, floor and walls of the tunnel are of concrete construction except at curves, where rubble walls were used to save the cost of forms for concrete. A considerable portion of the excavation was through rock, and in the construction special provision was made to keep water from entering the tunnel.

Fig. 4 shows the general arrangement of the steam and exhaust piping in the engine and boiler rooms. As will be noted, the boilers are connected to a 14-inch main steam header with two valves in each boiler connection, that at the boiler being a Foster automatic stop valve. An 8-inch ring main supplies the engines, and this is fed from either end of the 14-inch header in the boiler room. A valve in this header subdivides it into sections, so that either side may be used as desired. Connections from the ring

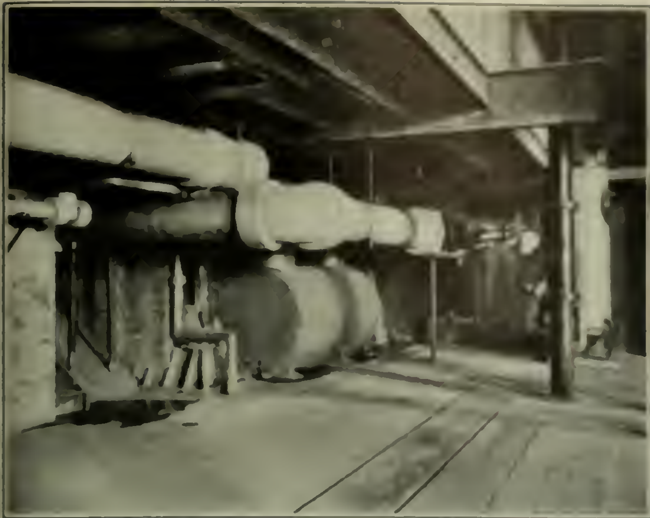

FIG. 15. MUFFLER TANK AND FEED-WATER HEATER

FIG. 16. LIVE- AND EXHAUST-STEAM CONNECTIONS AT ENTRANCE TO TUNNEL

main to the engines consist of long radius bends which enter Stratton separators of the receiver type, these being supplied to insure dry steam and also to provide a receiver of moderate steam volume close to the engine throttle. A 3-inch connection from the end of the boiler-room header supplies the boiler-feed pumps and fan engine, and in addition there is a separate 2½-inch line run from the end of the Holly main which may be used to operate the feed pumps.

Exhaust-steam pipes from the engines are connected into a 16-inch exhaust line which discharges into a Utility combined muffler tank and grease separator provided with the usual bypass, and from here the exhaust escapes to the atmosphere through a free-exhaust pipe of the same diameter running upward through the interior of the stack. During the heating season the exhaust steam passes through a 16-inch line to the tunnels, and as it rises from the basement of the engine room to the entrance of the tunnel, connection is made with the high-pressure line which supplies steam direct from the boilers through a Foster reducing valve when the exhaust is insufficient to heat the buildings. In the tunnels the exhaust steam is carried as far as the academy building. On the direct lines from the boilers to the buildings there is also provision to reduce the initial pressure of 125 pounds to from five to two pounds for the tunnel system.

All drip points on high-pressure lines are connected to the Holly system, and the condensation in the various buildings connected to the central plant is returned to the power house by Bundy pumping traps through a line that gradually increases in size up to 6 inches as it enters the power house. In the boiler room this return line connects to the top of a return tank which is provided with a vapor line to the atmosphere, so that it is practically an open tank. Ordinarily the boiler-feed pumps draw their supply from this return tank, but also have connection to the cold-water supply. To provide make-up water three ball cocks are placed inside of the tank, each with a valve connection, so that at least one of the valves will always be in working order. A perforated partition divides the tank, so that any discharge of water into the tank from the return lines will not affect the ball cocks.

Two 12x7½x10-inch Worthington piston pumps feed the boilers, and the dis-

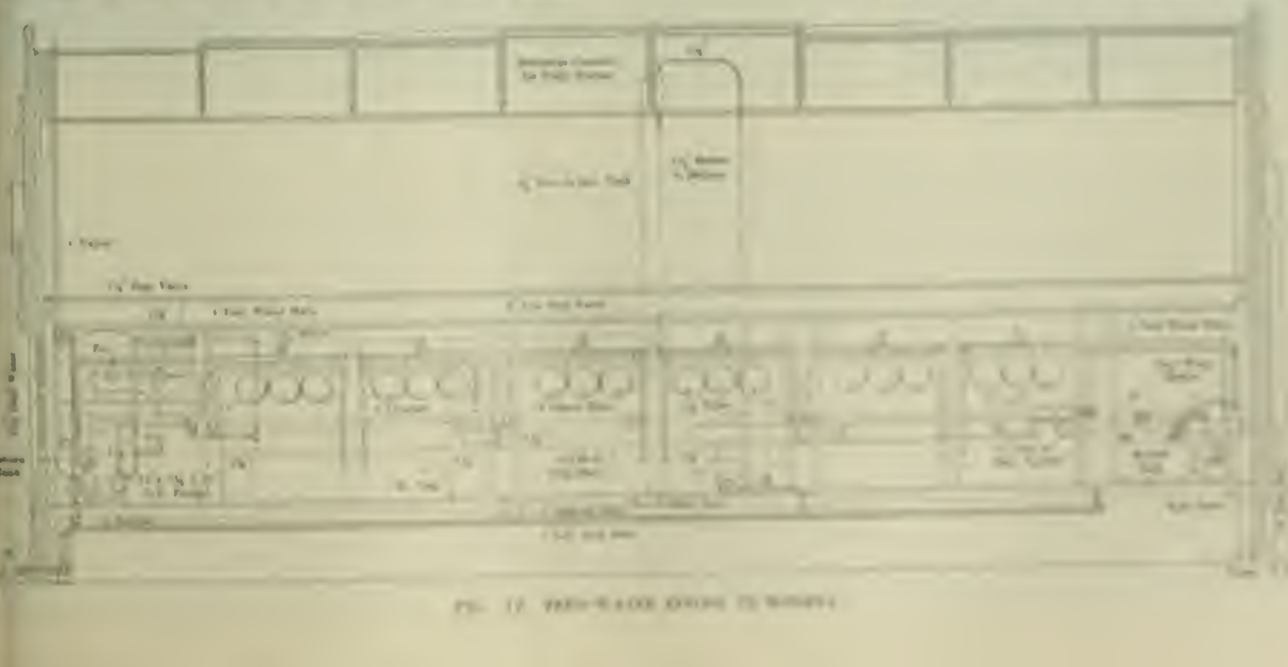

FIG. 17. FEED-WATER PIPING TO BOILERS

charge is so arranged that the pumps may feed into either end of the ring main which passes through the feed-water heater. From the main there is a double connection to the individual feed lines of each boiler and each of these connections is provided with a stop and check valve having an extension stem within easy reach of the boiler-room floor. The heater is of the Wainwright even-flow type and has a rated capacity of 1500 horsepower, which was considered large enough as the plant is run only to its full capacity during the heating season, when a large part of the water will consist of the hot returns from the buildings.

All greasy drips from engine and pump cylinders, grease separator and various points of the exhaust line are trapped into a low-pressure drip line connecting with the boiler blowoff main, to which are also attached the three blowoff connections on each boiler. Each blowoff pipe is provided with a straight-way valve fitted to a Homestead blowoff cock. Boiler pressure, the reduced pressure to buildings and the pressure in the exhaust system are all indicated on three special gages located on a marble board placed upon the side wall of the engine room.

In the entire piping system all high-pressure steam pipes 2 inches in diameter and over are provided with extra-heavy flanged fittings and with extra-heavy flanges for connecting the piping. In all piping 5 inches in diameter and over the Van Stone type of joint with rolled-steel flanges is used. All of this work and the pipe bends were manufactured by the M. W. Kellogg Company for the Thompson-Starrett Company, which firm had the contract for all piping in the plant and tunnels.

All low-pressure piping in the power house, excepting the blowoff piping, is provided with standard-weight fittings and flanges except in certain locations in the exhaust lines where it was thought necessary to install extra-heavy fittings on account of the expansion and contraction that might readily occur. In the tunnel the construction was such that it was possible to take care of the expansion by means of numerous right-angle bends in the line, and at curves the pipe was furnished with hangers which would permit lateral as well as longitudinal expansion to occur. The high-pressure and the return mains in the tunnel were suspended from the roof beams, but the exhaust main was supported by brick piers with a bluestone cap on which a roller resting in a chair was placed, the piers being constructed in every case so that the upper surface of the bluestone cap would be parallel with the axis of the pipe, even on a steep incline.

FIG. 18. PIPING TUNNEL

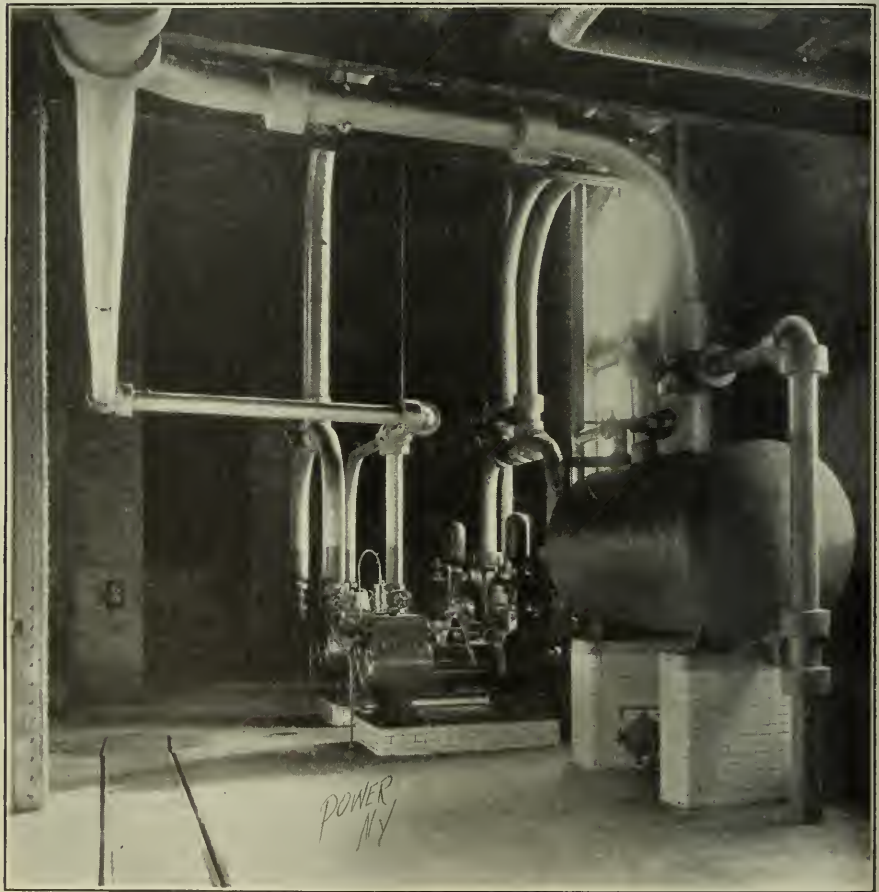

FIG. 19. RETURN TANK AND BOILER FEED PUMPS

Electrical Equipment

While the greater portion of the load consists of lamps, a number of elevators are to be used in the central group of buildings, and also a considerable number of small motors for various purposes. For instance, the cadet mess hall, containing one of the most elaborately equipped kitchens and bake shops anywhere in the world, uses a number of motors for dishwashing, breadmaking, food preparing and other purposes. The buildings requiring most of the power, however, are within 2700 feet of the power house. The buildings at the south end of the grounds, about 8000 feet distant from the power house and consisting of the cavalry and artillery barracks, had an estimated wired load of 75 kilowatts in incandescent lamps, and the soldiers' hospital and a number of other buildings located at the extreme north end of the reservation require current for lights only.

The desire to use direct current as far as it could be used economically led to the adoption of a 250-volt two-wire system for light and power, and it was found that this system could supply about 75 per cent. of the total load without great expense. The remainder of the load and the street lighting required alternating current, and it was decided to use motor generators delivering 60-cycle single-phase current at 2200 volts, the current being supplied to the street-lighting system through tub transformers. On the direct-current system, the maximum lighting load for the buildings amounted to 925 kilowatts and an additional 100 kilowatts for power. The maximum alternating-current lighting load approximated 250 kilowatts and the street lighting about 90 kilowatts.

To handle this load, two 400 kilowatt and one 200 kilowatt generators were installed. The normal full-load voltage of all the generators is 250, but means are provided for varying the shunt fields so that the voltage may be adjusted within reasonable limits. To compensate for the drop in the feeder system, each generator was designed to overcompound 10 volts from no load to full load, but this overcompounding may be reduced to various lesser amounts by means of a special series-field shunt.

To furnish alternating current three motor-generator sets have been installed, the generators having capacity to carry a normal load of 125 kilowatts when supplying single-phase current at 2400 volts and running at a speed of 600 revolutions per minute. The three sets are arranged to operate in parallel. All electrical apparatus in the power house was supplied by the General Electric Company.

Distribution of the current is effected entirely in an underground subway system consisting mainly of about 85,000 feet of single clay ducts and 83 manholes, with branches from the manholes to the buildings and from the manholes to the street-lamp posts when the latter are near enough to make this method advisable. Where the lamp posts are remote from the subway system, one duct in the upper layer of ducts opens into a pull box and a branch connection of fiber is run to the base of the lamp post. A total of 142 pull boxes have been installed. The clay ducts are of the 3 inch standard type laid in cement mortar with a concrete envelop on the top, bottom and sides, the top being not less than 2 feet 6 inches below the surface. The fiber ducts for the street lighting are 2½-inch American conduit laid on a bed of concrete and afterward inclosed on the top and sides with a concrete envelop not less than 2 inches thick.

Direct-current distribution consists of an extensive system of feeders in which the outer terminals of the feeders are looped together by mains. From the junction point pressure wires are run back to the power house and a sliding voltmeter switch is provided on the station desk for reading the voltage at these points. There is a double set of positive direct-current busses and one negative bus. The positive leg of each feeder circuit is connected to the middle point of a single-pole double-throw switch, so that the circuit may be thrown on either positive bus as required. With this arrangement and double-throw generator main switches, the generators may be run at slightly different voltages. For instance, one generator may be connected to the high bus and the other to the low bus, and each feeder may be thrown on the high or low bus as desired, in order to maintain equality of voltage at the mains and to compensate for unequal drops in different feeders. The switchboard is of blue Vermont marble and consists of 21 panels, having a total length of about 67 feet. The panels are fully equipped with the usual quota of direct- and alternating-current instruments, circuit-breakers, etc.

In the underground system, all cables are rubber-insulated and lead-covered. The direct-current cables are single-conductor lead-covered, and all alternating-current cables except transformer leads are of the duplex type in a single lead sheath. At the present time, 11 direct-current feeders have been installed, and each leg terminates in a watertight junction box in a manhole, where connection is made to the corresponding leg of the main and to such buildings as may be served from the manhole. The positive and negative sides are separate throughout, there being separate positive and negative junction boxes.

For house lighting the alternating-current system consists of 2200-volt duplex conductors connecting through single-pole cutouts to transformers located in a few instances in manholes and in most cases in vaults forming a part of the building supplied. The greater portion of the secondary alternating current is distributed on the 120-240-volt three-wire system. In the case of the officers' quarters, which are small residences, one transformer serves a number of buildings. A three-wire service is brought into each building to a three-pole cutout, and the two-wire distribution in the different quarters is connected alternately to the different sides of the three-wire circuit so as to obtain a proper balance.

In wiring the buildings supplied with direct current arrangements were made for changing over to the 120-240-volt three-wire system. Three-pole service cutouts were installed, and if the change is ever made, a neutral main may be pulled into the conduit system, to which neutral leads from the various buildings may be connected. This arrangement was made so that Tungsten lamps might be installed at a later date if desired.

Cram, Goodhue & Ferguson, of Boston, were selected as architects for the entire work, with Olmsted Brothers, of Brookline, Mass., associated with them in the landscape work. During the administration of Brigadier-General Albert L. Mills, superintendent of the Military Academy, until 1906, the general plans of the work were completed and many of the contracts awarded. Since the above date Colonel Hugh L. Scott has directed the preparation and approval of plans and carried on the work. Major J. M. Carson, Jr., constructor in charge of construction, has been the superintendent's representative in the matter of approval of plans and specifications and in carrying on the construction since the inception of the work, and Henry C. Meyer, Jr., of New York City, was retained as consulting engineer for the power plant, the street lighting and the distribution of steam and electricity to the walls of the various buildings.

"Notice to Visitors"

A correspondent sends us the following "Notice to Visitors (by an Old Engineer)," culled from the columns of a Tennessee daily:

1. When you enter the engine room spit on the floor. We have water, lye, soap, mops and brushes, and we will clean up as soon as you leave.

2. Rub your hand on all polished work. It will give someone work and use the surplus polish.

3. Put your hands on the engineer's bright work. You will then know if it is smooth, hot or cold. Tell others to do the same.

4. Stay in the engine room as long as you please. The engineer has nothing to do but entertain visitors.

5. Be sure to tell the engineer if his engine is pounding or running right, as he will not know it unless you do. He will stop and make repairs while you wait.

6. Don't tell the engineer who you are. He is a mind reader and always knows you. Go anywhere in the engine room and you will please him.

7. Advise him what to do, as you know best. The engineer is only there every day, and does not have a chance to see as much as you will in an hour.

8. If the engineer is busy making repairs, tell him a good story you heard the other day and, if possible, get in his way.

9. Be sure and tell all you know. "It won't take long."

10. Call again and repeat as above.

The newly established department of mining engineering at the University of Wisconsin has just published a bulletin announcing different special courses in mining engineering for undergraduates leading to the degree of bachelor of science in the mining-engineering course, and an advanced course is being arranged for next year for which the professional degree of engineer of mines will be conferred. As the courses of the mining engineer are diverse and comprehensive, the four-year undergraduate course is designed to give the student fundamental training in chemical, mechanical and electrical engineering, chemistry and metallurgy, and special work in geology and the application of these subjects to mining and dressing with metallurgy.

The Coming Hudson-Fulton Celebration

Description of the "Half Moon" and "Clermont," Replicas of Which Are Now Being Built to Participate in the Great Naval Parade

BY WARREN O. ROGERS

The celebration which will take place September 25 to October 9, inclusive, under the management of the Hudson-Fulton Celebration Commission, will commemorate the three-hundredth anniversary of the discovery of the Hudson river by Henry Hudson and the one-hundredth anniversary of the first successful steam navigation of that river by Robert Fulton. These men occupy prominent niches in the world's history. One brought to

FIG. 1. HENRY HUDSON (Ideal Photograph)

knowledge the Hudson river; the other gave to the navigable waters of the earth an inestimable commercial value.

Henry Hudson

On April 4, 1609, Henry Hudson (see Fig. 1) set sail from Amsterdam, with a crew of 18 Dutch and English sailors, to find a northern passage to China, but after rounding the North cape he was driven back by contrary winds, whereupon his crew mutinied and refused to continue the voyage. Hudson then proposed that a search be made to find a northwest passage. The crew agreed to this proposition and they set sail. The ship reached the American coast on July 12, and on September 2 arrived off what is now known as the Navesink Highlands on the south side of New York bay, and this date is recognized as that of Hudson's first view of the great river. The next day the "Half Moon" moved up the bay and anchored on the inside of what is now known as Sandy Hook, where several days were spent in exploring the nearby waters, and on September 12 the "Half Moon" passed in through the "Narrows" and entered the mouth of the river.

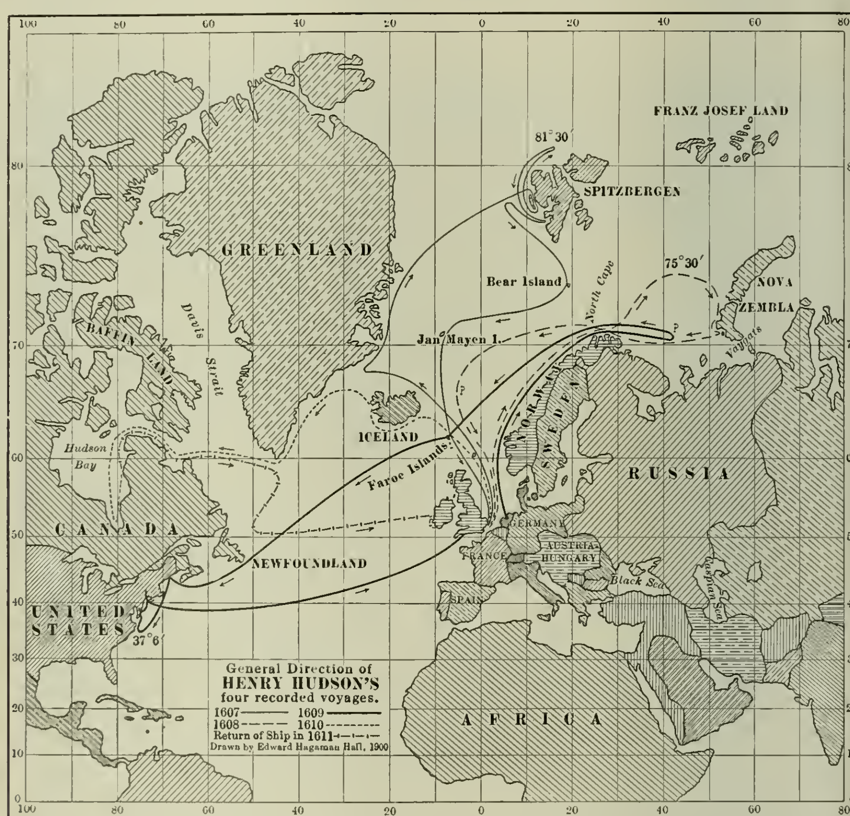

FIG. 2. SHOWING GENERAL DIRECTION OF HUDSON'S FOUR RECORDED VOYAGES

The voyage up the Hudson was made during the daylight hours, as wind and tide served, the ship being brought to anchor as soon as darkness set in. In this manner, the site of the city of Albany was reached on September 19, the farthest point north to which the "Half Moon" was sailed, though small boats were sent out to investigate the upper river in hopes that deep water would be found. When Hudson was convinced that this was not the passage to the Pacific, he weighed anchor on September 23 and returned to the harbor, passing out to sea October 4. The discovery of the Hudson river was on the third voyage of the four made by Hudson, the routes of which are shown in Fig. 2.

Hudson's fourth voyage proved to be his last in making the attempt to discover a northwest passage. This voyage took him through what is named Hud-

FIG. 3. LAST DAYS OF HENRY HUDSON

son's strait into the bay also bearing his name. The voyage was disastrous, as the crew, in mutiny, put Hudson, his son and seven companions into a shallop and set them adrift in a sea of ice and snow. No tidings of Hudson nor his companions were ever received, and Hudson's bay, without doubt, became his grave. Fig. 3 is a reproduction of a painting which represents Hudson and his companions abandoned

FIG. 4. REPLICA OF THE "HALF MOON"

FIG. 6. ROBERT FULTON

FIG. 5. COMPARISON OF THE "HALF MOON" AND OCEAN LINER "[illegible]"

on June 22, 1611. Strangely enough nothing is known of this determined explorer's life prior to April 19, 1607. Then in four short years, this man accomplished that for which thousands will do him honor during the forthcoming celebration.

The "Half Moon"

One of the most interesting and notable features of the celebration will be the presence of a replica of Hudson's ship, the "Half Moon." Patriotic citizens of Holland are now building it, and it will be delivered to the commission in ample time to participate in the various events. As there are no known drawings or paintings of the original "Half Moon," paintings and plans of similar ships were used in preparing the specifications, so that the 1909 "Half Moon" will appear as nearly like the "Half Moon" of 1609 as possible. The new "Half Moon" is shown in Fig. 4.

The dimensions of the replica will be as follows: Length over all, 74.44 feet; length between perpendiculars, 48.70 feet; breadth of beam, [illegible] feet; depth, 10.08 feet; draft, 7.05 feet.

The new "Half Moon" will make her first official appearance Monday, September 27, when she will be received by the officials of the commission and take her place in the line of international war vessels and merchant ships, where she will undoubtedly be given a greeting such as to few vessels, great or small, is accorded.

A wonderful opportunity for comparison will be afforded when the "Half Moon" reaches New York harbor and modern steamships pass her on their inward or outward bound voyages. Fig. 5 illustrates in a striking manner the gigantic strides that have been made in marine architecture since the Hudson river was first navigated.

Robert Fulton

In taking up events pertaining to the life of Robert Fulton, too much cannot be said as to the great benefits they conferred upon the civilized world. While it is true that other men had constructed boats propelled by steam power, their boats were not commercial successes. It is also true that if Robert Fulton had not constructed a steamboat that was enabled to steam the 150 miles between New York and Albany, someone else would have done so; but nobody else did, so the name and invention of Robert

Fulton will be honored in a fitting manner during the days of the celebration. A reproduction of a portrait of Robert Fulton is shown in Fig. 6.

The "Clermont"

A replica of the "Clermont" will also play a prominent part in the celebration. It will be an exact duplicate of the boat in which Fulton made his famous run to

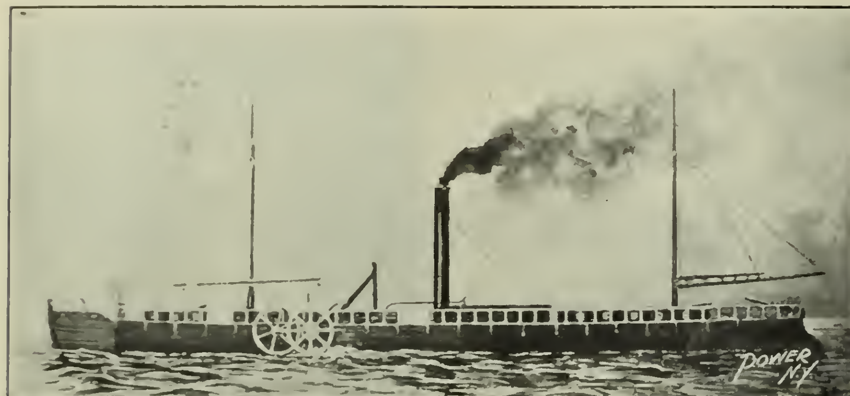

FIG. 7. THE ORIGINAL "CLERMONT"

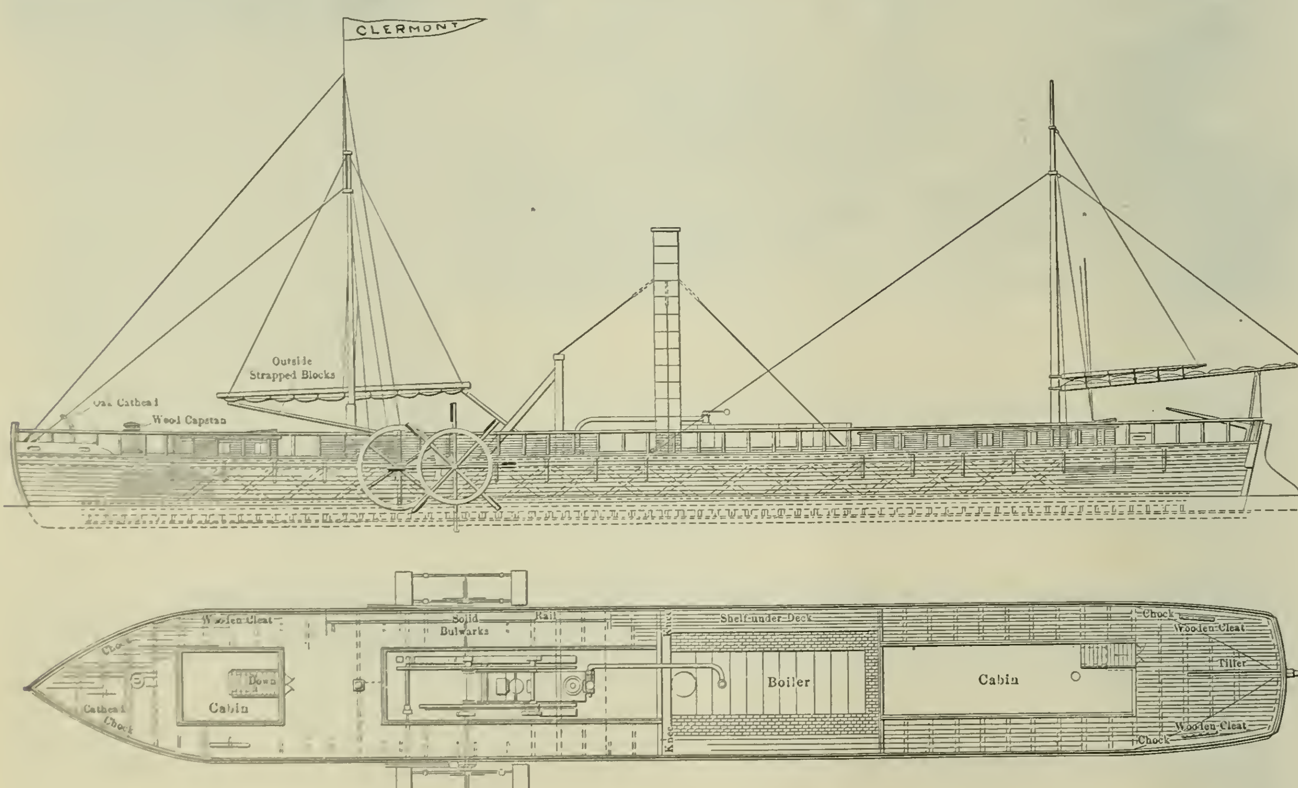

FIG. 8. PLAN VIEW AND SIDE ELEVATION OF THE "CLERMONT"

Albany and return, with the exceptions that the boiler will be equipped with a safety valve and life preservers will be placed on board, to comply with the United States marine laws.

The original "Clermont" is illustrated in Fig. 7. She was 150 feet long and 13 feet wide, had a depth of hold of 7 feet and drew 2 feet of water. The hull below the deck had a wedge-shaped bow and stern, cut sharp to an angle of 60 degrees. The sides were almost parallel, being a trifle wider on deck than on the bottom, which was flat and without a keel.

Referring to Fig. 8, it will be seen that the "Clermont" had two masts, one stack and two cabins, one fore and the other aft. The engine, which was made in England by Watt & Bolton, was placed just aft of the foremast. The engine was without housing and the boiler was constructed of copper. The paddlewheels were 15 feet in diameter and were originally uncovered, although later they were incased in wooden guards. The flywheels of the engine were placed outside of the hull forward of the paddlewheels. Fig. 9 shows a comparison of the "Lusitania" and the "Clermont."

Up the Hudson

The life of Fulton is so well known that it is not necessary to go into it here. While some of the incidents of the voyage from New York to Albany, 200 years after Hudson sailed up the river, were humorous, it can well be assumed that to the inventor the run was one of great anxiety. Several days before the beginning of this great run to Albany, the "Clermont" was taken around from the East river to the North river and anchored off what is now known as West Tenth street, or opposite the Delaware, Lackawanna & Western ferry slip, on the New York side of the river. It is conceivable, however, that the river did not appear then as now. The changes that have been made in the map of New York City are clearly illustrated in Fig. 10, the area outside of the heavy black line showing the made ground since Fulton's time. There were no great steamship docks on the river front such as are seen today, and the spectators had no difficulty in finding locations on the river bank from which they could hurl taunts and jeers toward the confident, expectant inventor. With the newspapers skeptical, it is no wonder that the public pinned little faith on the success of Fulton's steamboat.

The start was made at 1 o'clock and, with the throttle wide open and the paddlewheels slowly revolving, the "Clermont" began the momentous voyage, while the spectators looked on with astonishment. The run from New York to Albany was accomplished at practically an average hourly speed of five miles, the return trip being made at the rate of just five miles per hour.

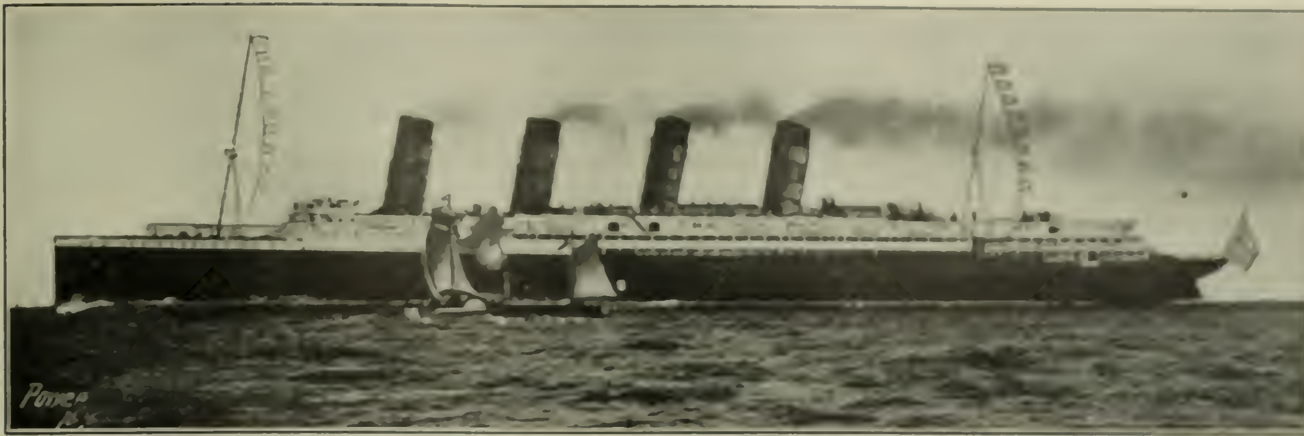

FIG. 9. COMPARISON OF THE "LUSITANIA" (1907) AND "CLERMONT" (1807)

The fame won by Fulton was won by a narrow margin, for a few days later Robert L. Stevens' steamboat "Phœnix" made a trial run on the Hudson. Owing to the monopoly secured in 1808 by Fulton and Livingston from the legislature, the "Phœnix" was put in service on the Delaware river.

Naval Parade

On Friday, October 1, the great naval parade of the celebration will take place. As many naval vessels, merchant marines, excursion boats and pleasure crafts as can possibly go from New York to Newbergh will escort the reproduced "Half Moon" and "Clermont" to the latter city. Thence the two ships of honor will be escorted to Albany by another division of the participating vessels, the division from New York returning to that city.

Another interesting feature will be a remarkable exhibition of flying machines. The *New York World* has offered a prize of $10,000 for the aeronaut who with a mechanically propelled airship sails over the course traversed by Fulton's "Clermont" in 1807.

Without doubt this impressive naval parade and airship flight, which are but two of many features of the week's celebration, will be two of its greatest features. Other attractions of especial interest will be rowboat races in six classes, rowing matches between crews of foreign and American war vessels, canoe races and sailing races. The city of New York alone will spend [illegible] on the celebration.

We are indebted to the Hudson-Fulton Celebration Commission for the illustrations in this article.

Isolated Plant vs. Central Station

Shall the public library of New York City be equipped with an isolated plant or shall it take its electric current from the mains of the Edison company? This question has been occupying the attention of the Board of Estimate and Apportionment for some time, and in regard to the isolated-power-plant side of the question, the following letter and brief, addressed to the board by Percival Robert Moses in behalf of the International Union of Steam Engineers, will undoubtedly be of interest. It will also be of interest to note that the board has decided on an isolated plant.

Letter [illegible]

"I have been requested by the International Union of Steam Engineers, a part of the Central Federated Union, to present on their behalf briefly some reasons why a private isolated plant should be installed in the New York public library for the manufacture of electric current.

"In the New York public library proposition, I understand that the Edison company estimates the maximum use of current at [illegible] kilowatt-hours a year, while the consulting engineers estimate the use at [illegible]. Even on the basis of [illegible] kilowatt-hours a year, the rate of Edison company at three cents per kilowatt-hour would be a mistake. The library commission would undoubtedly operate the plant and manufacture current at less than [illegible] cents per kilowatt-hour, and I understand, in the statement I presented, would be willing to enter into a contract to operate the plant and [illegible]

FIG. 10. MAP OF LOWER NEW YORK SHOWING [illegible]

for this price, in addition, of course, to the cost of heating the building.

"On the basis of the estimate made by your consulting engineer, the difference between 1⅔ cents and three cents per kilowatt-hour would make a difference of $22,000 a year to the library committee. It is proper also to call your attention to the fact that by making a contract with the New York Edison Company or any other member of the combined companies, at three cents per kilowatt-hour, you are sanctioning a discrimination in rate against the small consumer, which is entirely unjustified and which cannot continue to exist. There is no possible justification for a discrimination in rate based on quantity use alone. It is only because the combined electric companies are allowed to charge small consumers 10 cents per kilowatt-hour, giving them an exorbitant profit, that they are able to sell to the large consumer at three cents per kilowatt-hour, which is less than the average cost of production and distribution. The gas companies do not practice any such discrimination and the city, in its sale of water, sells to all alike. Why, then, should the city encourage the electric companies to discriminate against the small user by making a contract at less than a fair rate with the large user, because of their large use, knowing that every such contract made makes it harder to reduce the price to the small consumer.

"Finally, on behalf of the operating engineers, I ask that if your board is not satisfied that a private plant can be operated more cheaply than service can be purchased from the Edison company, they advertise for bids from responsible engineering concerns, asking such concerns to state the price at which they would sell current to the city from a private plant located in the building, such contract, of course, to be subject to the clause about paying the prevailing rate of wages, and to contain any necessary stipulation as to maintenance of the equipment in first-class condition. I am satisfied that if such bids are asked for many offers will be made, backed up by bonds and guarantees offering to sell current from the private plant at from 1¼ to 1⅔ cents per kilowatt-hour, in addition to the cost of heating the building.

"Summarizing: I base my plea for the installation of a private plant on the following grounds:

"1—The cost of current from the private plant would be less than Edison service by $22,000 a year, if your consulting engineer's figures are correct.

"2—You are entering into a contract for an illegal discrimination in rate against the small user, and by so doing you are preventing the small user from obtaining a lower price for current.

"3—You are placing your equipment in the control of a single lighting combine, which may or may not be always run in a fair manner, and you are subjecting yourselves to a far greater possibility of breakdown than would be the case if you had your own plant."

Brief Accompanying Letter

"Discrimination in rates in favor of a consumer of a large quantity of electricity and against the consumer of a small quantity of electricity, is wrong:

"In order to prevent the installation of isolated plants in buildings, the Edison company and its allies have adopted a system of giving low rates; that is, rates below the average cost of production, to large consumers, balancing this by charging excessively high rates to small consumers.

"That this proposition is radically wrong and unjust, is evident from the propositions made to the public library board and to other similar large consumers to sell them 833,000 kilowatt-hours per year at a rate of three cents per kilowatt-hour, or a total of $25,000 a year. For the same quantitative use of current, but divided between 100 stores, the charge would be $83,000, or over three times as much.

"The discrimination is based on the same principle as the freight-rate discrimination which has been universally condemned, and has been pronounced illegal. That is, the rate is fixed not upon the cost of production and distribution, but upon the amount the traffic will bear. This is evident from a consideration of the conditions:

"In the public-library plant there are 17,691 incandescent lights and 443 horsepower of motors. The total connected capacity figures up to approximately 1200 kilowatts. If the maximum demand is figured at two-thirds this amount, or 800 kilowatts, this would probably be approximately correct.

"In the long discussion before the Public Service Commission on the subject of breakdown or auxiliary service, it was shown conclusively by the New York Edison and its allied companies that it cost the Edison company at least $30 per year per kilowatt of maximum demand, $30 for fixed charges alone. This is exclusive of any cost of manufacturing the current; it merely covers the fixed charges on the installation of plant, buildings, mains, meters and connections.

"In the case of the public-library proposition, the offer to sell current at three cents per kilowatt-hour barely covers the fixed charges, making it necessary to make all the profit made by the Edison and its allied companies in some other direction. This profit can only be obtained from the small consumer, and the small consumer is forced to pay the profit not only on his own use of current, but on the use of current by the large consumer.

"The city has recognized the justice of equal charge to large and small consumers in the sale of water, the charge being alike to large and small consumer, no matter what quantity they use. The gas companies do not attempt to discriminate against the small consumer, and everybody has the right to buy gas at 80 cents per thousand cubic feet. The telephone company, it is true, does discriminate between the large user and the small user, but nothing like the extent proposed by the electric companies, and the question of the right of the telephone company to so discriminate has been seriously questioned.

"The objection to discrimination in favor of the user of a large quantity against the user of a small quantity does not necessarily mean that the Edison and its allied companies should be discouraged from encouraging a long-hours use of the equipment. This is quite a different matter. The electric companies claim, and with justice, that the consumer who uses his equipment 10 hours a day should obtain a better rate than the consumer who uses his equipment one hour a day; for the reason that the consumer who uses his equipment 10 hours a day requires no greater plant investment than the consumer who uses his equipment one hour a day. This statement is perfectly correct. A proper basis of charge would be one based on the maximum demand of the equipment, or on the constant capacity, to which should be added a charge for the amount of electricity actually used. But this rate should be open to all consumers alike, no matter whether they use 10 kilowatt-hours a year or 100,000 or 1,000,000. Such a rate has been proposed by the New York Edison and its allied companies in a number of cases recently and is as follows:

"The company makes a fixed charge of $30 per kilowatt of maximum demand, and in addition to this charge receives 1½ cents per kilowatt-hour for all electricity used. This is a perfectly fair form of contract, but it must be open to all consumers alike, and not only to such consumers who have isolated plants installed, or who intend to install such plants.

"If such a contract were proposed for the public library, the cost would be somewhat as follows:

800 kilowatts maximum demand @ $30	$24,000
1,000,000 kilowatt-hours @ 1½c. per kilowatt-hour	15,000
Total cost per year	$39,000

This is the least cost at which the New York Edison and its allied companies can afford to sell current and make a profit. If they sell at anything less than this cost, they must obtain their profit from the small consumer.

"The cost of manufacturing current from a private plant in the public library will be less than purchasing current even at the three-cent rate:

"From the figures given me on the amount of heating surface and the size of the public library, it is evident that during the winter months, that is, during at least one-half of the year, the amount of steam used for operating the electric plant, with a properly designed plant, will be less than the amount of steam required to heat the building. Hence, it may be safely stated, that the operation of the electric plant will not increase the amount of coal required during six months of the year, certainly not more than 10 per cent. I have a number of figures from buildings in New York City which show this to be the fact.

"During the summer months when the lighting load is least, the coal used for operating the electric plant will, of course, be a direct charge on the electricity.

"Insofar as the labor is concerned, a brief consideration of the conditions will show that the amount of labor required for the actual operation of the electric plant is very small. If the electric plant is omitted, there would still be 460 horsepower of motors to be taken care of, and there would still be the boilers to be fired for heating; there would still be the elevators to be looked after; the ventilating fans to be cared for; and the only things that would not be in operation during seven months of the year would be one turbine during the daytime and, perhaps, two at night. These turbines from their very nature cannot be interfered with. The usual instructions are to let the turbines alone, merely seeing that the oil is flowing. They are absolutely automatic in operation and it would not be possible to use more than one man on a watch to see that they were operating correctly. With a storage battery as an auxiliary, designed to supply the night lighting after the plant was shut down, this means that there would be two men required, one from eight to four, the other from four to twelve, in addition to the crew required for heating alone. Besides this, in the summer there would be two additional firemen.

"The other items making up the cost of electricity are the plant supplies, plant repairs, ash removal, water for boilers, oil, etc. A careful estimate of these additional items, gives a total of less than $12,000 a year; or, 1.2 cents per kilowatt-hour. If high-efficiency lighting is used throughout the building, the cost of the plant could be undoubtedly reduced materially from the present estimate. But even on the basis of the present estimate, and allowing 10 per cent. for interest, depreciation, insurance, etc., the fixed charges figure up to one cent per kilowatt-hour; which added to the operating cost of 1.2 cents makes the total cost per kilowatt-hour 2.2 cents, on the basis of one million kilowatt-hours a year. There are a number of companies in New York making a specialty of operating steam and electric plants, and if there is any doubt in the board's mind, as to the comparative cost of operation of central service and of isolated-plant service, I suggest that bids be invited from responsible concerns, subject to a bond, for operating the plant proposed for the library, the contract to contain the usual stipulations as to paying the prevailing rate of wages and requiring maintenance of the plant in accordance with certain standards of inspection. I am satisfied that if such bids are invited, many will be received offering to furnish current as low as 1½ cents per kilowatt-hour, in addition to the cost of heating and maintaining the rest of the equipment.

"The matter of reliability of service is also of moment. In one case the library will have its own plant on the premises with its very large storage of coal available at all times, so that nothing less than an earthquake would be able to stop the service. On the other hand, if the service is purchased from the Edison company or any of its allied companies, even

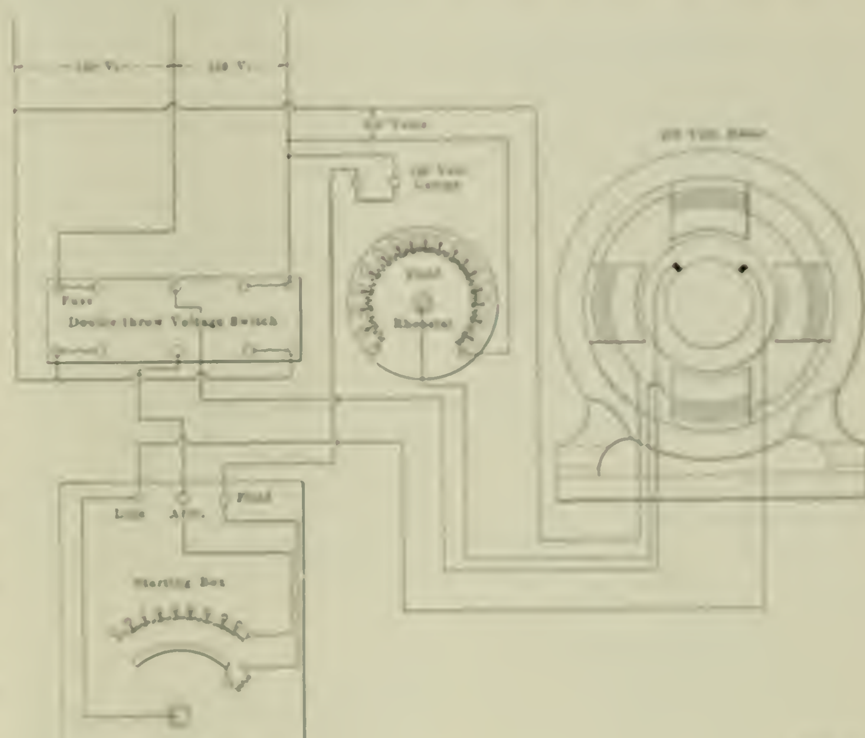

Fig. 1

with many connections, the service is subject to interruptions. It is hardly two years ago now since the Edison company's station at Thirty-ninth street was almost wrecked by the explosion of one turbine after another, with the result that the service had to be disconnected in a large part of the city, and where it was maintained it was only at a greatly reduced voltage. Just the other day, in Baltimore, on account of a blizzard, the whole city was without light and power for 24 hours, and the greater part of the city for 72 hours, or three days. In fact, the whole service was not resumed for over a week, and this only by almost superhuman efforts.

"My third plea, therefore, for the isolated plant in the public library, and other municipal buildings, is that the service will be more reliable than it would possibly be from an outside source."

Emergency Connections for Electric Motors

By C. V. H

Every man who has to do with power installations of any sort realizes that he must sometimes do things in other than the conventional manner. Conditions arise which are unexpected and which demand unusual methods. It is not a good plan to run a steam engine without a governor; yet I know an old steam-traction man who always threw the governor belt off when he was in a hurry to set up or to move to another place. He got along famously, but still it is not advisable for a careless or inexperienced man to do this kind of thing.

One of the largest gasoline-engine companies in the middle West has about 80 motors in operation, ranging from 1½ to 40-horsepower. Series, shunt and compound-wound types are used, though the shunt-wound type is preferred. These motors are used on woodworking machines, boring mills, radial drills and line shafts, and the working conditions are extremely varied and require that material and apparatus be kept on hand rather than order others which may be better adapted to the work of the moment.

Three-wire 220-volt distribution is used, but the dynamos are 110-volt compound-wound machines of different makes and sizes, which makes the use of an equalizer impracticable for parallel operation. To overcome this difficulty, a switch is arranged to short-circuit the series windings of the machines when operated in parallel. This has been satisfactory for power purposes and furnishes fair lighting service, although the voltage is apt to vary perceptibly if the load varies much.

Several boring mills, requiring considerable speed variation, are direct-driven. It was not feasible to use cone pulleys, because there is not sufficient room for them; so it was decided to use

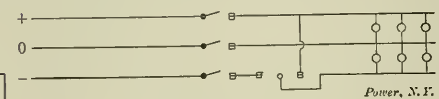

FIG. 2

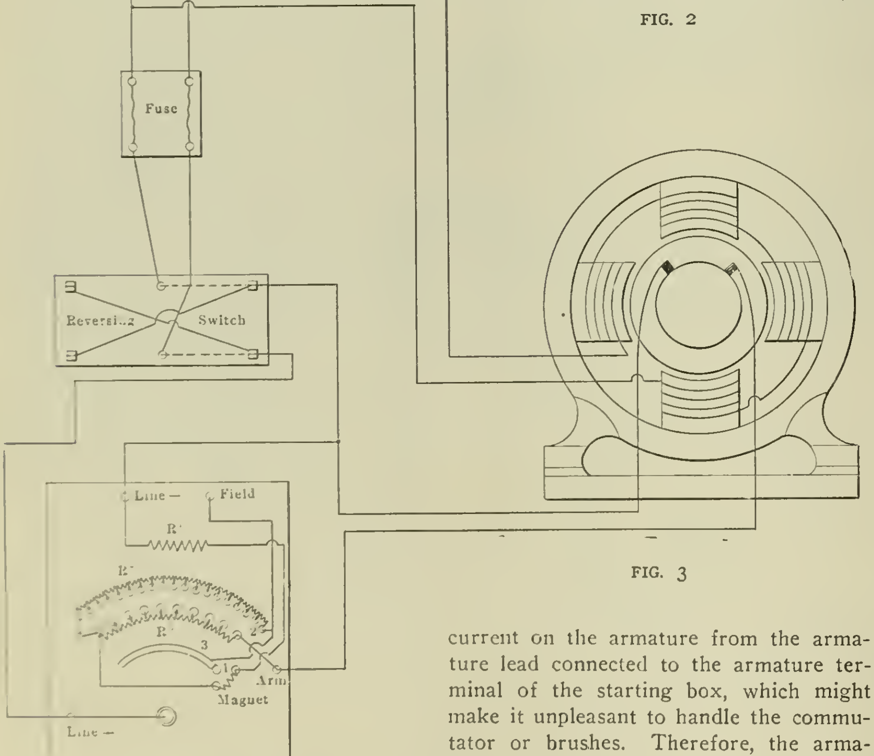

FIG. 3

220-volt motors and run them on either 110 or 220 volts, as speed demanded, with field adjustment for finer gradation. The wiring diagram for this arrangement is shown in Fig. 1. It will be seen that the shunt-field winding is connected directly across the 220-volt mains. This, of course, is open to the objection that there is always current in the field winding, but it was unavoidable because at 110 volts the field winding would not give good results, nor would the retaining magnet on the starting box hold the lever in the running position. It will be seen also that the lead to the armature terminal of the starting box is from one of the wires of the 220-volt main, whether the voltage switch is to the right or left, and the lead from the shunt terminal on the starting box goes through two incandescent lamps in series to the other wire of the 220-volt main. It is evident from the diagram that the starting lever will be held in the running position, whether the switch is thrown to the 110-volt or the 220-volt side, and that the field winding has always 220 volts at its terminals, regardless of the position of the switch or the starting box.

The two lamps burn as soon as the switch is thrown in on either side, and serve as pilot lights to indicate the position of the switch. If connected to the "line" terminal, the lights would not burn brightly until the lever of the starting box made the first contact, although they would burn dimly on 110 volts through the armature. Moreover, there would be current on the armature from the armature lead connected to the armature terminal of the starting box, which might make it unpleasant to handle the commutator or brushes. Therefore, the armature is entirely cut out, by putting the switch lead on the armature terminal of the starting box (which is contrary to rule) as soon as the lever falls down.

To provide for farther speed control a rheostat is put in the shunt-field circuit and is of such capacity as to make it impossible to weaken the field enough to cause sparking. It is evident that this rheostat control demands an excess of motor power; that is, a 5-horsepower load requires an 8- or 9-horsepower motor. But the company had the motors and it was better to use them than to buy new variable-speed motors. There is the added advantage that the 110-volt load can be put on either the positive or negative side of the neutral wire of the main circuit.

There are three dynamos running during the day and until 8 p.m., after which two carry the load. So it was decided to put the unbalanced load on the negative side of the system, running two of the three machines in parallel on that side. One of the larger 110-volt motors, driving a line shaft, is fed from the power-house switchboard through an individual feeder and switch. When three machines are running this motor is connected to the negative side and when only two machines are running the motor is fed from either the positive or the negative side, according to the requirements as to balancing the load. A single-pole double-throw switch was put in the lighting circuit of the machine shop, as shown in Fig. 2. When closed to the right it makes a two-wire lighting system with the load on the two dynamos running in parallel on the negative side of the system when three machines are running. When thrown to the left the lighting circuit is a three-wire system for use when two machines are running, after 8 p.m. It will be seen that the neutral wire becomes negative and the negative wire becomes positive when the machine-shop circuit is on the two-wire plan. Consequently, all arc lamps are connected between the positive and the neutral wires of the three-wire system and the polarity of their supply is not disturbed.

Fig. 3 shows an emergency wireup for a set of reversing rolls used in making wheel rims. A reversing starting box had been ordered, but failed to arrive in time, and an order was sent out that something be "rigged up." The shunt-field winding was connected directly to the line and a reversing switch was wired in the usual manner. At first the type of starting box shown in Fig. 1 was installed, but there was some question as to how to hold the lever of the starting box in the running position. It was not thought best to connect the holding magnet across the main line nor was there any room to put lamps in as in Fig. 1. A few days before the starting box shown in Fig. 3 had been removed from a grinder stand and repaired. This box had a special resistance R^1 in series with the the starting-lever magnet coil and was provided with four terminals, "line positive," "line negative," "field" and "armature." The box was connected as shown and the trouble was over. The resistance R^2 was intended for weakening the field excitation and was not needed for the rolls motor. The starting-box lever was a two-part one and when contact was made at *2* by the outer part of the lever it was broken at *3* and the shoe on the inner part of the lever passed to the dead button *1*.

This is but to show that one can use what he has if he must. Neither this motor nor those operated on the two voltages give any trouble from sparking. This is to some extent due to the fact that all are of ample power; no doubt the 110-220-volt motors would give trouble if used with too large a rheostat.

Domestic Steam-Turbine Development

The General Electric Company in the Horizontal-turbine Field. Recent Progress in Construction and Operation of Westinghouse Turbines

BY C. B. BURLEIGH AND J. R. BIBBINS

Following are abstracts of two interesting papers on steam-turbine development read at the recent meeting, at Boston, of the Association of Electric Lighting Engineers of New England.

Charles B. Burleigh's Paper

The paper read by Charles B. Burleigh, of the General Electric Company, was largely an explanation of the appearance of the General Electric Company in the horizontal-turbine field to an extent which has not been fully appreciated. The use of the Curtis turbine in large sizes and of the vertical type has led to a popular impression that, except in unimportant sizes and for special uses, the Curtis type of turbine was committed to the vertical position, and Mr. Burleigh's claim that there are in commercial service a large number of horizontal Curtis turbines in this country, ranging in size from 20 to 1500 kilowatts, than there are of the horizontal type of any other maker, came as a surprise to the audience.

Between February 1, 1909, and the date of the meeting, March 18, they had sold 278 horizontal-shaft turbines, of which 30,000 kilowatts capacity were of sizes from 500 to 3500 kilowatts each. As an offset to the possible impression that the vertical turbine had been found a failure and that its builders were changing to the horizontal type, Mr. Burleigh announced that the General Electric Company had sold over 230,000 kilowatts capacity in vertical machines during 1908, and that it has no idea of abandoning the vertical-shaft type, although in the early days of Curtis-turbine development, the desirability of its use was somewhat more apparent in certain sizes than is perhaps today the case.

The leading advantage with which the Curtis turbine came into the field was a lower rotative speed, and the designing of a turbine of such shell and wheel dimensions as best met existing conditions resulted in a diameter in proportion to length which readily adapted it to the gyroscopic action of the spinning top. With the vertical arrangement, floor space was economized, friction and bearing wear were reduced to a minimum; disalignment of foundations was of little or no importance; the cost of foundations was reduced, a smaller number of bearings were required and such bearings as were necessary were of smaller dimensions.

The Only Sacrifice Incurred

The only sacrifice incurred in the securing of these benefits was the maintaining of a pressure on one bearing approximately equal to the sum of the pressures necessary to be maintained on the several bearings of a horizontal machine of equal capacity.

Go back with me, the speaker said, some ten years, and ask yourself what you as the prospective purchaser of a steam prime mover of, say, 2000 horsepower would have said to the manufacturer who offered to furnish you at that time with a unit that was designed to operate at 1200 revolutions per minute. I doubt if you would have agreed to install and operate it if he had offered to give it to you.

Five years of experience have demonstrated the fact that in the majority of cases the reliability and economy have been pushed back to make room at the head for low first cost. How can this be attained? We cannot impair the two other necessary characteristics, reliability and economy; we cannot reduce capacity, but we can increase that apparently unnecessarily slow speed and thereby enable physically smaller machines to do more work, and these fast running machines, comparing more nearly in size, will compare more nearly in cost with those of competing manufacturers.

In doing this the work of the moving parts has been reduced to a point at which they have been continuously operated in a horizontal position. The diameter has been reduced in proportion to the length so that the gyroscopic effect of the moving member has been changed so that it can be as well, if not better, operated in certain sizes in a horizontal position. The change in speed entailed a redesign of generators and here again the manufacturers have been able to profit by experience.

Characteristics Adapting the Curtis Turbine to the Horizontal Position

Some of the characteristics adapting the Curtis turbine to the horizontal position are that the rotative speed of the shaft is within control and may be kept within low limits if desirable. The steam travel from admission to exhaust is shorter, resulting in a short steam path which permits of the bearings being placed near together. This again permits of the use of a shaft of smaller diameter to support a given weight without sag, which further reduces the surface speed of the shaft in its bearing. The expansion of metal being in direct proportion to its volume and the temperature changes to which it is subjected, the steam path being shorter and the shaft smaller, the expansion troubles are reduced to a minimum. The lack of end thrust very much simplifies the problem of horizontal operation.

Inasmuch as clearance either in an axial or radial direction has little or no effect on the efficiency of the machine, the necessity for strict alinement and the danger of disastrous contact by derangement of the bearings are very much minimized. And as steam at boiler pressure and temperature is not admitted to the interior of the machine, but reaches the moving parts only after its pressure and temperature have been reduced by expansion in the nozzles, it is possible as well as desirable to supply it with as high pressure and as highly superheated steam as local conditions will warrant without any detrimental expansion troubles being involved.

Alternating-current Generators

Referring to the redesign of generators, Mr. Burleigh said that the General Electric Company was prepared to furnish a line of alternating-current generators which has been designed for use in connection with the Curtis turbine, both horizontal and vertical, which will, when required, have an actual energy output at the generator, at 80 per cent. power factor, equal to the most economical load point on the steam end. These are known as "maximum-rated units" and will give their maximum kilowatt-ampere output at 80 per cent. power factor continuously with a rise in temperature not exceeding 50 degrees Centigrade above that of the surrounding air.

Compare one of these generators of, say, 1500 kilowatts, with the ordinary machine rated at 100 per cent. power factor to operate continuously at full load with a temperature rise not exceeding 40 degrees Centigrade; at 25 per cent. overload continuously (at 100 per cent. power factor), with a temperature rise not exceeding 55 degrees Centigrade, and at 50 per cent. overload for two hours.

The "maximum-rated generator," being capable of a full 1500 kilowatts output at 80 per cent. power factor, is capable of delivering 1875 kilovolt-amperes, which at 100 per cent. power factor, is equal to

1875 kilowatts. It is capable of delivering this output continuously with a temperature rise not exceeding 50 degrees Centigrade. The 1500-kilowatt old-rating generator (which is rated at 100 per cent. power factor, but capable at this power factor of delivering 25 per cent. overload or 1875 kilowatts continuously with a temperature rise not exceeding 55 degrees Centigrade above the surrounding air) is capable of operating two hours with 25 per cent. further overload. But when you think of it, is it any more capable of doing this than is the other? It is already 5 degrees warmer.

Direct-current Curtis Turbines

The General Electric Company has also a comprehensive line of direct-current Curtis turbines, all of the horizontal-shaft type, for which reason the commutators and brushes are accessible from the floor. The 300- and 500-kilowatt units are designed to deliver current at 600 volts and are particularly adapted for railway work. The smaller sizes, ranging from 20 to 300 kilowatts, are designed to deliver current at 125 or 250 volts and are adapted for use as exciters, or for the operation of lights or motors in industrial establishments.

The low-pressure turbine is designed efficiently to utilize the steam energy from 16 pounds absolute to the best vacuum which local conditions make it possible to attain, and finds its most available field where additions are found desirable in power plants operated either mechanically or electrically from either simple or compound condensing or noncondensing engines.

The Low-pressure Turbine Combined with Single and Compound Engines

The installation of a low-pressure turbine in conjunction with a single-cylinder engine practically converts it into a compound unit, and when installed with a compound engine converts it into a triple-expansion unit, with the turbine acting as a low-pressure cylinder. Due to the fact that the area presented by the turbine corresponds more nearly to the added volume of the steam when completely expanded than an engine cylinder could under any conditions, without entailing the use of moving parts of such size and weight as would make their use absolutely prohibitive, the turbine will as efficiently utilize the steam energy below the atmospheric line as the engine cylinders will above it. There being as many foot-pounds of energy in a pound of steam expanded from atmospheric pressure into a 28½-inch vacuum as there is in the same pound of steam expanded from 150 pounds gage pressure to atmospheric pressure, the low-pressure turbine enables us to double the output of a noncondensing engine and add some 30 per cent. or more to the output of a condensing engine without any increase of fuel consumption, and consequently with no increase in boiler plant.

If, however, the load on the engine is intermittent or extremely variable, steam-regenerating devices are desirable for use with low-pressure turbines, which adds to the expense of installation and upkeep. Again, if the desired increase is more than can be obtained by the addition represented by the capacity of a strictly low-pressure turbine with such exhaust steam as is available from the engine, additional apparatus must be installed to supply the deficiency. The mixed-flow turbine, however, overcomes both of these difficulties and the impulse or nozzle-expanding type of turbine is the only type of turbine the characteristics of which will permit of its use under these conditions and obviates the necessity of using regenerating apparatus.

Why the Curtis Mixed-flow Turbine Is of the Horizontal Type

The Curtis mixed-flow turbine is of the horizontal type for the reason that its installation is most always made in conjunction with engines already installed in equipping engine rooms where head room, in many cases, would not be available for the installation of the vertical type. The steam unit is fitted with two separate and distinct chests, each equipped with valves controlled by the governor. The low-pressure steam chest is connected with the engine exhaust and the high-pressure steam chest piped to the boiler. The low-pressure steam chest is fitted with nozzles designed to expand steam from 15 pounds absolute to the first-stage pressure and the high-pressure steam chest is fitted with nozzles designed to expand steam from gage pressure to the same first-stage pressure. The steam admitted from each chest to the interior of the turbine and brought into contact with the buckets is of equal pressure.

The output of the turbine, therefore, is, to a certain extent, independent of the engine, for which reason a mixed-pressure turbine can be installed of such capacity as will furnish the desired addition to the power plant without reference to the size of the existing engine and utilize the engine exhaust to its fullest extent and use only such steam direct from the boilers as is necessary to supply the deficiency. The governing being perfectly automatic, should the engine for any reason stop, it will in no way interfere with the operation of the turbine, for the governor will then operate a sufficient number of high-pressure valves to admit steam from the boiler in a sufficient quantity to operate its load.

On the other hand, if sufficient steam is available from the engine to operate the load on the turbine, all valves in the high-pressure steam chest are closed by the governor and the turbine is operated wholly by the exhaust steam.

J. R. Bibbins' Paper

This paper dwelt in some detail on the progress which has been made within the last two or three years in the construction and operation of Westinghouse turbines. Particular reference was made to the development of the double-flow and low-pressure types, which have been brought about by the necessity of very large units on the one hand, and the increase in economy of existing engine-driven stations on the other. Details of construction were also illustrated of the various improvements made from time to time in the single-flow turbine, which is now manufactured in sizes from 300 to 3000 kilowatts, while the double-flow design covers a range of sizes from 5000 kilowatts upward. In the single-flow type details of the cylinder construction were illustrated, showing the design employed entirely free from longitudinal ribs or ports cast in, and otherwise unencumbered; the whole being supported at the two ends in the form of a perfectly symmetrical envelop, anchored at one end and free to expand and contract.

A new parallel-motion governor was discussed, also other details such as water glands, oil pump, copper-clad blading, etc. Special mention was made of very complete bearing experiments which were carried out at the builder's works at East Pittsburg. These were made with a 70,000-pound dummy rotor, with full-sized bearings. To obtain greater unit pressures, the length of the bearing was reduced. In these experiments the bearing duty was increased to as high as 300 pounds per square inch of projected area and 80 feet per second velocity, without failure, which represents four to five times the bearing duty actually employed in the bearings of Westinghouse turbines. These bearing experiments were conducted with a view to determine the feasibility of solid-babbitted bearings for the double-flow type of turbine, which is essentially a high-speed machine. Units of 5000 to 6000 kilowatts operate at a speed of 1500 revolutions per minute, whereas the original single-flow units in this size operated at half this speed.

Development of Double-flow Turbine

The development of the double-flow turbine and the remarkable reduction in size was shown by a detail sectional drawing of the machine, as compared with a similar section of a single-flow type turbine; the center-to-center line of shaft being from one-third to one-half less, owing to the replacement of the high-pressure stage of the single-flow by means of a velocity element. Typical installations of the double-flow were exhibited; among them the Pittsburg Railways station and the large Kent avenue station of the Brooklyn Rapid Transit Company, where five 10,000-kilowatt double-flow turbines will ultimately be installed, in addition to the five 5500-kilowatt machines now in operation. Two of the former are already in operation. These 10,000-kilowatt units are frequently called upon to sustain loads as high as 18,000 kilowatts, and one of them recently tested sustained the equivalent of 15,000 kilowatts continuously, with a temperature rise considerably below the normal for its actual rating of 10,000 kilowatts. Under these conditions, if supplied with 200 pounds pressure, when operating at 28 inches of vacuum, this turbine would be able to sustain maximum loads of from 20,000 to 22,000 kilowatts; consequently, it is one of the largest machines in existence.

Mr. Bibbins claimed that in the smaller sizes, which do not entail extreme dimensions for rotor and stator, the Parsons type offered particular advantages, and has never been excelled in point of economy. On the other hand, the double-flow machine, by reason of the more favorable design possible with the higher speed, is able to attain economies equal to, if not better than, those of the straight Parsons system, and the double-flow design promises well for the future.

The Low-pressure Turbine

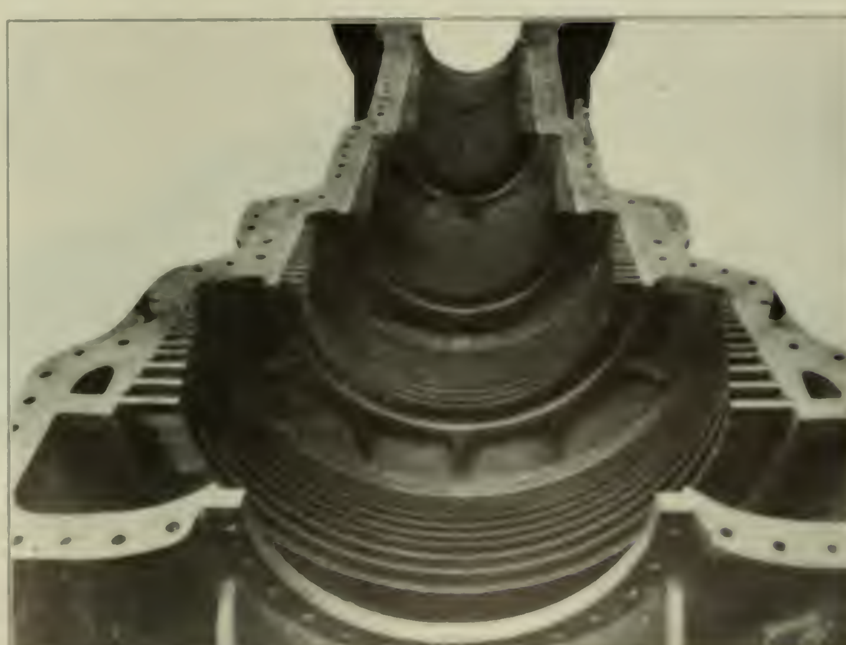
The low-pressure turbine was dwelt upon at some length as a recent development which occupies a unique position in power-plant design, and brought about by the desire for the utmost economy in operation, especially of old engine-driven stations. The low-pressure turbine was shown to be simply the low-pressure stages of a standard double-flow machine, in which the high-pressure velocity element was removed, requiring no nozzles, valves, balance pistons nor governor. This form is of the simplest possible design in turbine work and also very efficient, for the reason that the high speed permits a design of small diameter with blades of ample proportion to obtain efficient working. The secret of the high economy of the low-pressure system lies in the fact that the steam turbine is especially economical in the lower ranges of expansion, while the reciprocating engine is at best in the high-pressure ranges; the combination plant giving a resultant economy far better than could be obtained by either engine or turbine expanding through the whole range. It was shown that with a 1000-kilowatt engine and turbine of normal proportions a water rate as low as 16 pounds per kilowatt-hour could be obtained with saturated steam at 150 pounds boiler pressure and 28 inches of vacuum. This is equivalent to about [illegible] pounds per indicated horsepower-hour in a reciprocating-engine cylinder.

The method of determining the steam consumption of the combined plant from tests of the engine and turbine unit was outlined in the form of curves from which the relative saving in steam and the relative increase in capacity could be readily seen. For a 2000-kilowatt combined plant, an increase in capacity of from 30 to 40 per cent. was shown to be possible for a condensing engine, with a corresponding increase in economy, while for a non-condensing plant an increased capacity of from 80 to 90 per cent. could be realized with the same increase in economy.

Methods of Governing

The two methods of governing were examined; first, the constant-pressure system, such as would prevail in a plant receiving the exhaust from a large number of engines; and, second, the variable-pressure system, in which the low-pressure turbine was connected directly to the engine through the electrical end. In the first case, a turbine governor would be necessary; in the second, the turbine would run without a governor, being locked electrically in step with the engine and operating as the third cylinder of a triple-expansion system. In cases where a shortage of exhaust-steam supply is expected for brief periods during the day, a pressure-reducing valve may readily be installed to make up the deficiency from the live-steam line. This obviates the necessity of a steam regenerator, which is suited only to periods of deficiency of comparatively short duration, such as from one to seven minutes as in rolling-mill practice. For the average electric-

CONDITION OF LOW-PRESSURE BLADES, HARTFORD TURBINE; UPPER ROW, [illegible]

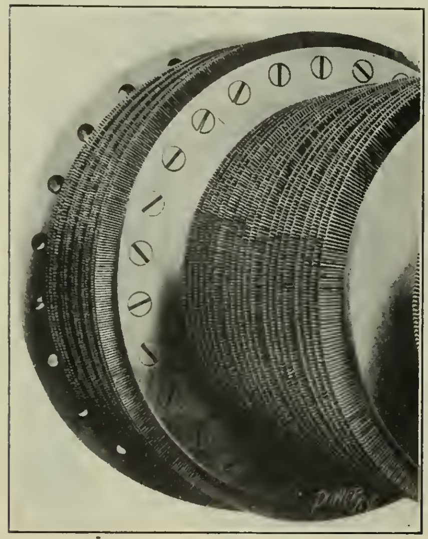


CYLINDER BASE, HARTFORD TURBINE—[illegible] light plant, having reciprocating engines in which the economy could be improved by the use of low-pressure turbines, it was shown that the turbine plant was reduced to its simplest dimensions, with practically no auxiliary apparatus except the condensing plant.

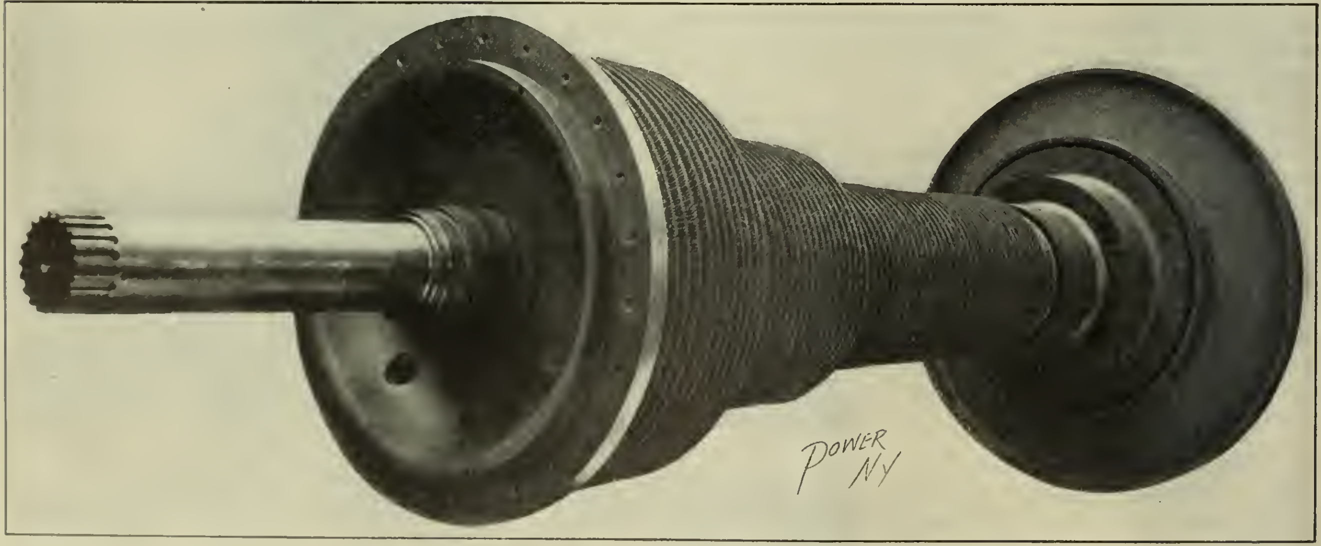
In the matter of central-station design a comparatively new type of station was discussed, the double-deck station, with turbines on the second floor and boilers beneath; the special advantages being extreme compactness, short and direct steam mains, direct-connection to the turbine nozzle by means of barometric condensers and extremely low installation cost. Plants referred to of this design were the Fort Wayne & Wabash Valley Traction Company at Fort Wayne, Ind., the West Point station of the Youngstown & Ohio River railroad at West Point, Ohio, and the Hamilton station of the Cincinnati & Northern Traction Company, Hamilton, Ohio, all of which have been in operation for more than a year, sufficient to prove the merits of the double-deck design.

First Large Turbine Installation

In conclusion, the first large turbine installation was shown, that of the Hartford Electric Light Company, a 1500-kilowatt turbine of the horizontal Parsons type. This machine, the eighth turbine built at the East Pittsburg shops, has been in service until quite recently, when it was removed to make way for a more modern and larger machine. The machine was thoroughly examined as regards blading, bearings, glands, valves, governor parts, etc. The average wear on the journals was about 0.002 inch in diameter, with no greater wear vertically than horizontally. The blading in the two low-pressure barrels was particularly examined for evidences of erosion due to entrained moisture in the steam, but the original blades put in eight years ago were found to be quite intact. These blades were of Delta metal, as used in the early construction, and these results should naturally be duplicated with the copper-clad blading of the present time. As an evidence of the rate of deterioration in turbine machinery, this Hartford turbine is of considerable interest. After six years of daily service, and two years as a reserve unit, it is practically in as good condition today as when first installed, which indicates that the rate of physical depreciation is actually much smaller than is often supposed.



CLOSE VIEW OF ORIGINAL BLADING IN INTERMEDIATE AND LOW-PRESSURE DRUMS



HARTFORD SPINDLE COMPLETE, HIGH-PRESSURE DRUM; LATER BLADED WITH COMMA LASHING

Referring to the view, on page 767, of the low-pressure blading, it should be explained that the few small nicks shown were made in removing the blading. The rough appearance of the blade surface is due to deposits of foreign matter carried over from the boiler-feed water.

Smoke Not Always Wasteful

A "smoke-abatement exhibition" was held at Sheffield, England, recently, at which the opening address was made by Sir Oliver Lodge. Among other things he said that it was customary to regard smoke as wasteful and as indicative of imperfect combustion. If this were entirely true, then in self-interest manufacturers would do their utmost to stop it. Unfortunately, smoke in practice was not wholly wasteful. Under certain circumstances it might be economical. He regretted to say this, but it was a fact. It was economical when fires had to be banked; it was also economical when they had to heat cold surfaces by means of flame, for in such an operation a smoky flame was more efficient than a nonsmoky flame. A luminous smoky flame was better than a nonluminous one for that purpose under present boiler conditions. It was impossible to bring a flame into contact with a cold surface and to have perfect combustion. The heat had to pass through a film of unburnt gas by radiation. That was the real difficulty, but things might be improved. It was possible, for example, to have studs or projections on the boiler plates which would get red hot in the flame and carry the heat in by conduction. It was important, however, that they should realize that they had to deal with radiation and should strive to obtain the best possible radiation.

Ten years ago gas and petroleum engines were not used in Japan, but within that period they have become so popular that they now represent nearly 15 per cent. of the total motors adopted by manufacturers.

Power Plant Accident

A few weeks ago a very peculiar accident happened in the power plant of the Hotel Racine. The general arrangement of the plant is illustrated in Fig. 1. There are two return-tubular boilers 56 inches by 14 feet, a 10x14 Ideal engine running at 247 revolutions per minute and belted to a bipolar generator, of 200 amperes capacity at 125 volts, running at 1330 revolutions per minute.

This plant has been in operation about fourteen years, during the first twelve of which a workbench was located in the corner now occupied by the desk, and within about 4 feet of the commutator of the generator. Yet in all that time with the large amount of work that has been done at that bench, there never had been any accident by any substance, metallic or otherwise, coming in contact with the generator.

About two years ago the chief engineer, desiring to have a better location for his workroom, removed the bench to a suitable room on the other side of the boilers from the engine (not shown) and put his desk in its place, as illustrated.

On the night in question the night engineer on watch, a most careful man, desired to trim off the ragged corners of his scoop shovel, and not caring to go into the work room to the bench (away from the engine) he laid the coal pick on the floor in front of boiler No. 1 at about the same spot marked *X*, and proceeded with the trimming by means of hammer and chisel, but with his back *toward the door* leading to the engine room, and in such a position that as the pieces were severed they would in all probability fly across the fire room toward boiler No. 2.

It is usually the unexpected which happens and in this case "the cussedness of inanimate things" was again exemplified by the severed piece of the scoop flying up and striking somewhere. It made a "three-ball combination play for the corner pocket," flew over the engineer's head through the door and into the air gap of the generator with the usual accompaniment of electrical display. At the next flash the engineer made a dash for the switchboard and threw the double-throw main switch over onto the city current, and continued on past the board, as indicated by the arrows, and closed the throttle.

Upon making a closer examination he found that the binding wire of the armature had been severed near the commutator end, and the insulation was also badly cut. A spare armature for this machine is kept on hand for just such emergencies. Taking the telephone from the desk he called up the chief engineer, who resides a short distance from the hotel, and upon his arrival the old armature was removed, and the spare one inserted and the machine placed in operation again in just an hour and a half.

Now, while the old one is undergoing repairs, spare moments are put in by all hands in trying to figure out just what course the last chips off that scoop shovel took to dodge the engineer, pass through a doorway and get into that dynamo.

GENERAL ARRANGEMENT OF HOTEL RACINE PLANT

Safety of Pipe Fittings

A. L. Dixon and W. G. Perkins have me "guessing." Mr. Dixon recently figured the original factor of safety on a valve-bonnet joint and presented a [illegible] of 42,120 pounds per inch tap acting, exerted in holding the bonnet on [illegible] against a stress of [illegible] pounds per inch [illegible] tending to blow the bonnet off. He admits that the joint leaked and I can't seem to figure out how it ever could be tight under those conditions. I have made several joints in my time and it has always been my endeavor to have the means of holding joints together overcome the tendency to pull apart.

When I came to Mr. Perkins' article afterward I thought someone else had seen the error of Mr. Dixon's ways, but he only adds confusion to what I thought I knew, for he says that the stresses tend to balance each other. When the steam pressure and the screwing-down pressure are equal, are we to assume there is no pressure on the joint? It seems to me that as the steam pressure and the screwing-down pressure both tend to strip the thread, both forces must be acting in the same direction and must be added.

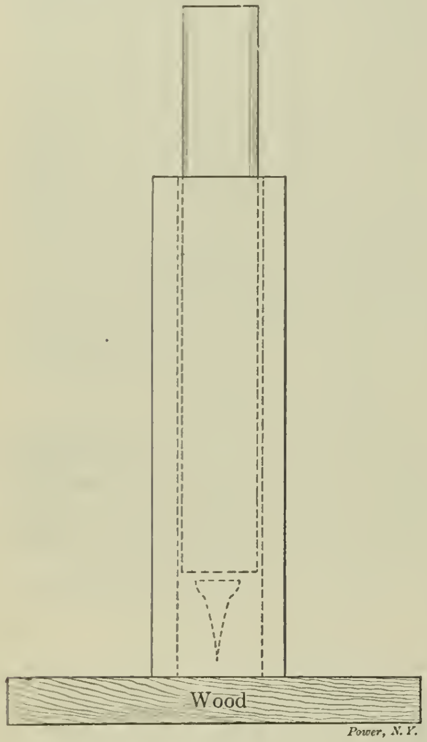
A Nail Driver

The accompanying sketch shows a little device for use in corners not easily reached with a hammer. The rod should be almost the same size as the inside diameter of the pipe. The method of operation is to put the pipe over the place where the nail is to be driven; then drop the nail into the pipe and place the rod in the pipe on top of the nail. Then pull



A NAIL DRIVER

the rod up and down until the nail is driven home.

Electrolysis and Superheat

Mr. Sawyer's article in the March 2 number, in regard to pump corrosion, is in some respects interesting and at the same time very amusing. Pumps do not show the conditions of which he speaks, except in rare cases.

There is no good reason for the "one pump" in question to be eaten away any more than any of the other pumps, and if the contents of this "one pump" was circulated through some one of the other pumps, I think that the same condition would exist in it, regardless of its location; and the only way to determine the result would be to try it. As it is not stated that all the pumps handle the same solution, it cannot be known why the electrolyte in this "one pump" should be any more active than in any of the other pumps, and the only way to determine this would be to make a very thorough test, which must be carried out as follows: Tap the discharge line from each of the pumps with a small pipe, and allow them to flow into a containing vessel, say for twenty-four hours, as it is stated that "at certain portions of the day some sewage which possibly might contain nitrates is carried through the different pumps in the condensing system." A portion of each of these solutions should then be given a test to determine what per cent. of alkali or acids they contain, and if this "one pump" had an electrolyte of a different character, it could then be noted. If they all show the same percentage of elements present, it would seem quite natural that each pump would be affected in the same manner.

To determine, then, if the iron and brass in this "one pump" was of a higher electromotive force, in comparison with the other pumps, take some of the decks or valves and a portion of the brass lining as positive and negative elements to make a cell, using a glass container and some of the solution as the electrolyte, having it as hot as when circulating through the pump. The connections to the piece of brass and iron should be very secure in order to reduce the resistance of the connections. With the cell thus made, as a voltaic cell, use a millivoltmeter or a galvanometer to determine what the electromotive force is, if any. This would tell if there was any local action taking place within the "one pump." The other pump parts and electrolyte should be likewise tested, to determine if there was a difference. It is possible there might be some marked difference in the composition of the pump parts, although hardly probable.

As to electrolysis taking place due to the wiring system of the plant being grounded, such a condition would be almost impossible to exist where there is a network of piping for water and steam. For electrolysis to take place, there must be a difference of potential, and in the case of the "one pump," there is no condition which would cause a difference of potential between the pump parts and the water or solution handled.

If, for any reason, the piping to and from the "one pump" was carrying any stray current, due to the wiring of the plant being grounded, there is no reason at all that the current should disobey the laws governing electrical energy, and take the course via the water route. As for the "electric-car line half a mile away" affecting the "one pump," it need not be considered at all.

The electrolysis due to electric-railway service is well known and thoroughly understood. Its effects are confined to gas and water trunk mains, and is carried on upon a grand scale when not properly guarded against.

I would feel perfectly safe in saying that the "one pump" trouble was due to the water or solution handled, and not to any electrical effects.

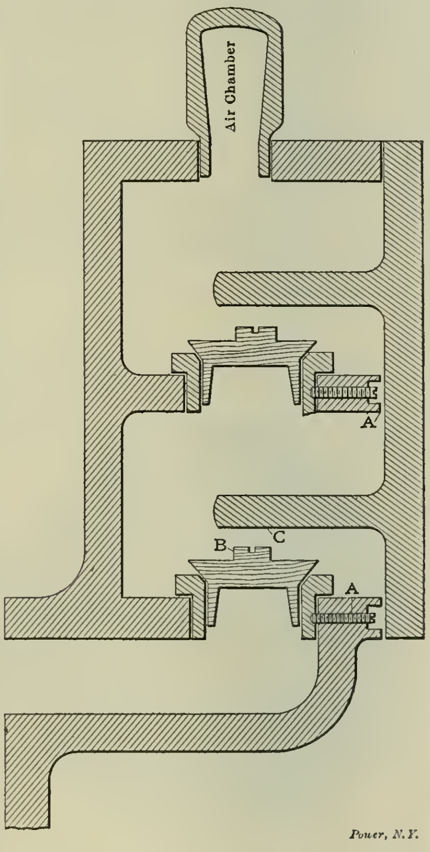
L. EARLE BROWN.

Ensley, Ala.

Loose Valve Seat

One day the oil pump on our turbine, after three years of faithful service, suddenly refused to work, and no amount of persuasion would start it. This pump circulated the oil through the cooling coils and up into the governor case, and then flowed by gravity to the bearings. As a temporary remedy we drew the oil in a pail from the base of the machine and poured it into the reservoir and in that way managed to keep going until noon, when we shut down to investigate.

After drawing all the oil from the system and removing the valve plate, the only thing that could be discovered was that a piece of gasket was gone from the partition between the suction and discharge



LOOSE VALVE SEAT

chambers, as at *A* in the illustration. The valves and seats seemed to be in perfect condition, with the exception of conconsiderable wear on the button on the valve at *B*, caused by the valve continually striking the stop bar at *C*. But as everyone was of the opinion that the trouble was caused by the gasket, we renewed it and started up.

Our oil level held up finely for two or three days, when it commenced to fluctuate. It would be first up and then down, keeping a man busy with a pail most of the time.

A final examination showed that the suction-valve seat was loose. This seat was fastened with a set screw, but had worn the metal away from the point of the set screw so that the valve and seat could lift together and check or shut off almost entirely the amount of oil that could pass through.

The remarkable part of it was that when the seat was down in position it fitted so tightly that it would not be noticed as being loose, and could only be raised by the use of some sharp-pointed instrument, and now the oil pump runs as of old.

Pipe Sizes Without Figures

The above is the title of an article in a recent number by J. E. Bates. Mr. Bates bases his method on the fact that the square of the diameter of a circle equal in diameter to two other circles is equal to the sum of the squares of their diameters.

For many purposes this method would be sufficiently accurate, but there are conditions under which pipes so calculated will not have equal capacities. It is true that if the velocities in the pipes are equal the capacities will be equal, but take the case of an elevated tank from which water is conveyed by a 2-inch pipe to the place of use, 300 feet away. Suppose this 2-inch pipe is replaced by its equivalent in 1-inch pipes. By Mr. Bates' method this would require four 1-inch pipes. Upon trial the flow from four 1-inch pipes will not be found equal to one 2-inch pipe, due to the increased friction of the smaller pipe. Correctly to proportion the sizes of the pipes for equal capacities the friction head should always be considered. Let

q = Volume of water delivered by a pipe,
d = Diameter of pipe,
h = Initial pressure head,
g = Gravity constant = 32.16,
f = Friction factor usually taken = 0.02 for new iron pipes,
L = Length of pipe line in feet,
V = Mean velocity of flow in feet per second.

The volume, in cubic feet, of water delivered by a pipe is equal to the product of its sectional area in square feet into its mean velocity.

$$q = 0.7854\, d^2\, V$$

but

$$V = \sqrt{\frac{2\,g\,h}{1.5 + f\left(\frac{L}{d}\right)}}\ ;$$

hence we have for full pipes:

$$q = 0.7854\, d^2 \sqrt{\frac{2\,g\,h}{1.5 + f\left(\frac{L}{d}\right)}} = 0.7854 \left\{\frac{2\,g\,h\,d^5}{1.5\,d + f\,L}\right\}^{\frac{1}{2}}.$$

From this we see that the relative discharging powers of pipes are nearly as the square roots of the fifth powers of the diameters. Or, in other words, the diameters required for equally effective deliveries will vary nearly as the fifth roots of the squares of the volumes.

The accompanying diagram was designed to facilitate the proper proportioning of piping systems. From it to determine the relative capacities of different-sized pipes and their equivalents

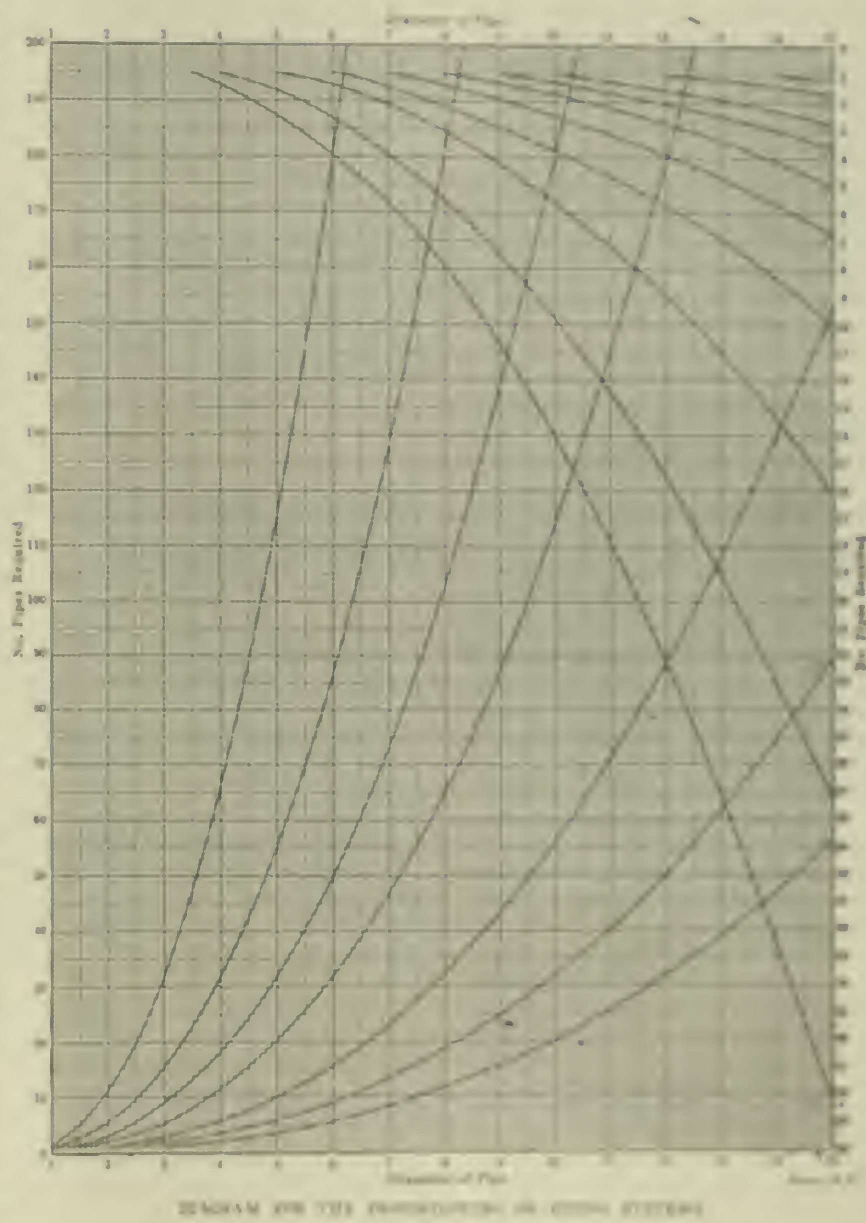

DIAGRAM FOR THE PROPORTIONING OF PIPING SYSTEMS

can be found. The usefulness of the diagram can best be shown by the solution of the following problems:

Problem 1.—From a centrifugal pump having one 8-inch suction opening with which to pump water from two wells, find the size of the suction pipes.

Solution: Start at 8 from the upper margin and proceed down two spaces (the number of suction pipes required), following the curve, and find the pipe to be a little larger than 5 inches. The difference is so small that it will be sufficiently accurate to use 5-inch suction pipe.

Problem 2.—Water is to be piped from four tanks at the same height, each tank having a 4-inch outlet. What size of pipe equal in carrying capacity to the four 4-inch pipes?

Solution: From where the 4-inch pipe curve crosses the "four" line from the upper margin, and proceed up to the top, where the size is found to be 7 inches.

Problem 3.—Find the size of pipe equal in capacity to one 3-inch pipe and one 6-inch.

Solution: By inspection we find that one 6-inch pipe is equal to 8¼ three-inch pipes. The capacity of the combined pipe must then be equal to 9¼ times that of a 3-inch pipe. By referring again to the diagram, we find the diameter to be 7.4 inches. If the velocity is not given, the 7-inch pipe would then be increased, but as a rule it would be better to use an 8-inch pipe.

Problem 4—This is Mr. Bates' problem. Find the size of pipe equal in capacity to one $3\frac{1}{2}$-inch, one 5-inch, one 2-inch, one $2\frac{1}{2}$- inch and one 6-inch.

Solution: The smallest pipe is 2-inch. From the diagram we have:

One 2 -inch pipe	= one	2-inch pipe.
One $2\frac{1}{2}$-inch pipe	= two	2-inch pipes.
One $3\frac{1}{2}$-inch pipe	= four	2-inch pipes.
One 5 -inch pipe	= ten	2-inch pipes.
One 6 -inch pipe	= sixteen	2-inch pipes.
Carrying capacity	= thirty-three	2-in. pipes.

From the diagram, the diameter is found to be 8.1 inches, or an 8-inch pipe. Mr. Bates, by his method found 9 inches to be the diameter.

Problem 5—This problem is the one given at the first of this letter. Find the number of 1-inch pipes equal in carrying capacity to one 2-inch pipe.

Solution: From the diagram this is found to be 5.7, or six 1-inch pipes.

John B. Sperry.

Aurora, Ill.

Criticism of a Criticism of Turbine Installation

In Power for October 13, 1908, there was a description of a mammoth turbine for Buenos Aires. In a somewhat later number, E. H. Lane calls attention to the amount of water the circulating pumps are capable of delivering per hour. In the Buenos Aires plant there are two circulating pumps designed to operate in parallel, each having a capacity of 112 gallons per second. Normally, it is the intention to operate the pumps in this manner at peak loads, giving a circulation of 224 gallons of water per second. According to Mr. Lane this amounts to 6,693,120 pounds of water per hour, he making the assumption that a gallon weighs 8.3 pounds "(critics, excuse the figure)". Now, there is only one country in the world where a gallon means 8.3 pounds of water, the United States. In every other part of the globe a gallon is 10 pounds of water or 4.543 kilograms or liters, and very, very few know of the gallon Mr. Lane uses. Right here there is an error of over 20 per cent. in the weight of water, which should be 8,064,000 pounds per hour, nearly 64 tons more than Mr. Lane's figure. So that Mr. Lane's figure of 47 for ratio between the weight of the circulating water and the weight of the steam should be changed to nearly 55 pounds.

Another discrepancy in Mr. Lane's figures arises from his comparing the normal rating of the circulating pump with the two-hour overload of the generating unit. The normal rating of the circulating-pump units is 90 horsepower each, and they are undoubtedly able to carry some overload. The normal rating of the steam turbine is 9000 kilowatts, which is equivalent to a steam consumption per hour of 124,800 pounds. Therefore, the normal ratio between the weight of the circulating water and the weight of the steam is nearly 65 instead of 47.

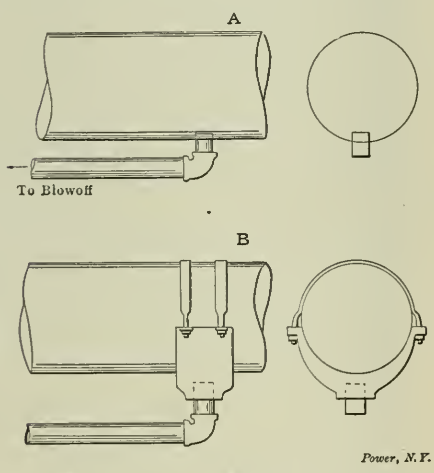
From the foregoing it is very easy to see that the deficiency in circulating-pump capacity cited by Mr. Lane is due entirely to his misconception of the weight of a gallon. It is true Signor Tosi did not state which gallon he meant in his article, but it is in the highest degree unlikely that he would think of the United States gallon of 8.3 pounds, which is given only the most casual sort of mention in foreign engineering handbooks, and is omitted entirely in many.

A. D. Williams, Jr.

Pittsburg, Penn.

Method of Draining Steam Pipe

I have had considerable trouble with water in the cylinders of my engines.



METHOD OF DRAINING STEAM PIPE

When a sudden load was thrown on considerable water would sometimes be drawn over and cause a click in the cylinders for quite a while.

The steam was supplied by four 72-inch by 16-foot horizontal return-tubular boilers, the steam passing through a 12-inch header to the engines. The boilers were not fitted with steam domes or dry pipes, but the header was fitted with a 2-inch diameter pipe which connected to the boilers through the blowoff pipe.

The nipple which was made into the header was screwed in so far that it extended up into the header about ⅝ inch, as at *A*, so it was necessary for the water to stand high enough in the header to run over the end of the nipple before the bleeder would carry it off; consequently when a sudden demand for steam came, part of the water in the header was carried over with the steam.

I took the nipple out and attached it to the header by a "service clamp," as shown at *B*. Since doing this I have had no trouble.

R. L. Rayburn.

Decatur, Ill.

Dashpot Troubles

In reading the comments by Messrs. Westerfield and Harding, as to the cause for Mr. Davis' dashpot troubles, I do not think that they have given all the causes for the failure of the dashpot's seating. As far as they have gone, well and good, but any engineer will naturally look at the dashpot leathers when they begin behaving badly, and if they are in bad condition, it will be seen at once and remedied.

There are other causes which, I think, deserve attention, in addition to the causes already given. A good working dashpot has a certain strength, and if it is loaded beyond that strength it will not seat; any air leak in the vacuum pot will weaken it, also.

Many of the old-type dashpots have a gasket at the point where the air valve is located, which is very narrow, and air leaks in at this point, destroying the vacuum. The pot will not close, but will have to be pushed down by the hook.

The dashpot and rod may not be in perfect alinement, causing too much friction, but I do not think this is the cause of the trouble under discussion.

I think there is an excessive friction at some point in the mechanism. If the bonnet is removed, I think it will be found that the head of the stem is rubbing on the bonnet, causing an excessive load on the dashpot. When the engine is running the tendency of the steam would be to force the head of the stem against the bonnet and cause binding. The distance between the head of the stem and bonnet should be at least as great as the thickness of heavy brown paper, and this distance is adjusted by the collar on the stem. I have had this kind of trouble with all types of dashpot. And from the fact that Mr. Davis' valves seat when the gear is worked by hand and no steam is acting on the head of the stem leads me to believe that friction is the cause of the trouble.

The packing on the stem frequently causes excessive friction and gives a similar trouble. A little water should at all times leak around the stem so that the packing may get lubrication from the steam. In addition to the above causes, the air valve, or flap button, which closes the air port when the plunger rises, may be leaking air, in which case the plunger will act badly and not seat.

John Jones.

Hamilton, Ohio.

In a recent number Elsworth Davis gives an account of trouble with nonseating dashpots. I had the same kind of trouble two years ago. I took the dashpots apart and releathered them, giving them a thorough cleaning, but still had the same trouble.

An additional amount of cylinder oil helped a little and gave me an idea that the steam valves were binding in their seats, but this, on investigation, proved otherwise. I found, however, that the trouble was in the valve stems. The oilways on the flange of the valve stem that seats against the bonnet of the bell were worn smooth and ground into the bonnet.

If Mr. Davis finds his trouble here, he can have temporary relief by taking a small diamond-pointed chisel and cut oilways in the flange on the valve stem.

Rogers, Ark.

Faulty Piping

I have often seen faulty piping diagrams and poor connections of various kinds illustrated in Power, but some piping I saw the other day puts everything else in the shade.

Referring to the sketch, it will be seen that the steam pipe to the engine leads from the safety valve. Never having seen such an arrangement, I inquired how it worked without blowing off when the engine was running and was told that there was a partition inside the valve. If this is so it would be well for someone to explain this type of valve, for it must be an old style.

The small ½-inch pipe was tapped to the engine steam pipe, passes along the wall to the steam gage and extends down to a sink, another pipe leading to a pail. It can be readily seen what the effect on the steam gage must be when the valve leading to the sink or pail is opened.

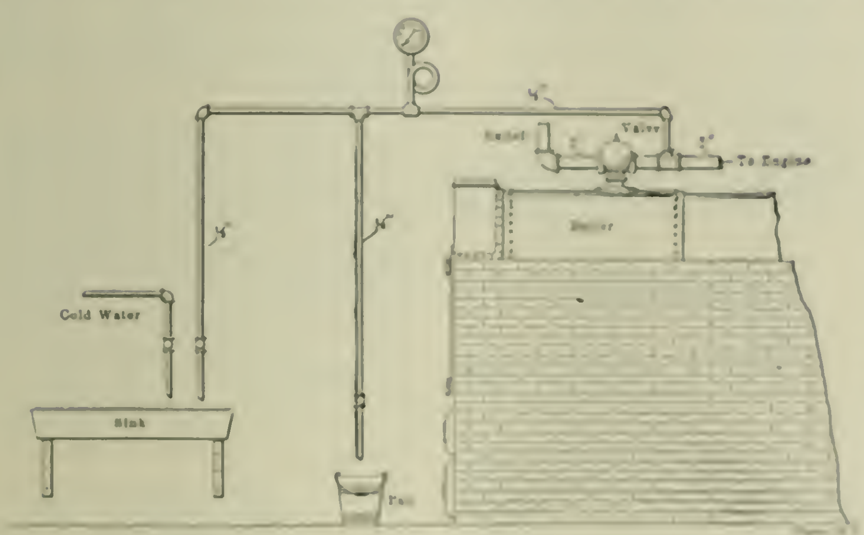
Saco, Me.



FAULTY PIPING

Increase of Salary

In the March 23 number, page 561, Charles W. Mitchell mentions an employer who is evidently willing to pay his engineer less than the engineer may actually be worth to him, in which respect this particular employer is not at all different from many others. As to the query: "Should the engineer ask for a raise, or should he refrain from asking, because he prefers to have increases come unsolicited and as a recognition of merit?" I believe that the greater part of the readers will agree that since the boss delighted in telling about paying the former man less than he might, it is clear that he will not offer the desired increase until asked, and not then unless he has to.

The salary of $25 per week and the fact that a visible saving of $30 per week may be made around the power house indicate that the plant is no backwoods sawmill or country lighting station, and suggests that the boss is very probably a man of at least a little experience in hiring men. If so, he probably has sense enough to know about where he can find another engineer without much delay, should it become necessary. Or, he may have a man or two in the power house who are, perhaps without knowing it, understudies for the job of engineer, and these men may have family, property or other ties that make it fairly certain that they will stay, especially in case the town is of but moderate size and there are no similar jobs to be had without going away.

If it is in a large town or city the important point is, what are other engineers of equal ability and in similar plants receiving? Also, is there anything unusual about this particular power house or the requirements of the industry it serves, making it difficult to break in a new man to the special duties required, no matter how good an all-round engineer he may be? Does the job require considerably closer attention to business or a higher degree of ability, technical knowledge or skill than is to be found in the ordinary available engineer who might be called in to take our friend's place?

After going on the boss and the conditions, does he think that a mere request not backed up by a better offer elsewhere will be favorably acted upon, and can our friend so back up his request, or, if not, is he prepared to hunt out a kind if it does not work? In other words, since the information given indicates that this concern, like some others, is not paying any larger salaries than it has to, and, furthermore, since the boss is probably willing that this fact be known, the question comes right down to the usual one: "Can he fill my place for the same money or does he think or know that he can't?" Until our friend can answer this to his own satisfaction he may as well consider his mind about asking for increases.

A. S. Williamson.

Urbana, Ill.

In answering Mr. Mitchell's query I should say yes, but the engineer should first study well the questions: "Am I worth more to my employer? Am I doing all I can to further his interests? Is my work good enough to justify my employer to increase his expenses by giving me more money? Have I his entire confidence as to my ability to run my part of his business on an economical basis?"

An engineer may save $30 per week for a few weeks, but he should be careful to see that he does not do so at the expense of a future shutdown, for a good reputation is worth as much in this business as in any other. Having decided to ask for more money, do not make the mistake of banking too much on another position you may have in view. Your employer may have another man in view as well.

I have found it best to approach my employer in a gentlemanly way, state the facts in the case, keep my temper and remember that he has more to worry and think about, and knows better what his own needs are, than I. It is well to remember that the goodwill of a former employer has been known to help a man get a position where he could get more money if his former place did not justify it.

D. L. [illegible]

Scranton, Penn.

My answer is that it depends on the type of employer and the fitness of the employee. Employers, generally speaking, are quick to recognize ability and reward it. Sometimes, however, there are employers who, although they realize the ability of a man, do not increase his wages until asked to.

I know of an instance where a young man entered the drafting room of a large electrical manufacturing company. He was a technical-school graduate, but had

had very little practical experience in drafting. For this reason, he accepted a lower salary than was paid to a new draftsman. Being a smart young fellow he soon grasped the work and was doing as good work and as complex drawings as men who were receiving 50 per cent. more salary. When he entered the drawing room he had made a resolution that he would never ask for a raise. He thought that if he did his best work his employer would reward him. After he had been working in the same drawing room for two years, although the chief draftsman recognized his ability, he was still working for the amount he received when he entered the employ of the company.

One day, when he spoke to the chief draftsman about his salary, that dignitary was painfully surprised. He was thinking by this time that our young friend was pretty easy. He agreed with the young man that he thoroughly deserved an increase and gave it to him.

Of course, many an employer would have recognized his ability and rewarded him, but there are quite a few employers who still wait until an increase is asked for before considering it. This is especially true in the case of large companies.

PAUL H. KERR.

McKeesport, Penn.

Criticism of Indicator Diagrams

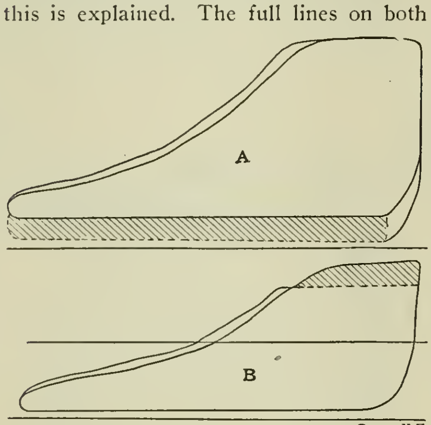
In regard to Lindon A. Cole's cross-compound engine indicator diagrams, I should say that, on the high-pressure side, the head end shows a higher mean effective pressure, and is consequently doing more work than the crank end. He can remedy this by changing the length of the governor reach rods. If changed very much the position of the safeties should be noted when the governor is in its lowest position, to see that the valves do not pick up. Changing the governor rods will change the position of the safety.

The crank-end diagrams show late release, which can be made earlier by changing the right and left exhaust rods. By doing this, the compression will start a trifle later on the crank end, which is not a bad condition to have.

The high-pressure diagrams show slight wiredrawing on the steam line, which is due either to insufficient steam pipe or port area. As to the low-pressure, I should first equalize the cutoff, with the precautions already mentioned, after which advance the eccentric to give a perpendicular admission line, and horizontal steam line to the point of cutoff. If the engine is single-eccentric, the compression will have been increased greatly by this act, which can be decreased by changing exhaust valves to suit.

Unless Mr. Cole has some particular reason for carrying a high receiver pressure of 15 pounds, I should advise him to cut it down by lengthening the low-pressure cutoff, or it may be that he is admitting live steam to the receiver, to get more work out of the low-pressure cylinder. If he will note the position of the governor on the high-pressure cylinder before and after lengthening the low-pressure cutoff, he will find it riding a trifle higher on an average, of course cutting off later in the low-pressure cylinder. Reducing the receiver pressure will decrease the amount of work done by the low-pressure cylinder and cause the high-pressure cylinder to do more, but the decreased resistance due to high receiver pressure, which is back pressure on the "high-pressure cylinder the entire length of the stroke," has a more favorable effect from an economical standpoint than does the high receiver pressure, from the fact that the low-pressure cylinder only gets the benefit of it a fraction of the stroke, while the high-pressure piston is pushing it out of the way all the time.

By referring to the diagrams *A* and *B* this is explained. The full lines on both



MR. WALDRON'S DIAGRAMS

the high- and low-pressure diagrams represent running with high receiver pressure; the dotted lines represent the diagrams after the receiver pressure has been lowered. On *B*, the part that is cross-hatched represents the decrease in the receiver pressure due to lengthening the low-pressure cutoff. It will be noticed that this loss of pressure is only on a portion of the stroke, say one-fourth, whereas the effect of decreased resistance on the high-pressure cylinder, as shown by the cross-hatching in *A*, is for the entire length of the stroke. It is not absolutely necessary for each cylinder to do an equal amount of work, as experience has shown that a compound engine will work satisfactorily, and the water consumption will be reduced per horsepower with low receiver pressure unless extreme conditions of load require the low-pressure cylinder to do an extra share of work.

A. C. WALDRON.

Lynn, Mass.

I should say that an improvement can be made with very little trouble. As far as steam distribution and valve adjustment are concerned, I think the following changes may be made with satisfactory results: The cutoff requires equalizing in the high-pressure cylinder by either shortening the cutoff at the head end, or lengthening it at the crank end. Both head- and crank-end exhaust valves should open a little earlier. The other features of the high-pressure diagrams are good, sufficiently so as to require no change.

For the low-pressure cylinder diagrams the following changes are necessary: The cutoff requires equalizing as in the case of the high-pressure diagrams. Both crank- and head-end steam valves require more lead, as shown by the rounding corners of the diagrams at the intersection of the admission and steam lines; the compression may also be changed to give less than that shown at present on both the crank and head ends.

I am of opinion that the receiver pressure may also be increased, which would tend to correct the sloping steam lines in the diagrams. If this is done, less lead will be required to reduce or do away entirely with the rounding corners referred to. It seems to me that the receiver pressure may be increased to 20 pounds with good results all round, in the case referred to.

I am simply judging from a number of cases I have in mind, and from my own experience with compound engines covering a period of fifteen years. Of course, surrounding conditions largely govern the things to which I have alluded, and judgment must be brought into play when contemplating any change at all. But speaking in general about receiver pressures, I think that in many cases a too low rather than a too high pressure is carried.

CHARLES J. MASON.

Scranton, Penn.

Use of Wooden Wedge Rings

The writer is amazed that any man claiming to be an engineer, either mechanical, steam or civil, would resort to such an expedient as inserting wooden wedges in a pipe line simply in order to get the pipe to "line up." How long does he expect these wooden wedges to last in the line? Could they possibly last one-fourth or one-third the life of the main iron pipe? How will he repair the line, in a few years, when these numerous wedges begin to rot and leaks appear at every joint? Probably by cutting out the service on the water main and again resorting to his famous "wooden-wedge idea."

Mr. Kavanagh evidently had no regard for his employers' interest, or for the permanency of his work, but simply got the line together so it would hold water until he could get away from it.

ROBERT L. RUDDELL.

Glenville, W. Va.

Some Useful Lessons of Limewater

How the Direction of Electrical Current Can Be Caught without Chemical Means; Introduction to the Study of Carbon Compounds

BY CHARLES S. PALMER

In the last lesson we studied the simple electric current, not with the purpose of going into electricity, but simply to show that chemical action is essentially electrical, and also that electrical action may be chemical. The two sets of facts which will be worth while to remember are that in the primary battery the current goes from the zinc to the copper in the battery, the hydrogen appearing at the copper pole or cathode, as the metals do generally, and when the connecting wire is cut anywhere in the circuit, the wire, or the end of the wire, leading from the cathode becomes itself an anode, and the end of the wire leading back to the anode becomes itself a cathode. You can easily clinch this last group of facts by remembering that acid and oxidizing properties are shown at the anode, and basic, metallic and reducing properties are shown at the cathode. It must be recollected that we are also speaking of the positive current, mainly; and to show how the direction of the current can be caught without chemical means, it will be well for you to try the simple experiment shown in Figs. 1 and 2.

The Direction of the Current

Take the simple zinc-copper couple, connected by the coiled insulated wire, and bend the middle part into several parallel

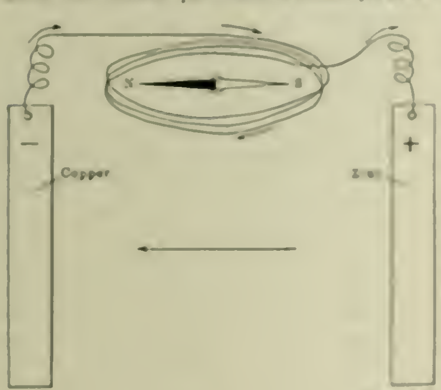


FIG. 1

turns, making a coil. Fix this coil so that in looking at it from one side the positive current from the copper plate goes in at the upper left and out at the lower right, in the direction of the hands of a clock, as shown by the arrows. This coil must be large enough to be held over and around any simple pocket compass. Let the compass lie with the needle pointing north and south. Then place the coil so that it lies north and south and looking from the west, with the current going around clockwise. We will suppose that the coil has been made and the compass needle and coil adjusted before the zinc and copper are dipped into the dilute acid. The moment the zinc-copper couple begins to act as the simple primary battery, the compass needle will swing around to the east (Fig. 2), so that the small elec-

FIG. 2

tric currents which are always rotating in and around the compass will have the needle with its currents parallel with the current in the coil from the battery. As stated, the compass needle will swing to the east, and you can see how this is from the simple rule of Clerk Maxwell that when looking at the compass needle from south to north, the direction of the small currents in the compass is clockwise. This is shown in Fig. 3. All this is given here mainly to show that chemistry is essentially electrical, and that in spite of its being a gas, hydrogen is chemically a metal, just as much as iron, or silver, or calcium, the lime metal which lies hidden in lime and its compounds.

The great advantage of clearing all this up is that we want to use these lessons as the basis for the broad and thorough introduction to chemistry. In this study it will be very handy to have some simple system to guide one in keeping the facts well classified. Now, it happens that one of the clearest and easiest of methods is first to study a few of the typical elements, with the aid of the natural contrast furnished by the hydrogen and the oxygen compounds of the elements in question. Thus, if we are studying such common things as the compounds of carbon, or sulphur, or nitrogen, it is easy to group and remember many hundred facts by making a sort of table, or chemical map of carbon, or sulphur, or nitrogen; and in each case, by writing down the compounds in order from the hydrogen or reduced compounds to the oxygen or oxidized compounds. You would not think of going off to travel or roam in an unknown country without a good guide, or at least a good map to rely on; and so, in the same way, the mapping or tabling of the more common and important compounds of each element in order is the guide map of the right road to an easy acquaintance with hundreds of important and valuable facts.

That is why we have been spending so much time in getting the chemistry of oxygen and hydrogen cleared up; they are not only important in themselves, but they are also important in serving as leaders to much other chemistry. I wish to make this clear, in regard to these ways of using hydrogen and oxygen. Make the tables and study them as they are given, week by week; but do not forget that the tables themselves are not chemistry. The tables merely serve to remind

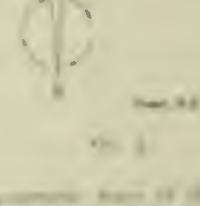

Fig. 3

you in systematic ways of the facts that you get at by your experiments.

Carbon

We will begin this more careful study of some of the commonplace or acid-making elements, by taking up the element carbon. You are fairly familiar with some of the more facts about carbon. You have made carbonic acid gas (CO_2) by burning some coal in the bowl of that tobacco pipe, when you sucked it through some filtered lime-water, and threw down the plain calcium carbonate. You also made some of this same carbonic-acid gas by decomposing some carbonate, like soda, or limestone (lime or calcium carbonate) by some acid such as hydrochloric acid. You also noted that carbon has another common oxide besides carbonic-acid gas, and that is called carbon monoxide (or one-oxide, CO); but you did not make any of this carbon one-oxide.

Yet this lower oxide of carbon is very common in some compounds right about you, as in the common city gas, of which it makes up from 30 to 40 per cent. This lower carbon mon-oxide (CO) is also always found burning in certain flames where you note the peculiar blue or bluish-green color: as in the furnace when you throw on fresh hard coal, or in the lower part of a common candle or kerosene-lamp flame, or in the flame of a common gas stove, or in the lower part of the common gas flame. This gas is found almost everywhere where there is any common burning; and yet it is not easy to make in the pure form, nor is it so easy to test as some of the other gases; but we will try to get at it in some practical way. Of course, you are familiar with plain carbon itself; you know that coal, charcoal, soot, lampblack, coke, etc., are all only so many kinds of carbon. Further, you have read that the so-called "lead" or graphite, "black lead," of "lead pencils" is carbon; and, of more remarkable interest, that the diamond itself is only very pure and hard-crystallized carbon.

Now it is easy to take such facts, and they are facts, it is easy to take such facts without testing them; but if one wants to keep his mind clear, he will ask such questions as these: How would anyone prove that such things as graphite or lead-pencil stuff and diamond are forms of carbon? Someone must have tried the proof. How did he do it? And what did he do? The answer comes back clear and satisfying. Someone burned these infusible and refractory things, graphite and diamond, and all that he got was so much of our old friend, carbonic-acid gas. Then carbonic-acid gas is only the oxidized form of graphite and diamond, just as carbonic-acid gas is only the oxidized form of coal. Then coal, graphite and diamond are all only so many different forms of the same one thing, carbon.

But more than this, if one had pure forms of coal, graphite and diamond, then the same weight of each would give exactly the same quantity of the oxidized form, carbonic-acid gas. Thus one ounce of pure coal, graphite or diamond would each give the same quantity of carbonic-acid gas, or carbon dioxide (or two-oxide). That is, in burning, one ounce of either pure coal, graphite or diamond would unite with just 2⅔ ounces of oxygen, making in all 3⅔ ounces of carbon dioxide from one ounce of pure coal or graphite or diamond. Just how the apparatus would be constructed, how one would weigh his different forms of carbon to be burned and, harder still, just how one would weigh the gas from the burning of the different forms of carbon, all this suggests much interesting material for cross-questioning; but it may be said that the carbonic-acid gas is absorbed in little tubes part full of caustic soda, which are weighed before and after the test, also the burning is done in pure oxygen which, you have already seen, is able to burn such hard things as iron.

But there are other forms of carbon compounds, such as the various kinds of "hydrocarbon," that is, compounds of hydrogen and carbon. There is "marsh gas" or methane, which has one atom of carbon and four of hydrogen in the molecule, thus, CH_4; there is its brother, ethane, C_2H_6; there is its cousin, ethylene, C_2H_4, not very common in large supply; and there is another cousin, acetylene, C_2H_2, now very common in the acetylene lamps of automobiles, where it is made from the action of water on calcium carbide, another product of electrical action and intense heat. Then there are hosts of things like benzine, and benzene or benzol. Do not get these mixed up; for benzine (*ine*) is a mixture of things which are only larger brothers of methane and ethane, and which come from natural petroleum. In refining crude petroleum, benzine and gasolene are only so many mixtures of kerosene-like things, all members of the so-called "paraffin" series; because paraffin wax is only a mixture of several of the still larger brothers of methane and ethane.

But benzene (*ene*) or benzol (C_6H_6) is a hydrocarbon, or compound of hydrogen and carbon, from coal tar mainly, although it is also found in some native petroleums from the Caucasus. This benzene or benzol (C_6H_6) is the first of a class of its own, just as marsh gas or methane (CH_4) and ethane (C_2H_6) and the gasolenes, the benzines, the kerosenes, etc., are in a class by themselves. Now you begin to get restless, and you feel like throwing this blind chapter right out of the window. But, wait a minute and see how easy it is to put it all in clear form so that you can see it and remember it. Just look at the accompanying simple table of these compounds arranged in regular order from the hydrogen or reduced end to the oxygen or oxidized end. Now you see the advantage of getting hold of oxygen and hydrogen as a basis for rounding up hundreds of other compounds of other elements.

But here is the table. Let us look at it for a few moments. It is one of the most wonderful condensations of information in a nutshell ever made; and if you master it, you have simply clinched the chemistry of carbon. First, at the left, come methane, ethane, the gasolenes, benzines and kerosenes; then come the ethylenes, represented by common ethylene (C_2H_4); then the acetylenes, represented by common acetylene (C_2H_2); then such things as the "aromatic" hydrocarbons, represented by benzene or benzol (C_6H_6), and so on, for we have merely put down here some of the more common and important of the hundreds of hydrocarbons, or compounds of hydrogen and carbon. And let us not complain at the deceptive appearance of complexity here. It is Mother Nature who has made all these things, and we are taking up only some few of them as types of the others which you may, or may not, study later; but, if you wish to go on, this simple scheme will guide you through many a maze into clear light.

TABLE OF CARBON COMPOUNDS.

Reduced Extreme. Paraffin Series.	Ethylene Series.	Acetylene Series.	Benzene Series.	Carbon.	Carbon Monoxide.	Oxidized Extreme. Carbon Dioxide.
Marsh Gas CH_4 Ethane C_2H_6 Gasolene Benzine Kerosene	C_2H_4	C_2H_2	C_6H_6	Coal Graphite Diamond	CO Formic Acid H CO_2H Acetic Acid CH_3 CO_2H	CO_2 Carbonic Acid. H_2CO_3

Now comes carbon itself, with its various forms; then, carbon monoxide or one-oxide, related to formic acid, the "red-ant" acid (that is no joke, but simple truth); then carbon dioxide or carbon two-oxide, the type of carbonic acid, and there you have the whole story of what it would take a whole library to tell.

There is one other point which you will want to notice here and that is that the chemistry of water is very closely related to many of the compounds noted in this table of reduced (or hydrogenized) and oxidized forms. You remember that we have mentioned repeatedly that carbonic-acid gas is the anhydride of carbonic acid proper; that is, the difference between carbon dioxide (CO_2) and carbonic acid proper (H_2CO_3) is only a molecule of water. You can see this clearly by noting this simple equation:

Carbonic Acid.		Water.		Carbonic Anhydride or Carbonic Acid Gas.
H_2CO_3	=	H_2O	+	CO_2

This relation between carbon dioxide and carbonic acid is noted in the table;

and here and elsewhere in other tables similar relations imply similar equations which you can readily work out for yourselves by simply adding the number of atoms in the formula of water (H_2O). A little practice in writing such equations will show you just what is the relation between any acid and its anhydride. This tendency of many compounds to unite with water or to give up the ingredients of water is one of the great characteristics of the chemical conditions under which we live; and it is no exaggeration to say that we live in the midst of a water chemistry. To show this, suppose you step right here and take a lump of quicklime and slack it with water. You have already done this repeatedly in making limewater and the equation for this is

Quicklime or Calcic Anhydride.		Water.		Calcium Hydrate or Hydroxide.
CaO	+	H_2O	=	$Ca(OH)_2$

Similarly, you made carbonic acid, as when you treated marble with hydrochloric acid and the equation for this reaction is:

Calcium Carbonate.		Hydrochloric Acid.		Calcium Chloride		Water.		Carbon Dioxide.
$CaCO_3$	+	$2HCl$	=	$CaCl_2$	+	H_2O	+	CO_2
						Carbonic Acid.		

Thus, we see that a base may exist in the form of the base proper combined with the ingredients of water, or it may exist as the base anhydride, and, similarly, an acid may have the ingredients of water, or it may exist as the acid anhydride, that is, without the water. There is one point which must be noted here and that is that it is only oxygen acids (that is, acids containing oxygen) that show this relation between acids and their anhydrides or waterless forms.

As you look at this table you will note that many common compounds of carbon, such as wood, paper, starch, sugar, fats, etc., do not seem to have any place in the table. We shall take up some of these substances later, but here we will perform one or two simple experiments to show that they do contain carbon, and also to show that they illustrate other aspects of this same water chemistry just mentioned. Thus, for instance, pour into a common fruit jar about an inch of common molasses. Then pour over this about an inch of strong sulphuric acid and stir the two together with a glass rod. You will remember that the sulphuric acid is very thirsty, and you will see it attack the molasses by taking out the ingredients of water and leaving the molasses as a black, foamy pudding of carbon. Also, if you pour a drop or two of the strong sulphuric acid on some common wood, you will notice at once the black inky spots produced by the acid, as though it had charred the wood; which it has done, not so much by direct burning as by removing the ingredients of water, leaving the carbon. That is, the wood and the molasses, and similarly starch and sugar and paper, act as though they were made up of plain carbon with the ingredients of water; and for that reason such substances are called "carbohydrates," that is, carbon-water compounds.

This is only the introduction to the study of the compounds of carbon. If you begin to wonder where your friend limewater comes into all of this, just be patient and remember that sometimes "the longest way around is the shortest way home," and though calcium the lime metal may not form many compounds directly with all the other elements, yet it does form a few. In these compounds we shall find that hydrogen is the same sort of thing, chemically, for a gaseous metal that calcium is for a solid metal. We did not include in the list of chemicals and apparatus any calcium carbide, but if you happen to know any chauffeur among your friends, perhaps before the next lesson he will give you a little piece (say an ounce or two) of the calcium carbide which he uses in his automobile searchlight. We will use some of this in the next lesson, but meanwhile be sure to keep it in a dry jar, for it will not stand long in contact with moisture.

Now that we have a simple chemical map of the carbon compounds it will be easy to master the relation of the more important ones, which we will consider in the next lessons.

The Illinois Coalfield

This is the title of a paper presented to the Western Society of Engineers, of Chicago, April 7, by A. Bement. Among other things the author stated that the Illinois coalfield has produced [illegible] tons of coal having a total value of at least $1,[illegible], during which time, on a basis of 57 per cent. recovery, approximately 270,518,101 tons of coal has been wasted. Illinois is the second largest coal-producing State in the country, having a coal area of 37,486 square miles, or 66.4 per cent. of the entire area of the State. Also, according to best recent calculations, it would appear that it contains more unmined coal than any other in the country.

Mining in Illinois has been a very simple proposition. Wasteful extravagance and crude methods have prevailed, but the general awakening of the people of the whole country to the necessity for the conservation of natural resources, and the fact that Illinois mining is advancing into territory of thick seams which lie at considerable depth and produce a dangerous amount of gas, present many new problems of an engineering as well as of a commercial nature.

From the standpoint of future prosperity it is probably fair to say that one of the misfortunes of the Illinois coalfield was the great abundance of cheap coal available in the past, as this led to extravagance and wasteful mining methods.

While Illinois contains a very large amount of coal, it is not all available for mining under present conditions, that as a matter of fact the thinner and deeper coal will always be at a disadvantage as long as it must meet competition with more cheaply mined coal from this or other fields. This is a fact that is usually not understood in its full significance. Really the question is not how much coal we have, but how much is there that may be mined to advantage in competition with other fields.

Thus far Illinois has not suffered to the extent that other States have from large mine disasters, because there is only a comparatively small amount of gas generated, although operation in the deep mines in the No. 7 seam in Franklin county has been attended thus far with very disastrous results, notwithstanding that only three mines have reached a fair stage of development. The reason therefor is that a larger quantity of gas is given off in these mines, which together with the reckless disregard of safety that prevails, changes what would otherwise be a good safe field to a very dangerous one, giving promise that if present disregard for safety continues, it will surely distinguish itself by such appalling disasters as have occurred recently in Pennsylvania and West Virginia. The chief cause of such accidents is the excessive use of powder, which is on the increase and threatens to become still more serious unless proper corrective measures are enforced.

Calculation shows that about one-half of 1 per cent. of the amount of coal in Illinois has been exhausted, and such figures as this is liable to cause one to feel that the supply will last a very long while. In the past people have been led to believe that our coal would last almost "forever," which gave rise to such expressions as "inexhaustible supply," "coal to serve us for untold ages," etc. In this connection Dr. I. C. White has recently shown that when the Pittsburg coal seam is exhausted, [illegible] with present mining methods, the industries dependent thereupon will suffer seriously, and it seems reasonable to conclude that [illegible] these localities of the industrial [illegible] they now enjoy. In Illinois the [illegible] per cent. of coal produced from the [illegible] and [illegible] is wasted [illegible], and the Illinois [illegible] practically dependent [illegible] for fuel [illegible] which contained originally about [illegible] tons of which [illegible] has been exhausted [illegible] the supply available [illegible] of one per cent. of the original, but while this coal remaining is about [illegible] the [illegible] one-half of one per cent.

Turbines vs. Reciprocating Engines

From 10:45, April 12, and continuing to the same time on April 13, the 24-hour speed test of the U. S. scout cruisers "Chester," "Salem" and "Birmingham" was conducted. This is the last of a series of tests under the personal supervision of the Board of Inspection and Survey of the Navy Department in Washington and completes the data for a thorough comparison of the three types of prime mover installed in these vessels. As previously mentioned in these columns, the "Chester" is equipped with Parsons turbines, the "Salem" with Curtis turbines and the "Birmingham" with reciprocating engines. The "Chester" was a winner by about 14 miles over the 24-hour course and during the trial covered a distance of 601.92 nautical miles, an hourly average of 25.08 knots. The "Salem" made 589.12 miles, or an hourly average of 24.54 knots, and the "Birmingham" unfortunately was obliged to retire from the race at the end of the twelfth hour, due to an accident to one of the crosshead boxes. When the test had been in progress for about 11 hours, the babbitt metal in this box suddenly shifted to one side, tearing away the oiling gear. By using a syringe on the crosshead pin the engine was retained in service for another hour, when a brass liner suddenly flew out and necessitated that the engine be shut down. As it was impossible to continue the trial under full speed the "Birmingham" was withdrawn from the race. During the 12 hours she made an average of 24.02 knots per hour, and estimating a continuance of this performance, she would have covered a total distance of 576.48 nautical miles in the 24 hours.

Previously, tests of 24 hours' duration at speeds of 10, 15 and 20 knots per hour were made, and the consumption of the finest steaming West Virginia coal for the entire series of four tests for each vessel is given in Table 1. The results of the full-speed test are given a little more in detail in Table 2. The figures are unofficial, and when the data have been worked up by the commission and analyzed, which will probably be within the course of a few weeks, the results will be published in these columns.

TABLE 1. COMPARATIVE COAL CONSUMPTIONS OF THE FOUR TESTS.

Vessels.	Coal Consumption in Tons.			
	10-knot.	15-knot.	20-knot.	Full Speed.
"Birmingham" (reciprocating engines)....	30	70.2	154.5	364*
"Chester" (Parsons turbines)............	40	83.8	157	415
"Salem" (Curtis turbines)................	49	105.6	209	420

*Estimated from 12-hour run.

In all four of the tests, the data on coal consumption is much in favor of the "Birmingham." This was expected for the slow cruising speeds, but at the higher speeds and especially on the full-speed run, it was predicted that the turbines would easily win in this regard over the reciprocating engines. It must be remembered, however, that the speed of the "Birmingham" was approximately one-half a knot slower than that of the "Salem" and the difference in speed between the "Chester" and the "Birmingham" was a little over a knot. The amount of coal required to gain this last knot or even half a knot of speed is out of all proportion to the increase in speed, and perhaps when the tests are analyzed and the official figures are given out, the figures on coal consumption will be much closer together than they appear to be in Table 2.

TABLE 2. DATA ON FULL-SPEED 24-HOUR RUN.

Vessels.	Nautical Miles Covered.	Average Speed, Knots per Hour.	Tons of Coal.	Coal per Hour, Tons.	Coal per Hour, Lb.	Nautical Miles per Ton.
"Birmingham"............	576.48	24.02	364	15.166	30,333	1.58
"Chester"...............	601.92	25.08	415	17.291	34,583	1.402
"Salem".................	589.12	24.54	420	17.500	35,000	1.45

All data for Birmingham estimated on 12-hour run.

It will be of interest to note that the "chester" developed 26,000 indicated horsepower during the test, and the "Salem," which in her trial test had developed 20,000 horsepower, could attain only 17,000 horsepower upon this occasion. It was reported that something had gone wrong with her starboard turbine and as a consequence, this machine made 15 revolutions less than the port turbine. Previous to the test it was thought that water was being carried into the turbine, but during the trial special precautions were taken to drain the separator on the steam pipe, and it was concluded that there must be some other defect which could be determined only upon an internal inspection. This difference in revolutions undoubtedly slowed up the vessel, and it is asserted that the results of the test might have had a different outcome with the starboard turbine in first-class condition.

From the data in Tables 1 and 2 it is apparent that in the four tests the reciprocating engines had all the best of it as regards coal consumption, and this is all the more surprising when a comparison is made with the trial tests of the three vessels. Table 3 gives a brief summary of these tests in which a screened Pocahontas coal was used, and it will be noted that in the 12-knot 24-hour run, the coal consumption of the turbines was less than that of the engines. It is true that the engines had a little the best of it in the four-hour full-speed run, but why there should be such a difference in coal consumption of the three vessels in the recent tests and not in the trial tests is a question that may perhaps be answered by the commission.

TABLE 3. COMPARATIVE DATA ON TRIAL TESTS.

	"Birmingham."	"Chester."	"Salem."
Full-speed, 4-hour Run.			
Mean speed..........................	24.32	26.52*	25.94
Coal per hour, pounds...............	29,904	38,332	38,502
Miles per ton of coal...............	1.82	1.54	1.51
12-knot, 24-hour Run.			
Mean speed..........................	12.22	12.2	11.93
Coal per hour, pounds...............	4,629	4,091	4,051
Miles per ton of coal...............	5.96	6.68	6.60

*Estimated and probably too high.

As regards construction, the three cruisers are said to be identical in everything except their motive power. They are of a highly creditable design and are greatly superior to the "Attentive" class of scouts in the British navy. The "Salem" measures 420 feet between perpendiculars, has a breadth of 47 feet 1 inch at the water line and an official normal displacement on a draft of 16 feet 9 inches of 3750 tons, the full-load displacement being 4687 tons. She has two masts, four funnels and carries a light armament of two 5-inch and six 3-inch rapid-fire guns. The vessel is also provided with two 21-inch submerged torpedo tubes and has been given a water-line belt of 2 inches of nickel steel. The maximum coal-storage capacity is 1250 tons. The "Salem" and "Birmingham" are twin-screw vessels, while the "Chester" with her Parsons turbines required four screws.

Due to the slower speed of rotation of the Curtis turbine, when compared with the Parsons, it was possible to use larger propellers and develop the power in two turbines working on two shafts. With this arrangement the two turbines operate economically, both at high speed and at low cruising speed, and develop a large percentage of the total power when going astern. As no additional turbines were required for the lower speeds, the engine space required was considerably less than that of the equipment of the "Chester," which contains six Parsons turbines operating on four shafts. When running at high speed, steam is admitted to the two high-pressure turbines, from which it is exhausted to the two low-pressure turbines and thence to the condensers. For low cruising speeds of 10 to 12 knots an hour this arrangement could not be economically used and it was necessary to provide a pair of cruising turbines. When these machines are in service, steam is admitted to them direct from the boilers, then passes to the high-pressure turbines, is exhausted to the low-pressure turbines and finally discharged to the condensers. With this arrangement the "Chester" showed a better economy at cruising speeds than the "Birmingham" in their trial tests, but the arrangement, of course, is subject to the disadvantage that two extra units have to be employed, which ordinarily are idle.

In the Curtis turbine, steam at high-pressure is fed through a series of nozzles placed around the circumference of the casings and the power is reduced by simply closing down the proper number of nozzles, instead of reducing the pressure of the steam supply by throttling it at the valve. For this reason the cruising turbines required in the Parsons system to obtain reasonable economy at low speeds are not necessary with the Curtis turbine installation.

From the standpoint of propellers, the Curtis turbine has the advantage. For the best results, the propeller requires a moderate speed of revolution and a turbine, especially of the Parsons type, gives its best economy at high speeds of revolution. It is usually necessary to effect a compromise, making the propellers smaller and running them faster, and the turbines larger, the design calling for a speed less than is desirable for the best economy.

With the reciprocating engine, this difficulty is not experienced, for large-diameter propellers and slow speeds of revolution may be adopted without reducing the efficiency of the engine. Between the Parsons turbine and the low-speed reciprocating engine, the Curtis turbine occupies a middle position, and on this account it was possible to equip the Salem with propellers of unusually high efficiency. At the contract speed of 24 knots their efficiency equaled 62.8 per cent. and at 12 knots only dropped to 55 per cent. As a comparison it may be noted that the propellers of the "Lusitania" have an efficiency of 48 per cent.

A feature of the race which adds to the interest of the full-speed test was the performance of the two turbines recently in running for 24 hours on conditions above that required by the guarantee. Usually full-speed tests have a duration of only four hours, so that continuation of the performance attained in a four-hour test for a period six times as long is worthy of note and goes to show what may be expected of this type of cruiser in actual service.

Spring Meeting of the American Society of Mechanical Engineers

The American Society of Mechanical Engineers will hold its spring meeting in Washington, D. C., May 4-7. Professional sessions will be held, at which papers on the conveying of materials, gas-power engineering, steam turbines, the specific volume of saturated steam, oil-well pumping and various other subjects will be discussed.

The papers to be presented are as follows:

"A Unique Belt Conveyer," Ellis C. Soper.

"Automatic Feeders for Handling Material in Bulk," C. Kemble Baldwin.

"A New Transmission Dynamometer," Prof. William H. Kenerson.

"Polishing Metals for Examination with the Microscope," A. Kingsbury.

"Producer Gas vs. Steam for Marine Service," C. L. Straub.

"Operation of a Small Producer Gas Power Plant," C. W. Obert.

"A Method of Improving the Efficiency of Gas Engines," T. F. Butterfield.

"Offsetting Cylinders in Single-Acting Engines," Prof. T. M. Phetteplace.

"Small Steam Turbines," George A. Orrok.

"Oil Well Tests," Edmund M. Ivens.

"Safety Valve Discussion."

"Specific Volume of Saturated Steam," Prof. C. H. Peabody.

"Some Properties of Steam," Prof. R. C. H. Heck.

"A New Departure in Flexible Staybolts," H. V. Wille.

Correction

In the description of the [illegible] steam turbine, in the April 6 number, it was incorrectly stated that this turbine is handled in America by the [illegible] Company.

Eccentric Firemen's Local No. 56 Has Grown

On Saturday evening, April 10, the Eccentric Firemen's Association, Local Union No. 56, of Greater New York, held a "housewarming" to celebrate its removal to the new headquarters, 12 St. Mark's place. While the hall is quite large, it proved inadequate to accommodate the attendance, and consequently was overcrowded, although everybody had a good time.

Timothy Healy, general president of this organization, gave an address of welcome and his remarks proved most interesting. He said that 10 years ago, when they first occupied the premises at 195 Bowery, they had 300 members, and now it is next to impossible to find a hall conveniently located to accommodate its membership of 2500.

The entertainment given by the "bunch" was warmly received. Refreshments were served during intermission.

The State University of Illinois, among all the American universities, ranks fifth in attendance, but it has no school of mines nor department of mining engineering, although Illinois is the second largest coal-mining State in the country. Therefore the Western Society of Engineers, through its president, Andrews Allen, has appointed the following committee to draft a memorial for presentation to the State legislature petitioning for the establishment of a department of mines at the State University: A. Bement, chairman; F. A. Delano, Prof. J. Arnold, John M. Ewen, Isham Randolph, Capt. R. W. Hunt.

The executive committee of the Museum of Safety and Sanitation, of 29 West Thirty-ninth street, New York, has detailed Dr. William H. Tolman, the director, for field work, and he will start May 1 on a lecturing tour. Chambers of commerce, manufacturers' associations, engineering, insurance and architectural societies, schools and other clubs may avail themselves of this illustrated exposition of devices and methods for reducing damage risks and preserving efficiency, for the cost of the lecturer's expenses [illegible]

Another old-time engine, "still in the ring," is about to be replaced by an up-to-date machine. The engine in question is a [illegible] built by George H. [illegible] in [illegible] and installed in the plant of the [illegible] Company, [illegible], N. Y., where it has been in daily operation ever since. It is to be replaced by a [illegible]-horsepower Rollins engine built by the Rollins Engine Company, Nashua, N. H.

Air in Feed Water Heaters

The recent papers by D. B. Morison and others upon the effect of air in condensers suggest a similar investigation of its effects in heaters. These papers point out the fact that the deleterious effect of air is not confined to the diminution which its pressure produces upon the vacuum, but that the fact that more or less of the cooling surface is air-drowned seriously interferes with the access of steam to that surface and with the efficiency of the condenser.

In the open heater the steam mingles freely with the water and is condensed, while the air escapes by the vent, and no steam will get away until the water is heated to the full temperature of the exhaust if the construction is such that the mixture is sufficiently intimate. When the steam is condensed the air which is carried is left behind and simply crowds out an equivalent amount of other air, to be itself crowded out in its turn with air which will come in with other steam. As long as the heater is so well vented that air pockets cannot form through which water shall shower without coming in contact with the steam, the presence of the air will make no difference.

In the case of the closed heater the air left by the condensation of the steam would fill the shell and drown the heating surface, just as a condenser would fill up with air without an air pump, were it not that it were swept out by the steam; and unless there is enough of the surface still accessible to condense it all some of the steam will escape, although the water which it was designed to heat may be considerably below the temperature at which it would cease to condense steam. This, rather than the effect of deposits upon the heating surfaces, may be the reason for the low rate of heat transmission in some heaters, and for the fact that more steam is required in them to raise a given amount of water to a given temperature than when the steam and water are directly mingled. The steam has not only to do the heating, but enough of it must be left to do the air scavenging.

Boiler Inspection and License Laws Desirable

A recent boiler explosion, followed by fatal results, occurred at Farmingdale, Me. Newspaper reports say that the boiler was considered safe, although it had been in use for thirty or more years and had passed through one fire.

Maine, as is well known, has no license or inspection law and it is stated on what is believed to be good authority that all attempts to call public attention to the necessity of such legislation through the daily and weekly papers of the State were promptly and effectively checked.

Boiler inspection and engineers' license laws are regarded by a great many power-plant owners and users as a species of class legislation which must be discouraged, and the press has almost invariably echoed this sentiment.

To the average business man a boiler is a boiler, and he resents the idea that another should dictate whether he shall or shall not use a certain boiler and, if used, what pressure shall be allowed. He seems to forget that the community has an interest in the matter greater than his. His interest is primarily a financial one, while that of the community is one of public safety, which should outweigh any private interest.

It is not assumed that anyone would knowingly purchase, install and operate a dangerous piece of apparatus, but, unhampered by legislative restrictions, one would be very liable to take the chance that a boiler which was old and apparently defective would be safe for a few years longer.

This kind of guesswork should not be allowed and the public, which is usually inert, should be protected from the probability of loss of life or destruction of property by the intelligent administration of proper inspection laws. As an example of what may be expected in a community where inspection laws are intelligently administered may be cited New York City, where but three boiler explosions have occurred since the adoption of inspection ordinances forty-three years ago. Furthermore, it is a fact that where license laws prevail myriads of defects have been found in boilers and their effacement ordered.

Of course, inspection will not make a dangerous boiler a safe one, but it will bring to light all discoverable defects and render the operation of boilers and engines a comparatively safe occupation by eliminating as far as possible all doubtful elements.

Society makes its roads and bridges safe and will not allow the erection or occupancy of unstable or unsanitary buildings and it should not permit in the use of machinery anything that through carelessness or ignorance on the part of one person may cause another to be maimed or killed.

There is one class in society which should be actively engaged in the work of agitating for the enactment of boiler-inspection and engineers'-license laws where there are none, and for the improvement of those which are already in force. This class is composed of the great body of stationary engineers, whose interest in the matter should be impersonal.

If increased wages and better working conditions result from the enactment of laws and ordinances so much the better, but these results should come as a sort of by-product of the operation of rules of action which are founded in a desire to secure public safety and aim for the good of all.

Engines of High Efficiency

In the leading article of this number appear some remarkable figures on the steam consumption of the noncondensing Corliss engines installed in the West Point plant. One of these units is a 300-horsepower simple engine and the remainder of the engine installation consists of two 600-horsepower cross-compound engines. It will be noted that the steam consumption per indicated horsepower-hour of the simple engine is given as 20.98 pounds, and that one of the cross-compounds consumes but 18.33 pounds of steam for the same unit of power. It is not necessary to say that these figures are good. Such a performance on either engine is excellent, and is seldom equaled on units of much larger capacity.

Using the data of the test and bearing in mind that the steam was without superheat and assumed to be dry, it is an easy matter to compute the amount of heat chargeable to the engines, the equivalent heat of a horsepower-hour, and from these figures the potential efficiency, or in phraseology more common, the efficiency ratios of the engines. For the 300-horsepower simple engine the proportion of available heat converted into work proved to be 69.6 per cent., and 79.2 per cent. for the 600-horsepower cross-compound.

As a basis for comparison it may be stated that standard compound engines of 5000 horsepower using dry steam and running condensing on a vacuum of 25 to 27 inches rarely exceed an efficiency of 73 per cent. Their range of temperature is, of course, greater, and as a perfect vacuum is never attained it is hardly possible to convert into work as large a proportion of the available heat as in the case of the noncondensing engine, in which the steam will expand approximately to 212 degrees Fahrenheit. With noncondensing compound engines approximating the capacity of those under discussion, an efficiency ratio of 75 per cent. is high, and a ratio of 65 per cent. for a simple noncondensing engine of medium capacity would be considered good performance. For turbines the efficiency ratio is lower, and will vary from 50 per cent. for the smaller sizes up to 70 per cent. for turbines of the largest capacity, and only when using superheat of 100 to 150 degrees and employing a vacuum of 29 inches.

From the previous data a fair idea will be obtained of the unusual performance of the engines in the West Point plant, and of the two the steam consumption of the simple engine is perhaps the more remarkable. It should be borne in mind that the figures were obtained in a test performance with all conditions favorable. A duplication of the results in ordinary everyday practice would scarcely be expected. It is not our purpose, however, to detract from the exceedingly good showing made by the engines, for even as test figures the values obtained are of the best and the performance of the engines highly commendable.

Engineer Heroes

In the distribution of hero medals individuals in the humbler walks of life, whose title to the honor of being classed among real heroes is unquestioned, have been overlooked. Two possible boiler explosions have recently been prevented, one in Massachusetts and the other in Rhode Island, by the prompt and heroic action of the men under whose charge the boilers were being operated.

In general features the incidents were identical. Passing along the side of the boiler the men noticed steam issuing from the brickwork covering the top of the boiler. Seeing the source of this unusual steam flow, bricks were removed until the entire seam was uncovered, when it was seen that the steam came from a crack extending along a row of rivets in the boiler shell. Fires were drawn, pressures reduced and then, and not until then, when all possibility of danger had been removed, the owners and others were notified of what had taken place.

When each of these men saw the steam issuing from a part of the boiler where there was no legitimate opening, they knew that it was something more serious than a leaking rivet. They knew that a crack in the shell was to be expected and they knew, too, that if a crack existed the boiler was dangerous. They did not run; they did not lose their heads and raise an alarm. They calmly investigated and when the investigation was finished did the right thing, not with flourish of trumpets and a splurge, but so quietly and sensibly and in such regular order that no one knew what was going on until the danger was passed.

Perhaps neither of these boilers would have exploded immediately, but might have held on for some time, until some morning, just as the operatives were gathering for work, the explosion would come and another "golden-crack" boiler explosion, with its attendant loss of life and destruction of property, would be telegraphed across a continent.

There are many human beings alive and well today in Massachusetts and Rhode Island, who owe their lives to these two [illegible] engineers, whose names have never been heralded in the daily papers nor slated for hero-medal awards.

Boston Meetings of the Mechanical Engineers' Society

Nearly 200 engineers of Boston and vicinity assembled in the auditorium of the Edison Company, at 39 Boylston street, Boston, on Friday evening, April 16, to consider the advisability, or, as it turned out, to express their unanimous approval, of holding local meetings in that city of the American Society of Mechanical Engineers. The meeting was called to order by Irving E. Moultrop, of the Edison Company, who stated that about 10 per cent. of the entire membership of the American Society of Mechanical Engineers resided within an hour's ride of Boston and that the meeting was a result of numerous expressions on the part of members of the engineering profession that frequent local meetings of the society should be held in that city.

President Jesse M. Smith and Secretary Calvin W. Rice were present and explained the policy of the council of the society to encourage local meetings and announced the fact that the St. Louis members had just inaugurated the practice. Remarks in favor of local meetings were made by Mr. [illegible], of the Boston & Maine Railroad; Mr. [illegible], vice-president of the civil engineers; Paul Winsor, of the Boston Elevated; Professors Marks, [illegible], Swain, Lanza and Anthony; Mr. Jackson, of the electrical engineers; Frank W. Dean and others, and a committee was appointed to carry that purpose into effect.

"Some Nice Warm Spring Morning"

"You see," said the central station man, "if we can't get the building manager to close down his private plant and buy electricity from us in the winter time, we don't give it up." And then as [illegible] smile [illegible] into a hard smile he said: "We just call on him on some nice warm spring morning and suggest that he had better [illegible] for a few months to prove our [illegible] our claims regarding the economy of central-station service. [illegible] running down [illegible] necessary, [illegible] early closing hours, [illegible] by the time the cold weather [illegible] so that it won't cost very much for low-pressure steam during the following winter, and if we are smart enough he'll figure it the same [illegible]."

"Yes," said I, "when the dark days come on, when the people return from the country, and when the heating season starts the bill will be on, doesn't he?"

"Well, hardly," said the central-station man, "sometimes they have sense to see through it."

The Elliott Mechanical Stoker

The Elliott mechanical stoker, manufactured by the Ridgway Manufacturing Company, Ridgway, Penn., mechanically grinds and regulates the feed of coal to the furnace, distributes it over the grate and removes the ashes from under the grate. The coal is fed, from a storage bin over the boiler, to what is termed a crusher and regulator, the crushed coal passing to either side of the crusher *A*, Fig. 1, into the worm conveyers *B B*, which carry it into the rotary turbines *C C*, located at either side of the boiler front, as shown. These turbines distribute the coal to the grates through the delivery chutes *D D*, Figs. 1 and 2. The passage of the coal is assisted by a small jet of steam, a ⅜-inch pipe supplying sufficient steam to operate the two stokers. The steam jets are arranged as shown in Fig. 1. There are two wheels for regulating the amount of steam for each delivery tube, only one being used under ordinary operating conditions, however.

"Crusher and regulator" is a term properly applied to the device shown at *A*, as it not only crushes the coal but regulates the amount fed, through the turning of the handwheel *E*, which throws the gears into position to operate the crusher faster or slower, as desired. At the same time the worms revolve at increased or decreased speed in response to the speed of the crusher and regulator. The worm

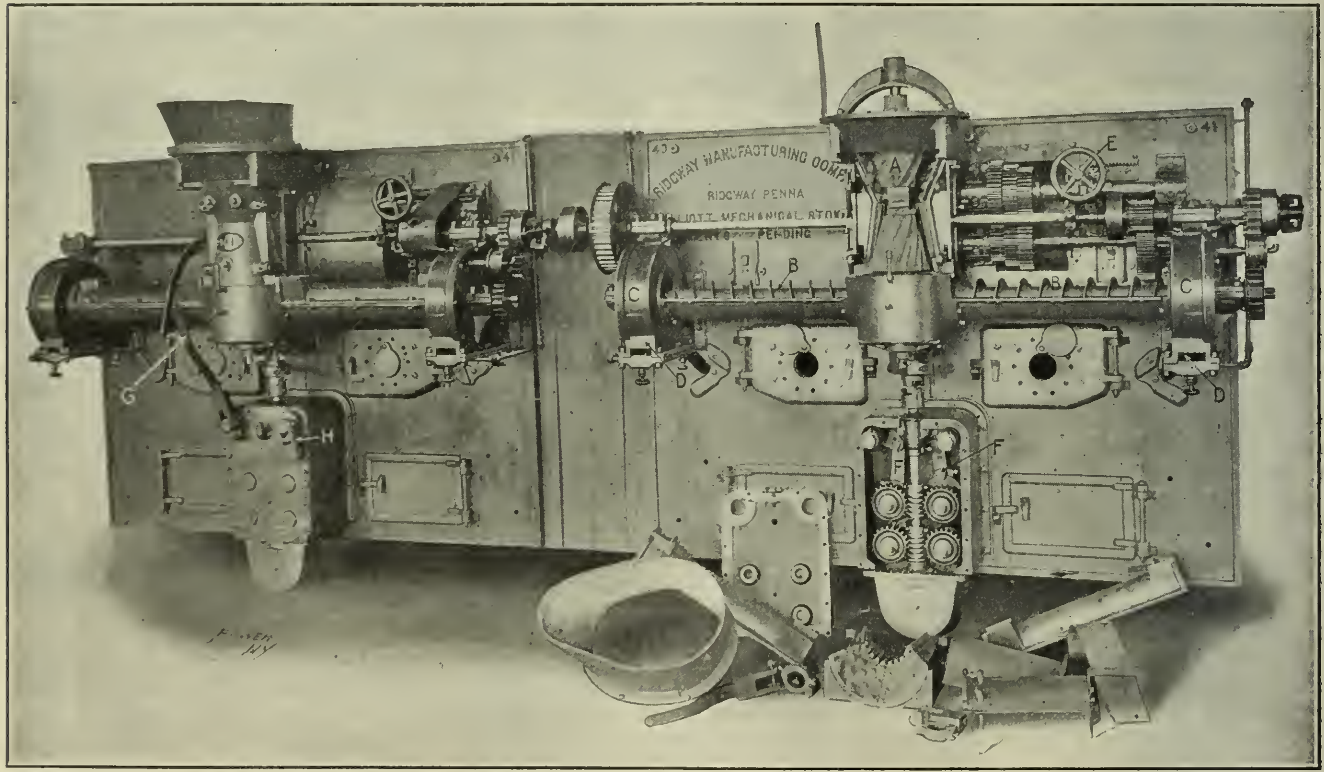

FIG. 1. ELLIOTT MECHANICAL STOKERS, WITH AND WITHOUT CASING

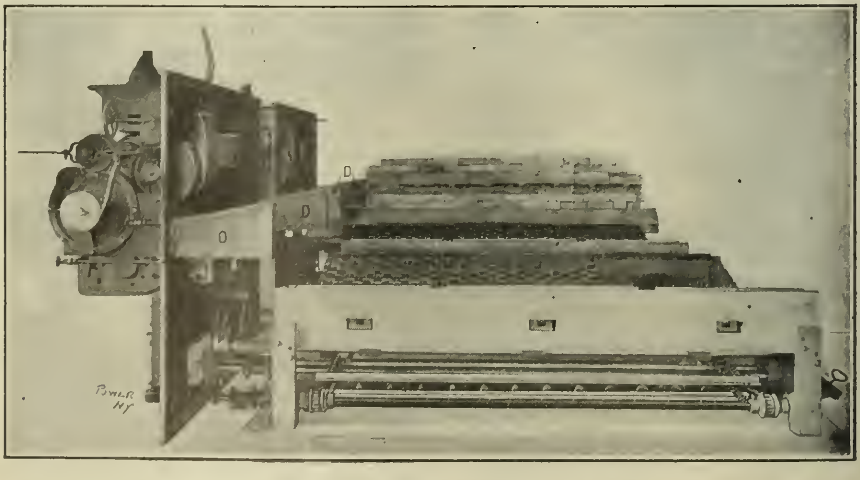

FIG. 2. SIDE VIEW, SHOWING DELIVERY CHUTES, ETC.

FIG. 3. ELLIOTT MECHANICAL STOKERS AT THE RIDGWAY DYNAMO AND ENGINE COMPANY'S PLANT

is operated by a noiseless chain belt as shown. Fig. 1 shows stokers with and without the casing in place. The driving shaft which extends across the front may be coupled to as many stokers as desired. The stokers are usually motor driven, but may be operated by a small steam engine. Fig. 3 shows an installation at the boiler plant of the Ridgway Dynamo and Engine Company, Ridgway, Penn.

The grates are inclined toward the center, Fig. 4, and are actuated slowly by the eccentrics *F F*, Fig. 1, designed to provide a constant, slow opening-and-closing movement, thereby keeping the fire in a clean, bright condition, at the same time spilling the ashes and preventing the fuel from coking and the dead ash from interfering with the air supply.

Provision has been made in case of extremely poor fuel, to dump the larger pieces of clinker and refuse as found, by means of levers, one of which, *G*, is shown at the left of Fig. 1. As shown, the lever is in proper position to dump the lower section of the grate, so as to rid it of accumulated clinker, etc. After the refuse has been dumped the lever is removed and the lever holder drops downward, causing that section of the grate to be interlocked with the rest in position to be operated by means of the eccentrics. At *H* is shown one of the lever holders in the locked position. In this manner every square inch of grate area can be made available to handle its proportion of fuel. The ashes not spilled by the grate are gradually worked to the center, by the constant movement of the grate, and fall into a worm conveyer, as shown in Fig. 4. Under the grate (Fig. 4) will be seen four shafts, two for each side of the furnace, each set being connected by means of chain belts, to which are secured angle irons which scrape the ashes from top of the level concrete flooring of the ashpit. As the frame of the worm is imbedded in the cement there is no possibility of its being thrown out of position. The worm conveyer is operated by means of a gear driven by the upright shaft shown in Fig. 3.

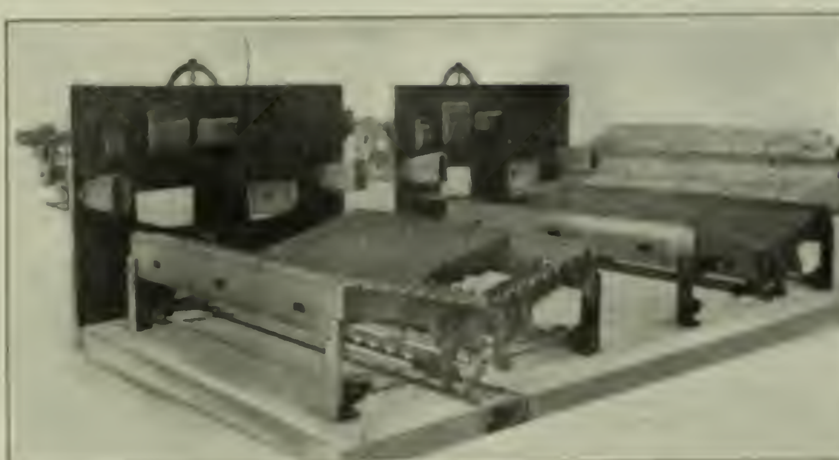

FIG. 4. SHOWING POSITION OF GRATES, WORM CONVEYOR, ETC.

The grates are set at an angle of 28 degrees, each section being removable by operating similarly to the links and lifting them from the frame. As the grate bars are provided with round projections at each end, there being no bolts, rivets, etc., the renewing of the grate is easily accomplished. Top and bottom views of a grate bar are shown in Fig. 5. That the design is eminently suitable for this type of furnace was evident from the appearance of an old grate, which the writer saw, which had been in use in a stoker of different design for two and a half years and showed no indications of warping or burning.

Obituary

We regret to record the death of Ira Watts, who died of Bright's disease, on April 15, at Spokane Falls, Wash. He was 49 years of age, and was born in Malden, Mass. Early in life he was connected with the Bell Telephone Company and, being an earnest student, became an expert electrical engineer when quite a young man. He served two years in the engineering department of the United States Navy. He was for many years chief engineer of the Knickerbocker building, corner of Broadway and Thirty-eighth street, New York, and superintended the many plants belonging to the Goelet estate. About three years ago he removed to Spokane Falls, where he was engaged as consulting engineer. Mr.

THE LATE IRA WATTS

Watts was for 12 years secretary-treasurer of the Life and Accident Department of the N. A. S. E. and a member of James Watt No. 7, of the same organization. He also instituted an association of this order at Spokane Falls. Mr. Watts was an ardent worker toward the betterment of engineers and he will be mourned by a great many friends.

The late John McKay, chief engineer and superintendent of the City Investing building, New York City, whose death we announced in the April 20 number, was 50 years of age. His death occurred on April 10, after a brief illness and following an operation for appendicitis. The funeral services were held at his late residence, 1429 Forty-eighth street, Brooklyn, on Tuesday evening, April 13. Mr. Mckay was a charter member of Phœnix Association No. 24, N. A. S. E., and a member of Sandalphon Lodge No. 836,

THE LATE JOHN MCKAY

F. and A. M. He was one of the most prominent engineers in New York and had a host of friends.

Marine Engineers' Annual Dinner

The fourteenth annual dinner of the Marine Engineers' Beneficial Association No. 33, of New York City, was held on Wednesday evening, April 14, at the Broadway Central hotel. The inclement weather did not damper the ardor of the members and friends and the large dining room was well filled, there being fully 250 seated at the banquet. Among them were many prominent in the engineering world. The subjects chosen by the speakers were of a nature to engage strict attention and to impart important knowledge to those present. During the evening William Du Boise introduced the following: John E. Berry, president of No. 33; Captain John H. Pruett, national president of the Master Mates and Pilots Association; Captain John M. Cherry, marine superintendent, Lehigh Valley Railroad; J. L. Du Broque, assistant superintendent of motive power, Pennsylvania Railroad; L. B. Dow, general manager of Harbor No. 1, Mates and Pilots Association.

An enjoyable entertainment was given by Herbert Self, Henry Elder, "Joe" McKenna, William Murray, Frank Corbett, Edward Campbell, Robert Webb, John L. Wilson and "Jack" Armour.

Help Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

WANTED—Thoroughly competent steam specialty salesman; one that can sell high-grade goods. Address "M. M. Co.," POWER.

AN ENGINEER in each town to sell the best rocking grate for steam boilers. Write Martin Grate Co., 281 Dearborn St., Chicago.

WANTED—By manufacturer, thoroughly experienced man to sell hangers, shafting and transmission machinery in New York City and vicinity. Must be capable, energetic. We want the best man in this line of business. "J. C. D.," Box 36, POWER.

WANTED—One or two experienced salesmen in line of engines, boilers, tanks, pumps, etc., thoroughly acquainted with market in and around New York City. Only experienced men wanted. Good positions open for right men. Box 37, POWER.

WANTED—First-class salesman, must have established trade among steam users in engineers' and factory supplies in Greater New York and vicinity. Fine position for right man Box 35, POWER.

WANTED—By manufacturer, thoroughly experienced man to sell hangers, shafting and transmission machinery in New York City and vicinity. Must be capable, energetic. We want the best man in this line of business. "J. C. D.," Box 36, POWER.

WANTED — AT ONCE, one practical engineer suitable for a large power plant, equipped entirely with gas engines which furnish current for electric railroad and lighting purposes. Plant located in a western town. First-class reference must be furnished from last employer. "K.," Box 38, POWER.

Situations Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

POSITION as fireman or assistant electrician by young man of 20 Student I C S. Two years' experience with small boilers and engines. Box 93, R. F. D. No. 1, Deshler, Ohio.

EXPERIENCED GAS ENGINE MAN wants position with manufacturer, contracting engineers or take charge of large gas engine plant. Has technical education and experience as salesman, erector and repairman "H K. W.," Box 178, Edgartown, Mass.

POSITION—Single man, eight years' experience, steam-electric plants as chief and assistant. Good references, speak Spanish, prefer Mexico, Hawaii or Spanish country Employed steam turbo-electric plant in Mexico. Address "R," Box 184, Seneca Falls, Kans.

POSITION with large company as traveling or supervising engineer of power plants and machinery. Hold such position at present with large corporation, having charge of power plants and machinery upkeep, boiler tests, engine indications, etc. Box 40, POWER.

WANTED—Position by an experienced engineer and electrician capable of handling a large proposition, now holding a responsible position with a large corporation; will give good reasons why change is desired to interested parties; would like a hard proposition. Box 39, POWER.

POSITION wanted by a mechanical graduate of a leading Western university. Experienced in drafting, two years' practical experience in machine shop, and two as assistant master mechanic with a company operating sixteen iron mines Prefer similar position, but will consider any good mechanical engineering work. Can furnish references from above company and present employer. Box 41, POWER.

Miscellaneous

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

PATENTS secured promptly in the United States and foreign countries Pamphlet of instructions sent free upon request. C L. Parker, Ex-examiner, U. S. Patent Office, McGill Bldg., Washington, D. C.

For Sale

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

150 HORSEPOWER tandem compound Corliss engine in good order; 16' wheel; 24 in. face F. W. Iredell, 11 Broadway, New York.

GET THE MEAN PRESSURE of diagrams by "Bill," the best planimeter; $1.50 to P. Eyermann, Consulting Engineer, Du Bois, Pa.

FOR SALE—20x48 Wheelock engine and two 72"x18' high pressure tubular boilers in good condition cheap. Address "Engineer," Box 2, Station A, Cincinnati, Ohio.

An Exhaust-Steam Turbine Installation*

With No Additional Steam Net Output of Noncondensing Engine Plant May Be Increased 75 Per Cent. by the Use of Exhaust-steam Turbines

BY W. S. TWINING AND W. C. KERR

While the title of this paper is a general one, it really deals with the exhaust-steam-turbine plant recently installed in connection with the Thirteenth and Mt. Vernon streets power house of the Philadelphia Rapid Transit Company. This station is part of the original Philadelphia Traction Company's power equipment and was built some years ago when the system was smaller and the problem economy, as far as the operation of the plant was concerned. The cost of the feeders and the money invested in them was a much larger item to be considered than any increase in economy which might be obtained from operating the station condensing. The station was therefore located in the central part of the city, where no water supply was available and consequently was operated noncondensing.

After a time, however, new stations were in course of construction which were equipped with steam turbines and in every way more modern appliances and promised very much better economy. At the same time the output of the Mt. Vernon station was increasing steadily and no facilities were at hand for increasing the amount of power at this point. These two facts combined caused the condensing

FIG. 1 LOW-PRESSURE 800-KILOWATT TURBINES INSTALLED BY PHILADELPHIA RAPID TRANSIT COMPANY

of distributing by means of high-tension feeders and rotary-converter substations had not been satisfactorily solved. The station was equipped entirely with direct-current machinery and the location was determined more with the idea of shortening the length of the feeder cables than with the idea of securing a maximum

the engine cylinders being proportioned for this condition. The load conditions at this station are very constant, and even though it operated noncondensing its records compared quite favorably with the possible results obtained in other stations which operated condensing, but under poorer load conditions. For a considerable period of time no thought was given to changing it to a condensing station, as this involved numerous difficulties.

problem to be considered again. As no water was available it was necessary to install cooling towers, or some other means of cooling the water. The layout of the station is not such as to adapt itself readily to the installation of condensers, as all available space had already been used. The engines and generators also were of insufficient size to stand any great increase of load for a long period of time. This increase of load could

*Paper read before the American Institute of Electrical Engineers, Philadelphia section, October 12, 1908.

readily be obtained by running the engines condensing, but it was felt that this would overtax them, and the generators could probably not stand this increase of load, which the engines would be capable of driving, as they would be operating at all times under an overload condition. Another difficulty which presented itself in connection with the changing of the plant to noncondensing was the exhaust piping. This piping had been in service a number of years and no provisions were ever made to make it vacuum tight, as it exhausted directly into an open exhaust stack without any back-pressure valve. To place condensers on the engines meant tearing out all the exhaust piping and rebuilding the system to operate under vacuum, and as this station is in service at all times, it would have been a more or less difficult and expensive undertaking.

About this time the exhaust-steam turbine proposition presented itself, and while it was considered theoretically possible, it had not been tried on a large scale. However, it was finally decided to try an experimental installation at this plant. The cost of the equipment was estimated and the probable operating expense as well. There appeared to be a decided advantage in favor of the turbine from the fact that the station output could be increased, even though the total station economy was not materially improved. Investigation finally resulted in the purchase of two 800-kilowatt direct-current machines, which were placed on the top of part of one of the foundations provided for a future engine unit.

Original Noncondensing Plant

The original design of the station provided for six Wetherill twin tandem compound Corliss engines, 26x40x48 inches, operating at 80 revolutions per minute with 160 pounds initial steam pressure. Each pair of engines is direct-connected to a 1500-kilowatt direct-current generator. Part of the exhaust steam was used in a system of open heaters for heating the feed water. All the auxiliaries were steam driven and exhausted direct into the main exhaust stack of the station. The layout of the station provided for six units, three on each side, with the high-pressure cylinders facing each other, making two lines of three engines; the generators facing the east and west walls of the station. Four of these units were installed at first. The original heater equipment was located in the boiler room, but this, after a short time, proved to be insufficient for the requirements, and provisions were made for installing a large heater and purifier plant. As the space required was considerable, the only available location was in the engine room, and in order to do this it was necessary to take half of the space allotted to the sixth unit. About this time, the fifth unit was installed, which then completed the station as far as the original building was concerned; it being impossible to place a sixth unit as originally intended.

The boiler-room equipment had also reached its maximum at this time, which consisted of nineteen 375-horsepower Babcock & Wilcox boilers, and one 400-horsepower Parker boiler, making a total of 7525 boiler horsepower. This would not permit of any farther increase, as all available space in the boiler room had been used.

The main exhaust system consists of two exhaust lines, one on each side of the engine-room basement, each designed to take care of three units. These lines join at the center of the station and enter the exhaust stack by means of a 36-inch main. The stack is placed at the end of the engine room and is 8 feet in diameter by 125 feet high. It is designed to take care of the exhaust of the entire plant. Three tees are placed in the main exhaust line just before it enters the stack and these connections turn upward and supply steam to the three feed-water heaters, which have been referred to. This will give a general idea of the arrangement of the exhaust connections of the plant previous to the installation of the exhaust-steam turbines.

Exhaust-steam Turbines Installed

In placing exhaust-steam turbines in this plant very few changes were made in the general scheme of exhaust piping. The east and west mains in the original design were left exactly as they were. The only change made necessary to install the turbines was to replace an ell by a tee in the 24-inch exhaust line on the east side of the station. Steam in passing from the 24-inch line is carried into an oil and water separator placed in the basement, from either side of which a 16-inch connection carries steam up through the throttle of the turbines. As

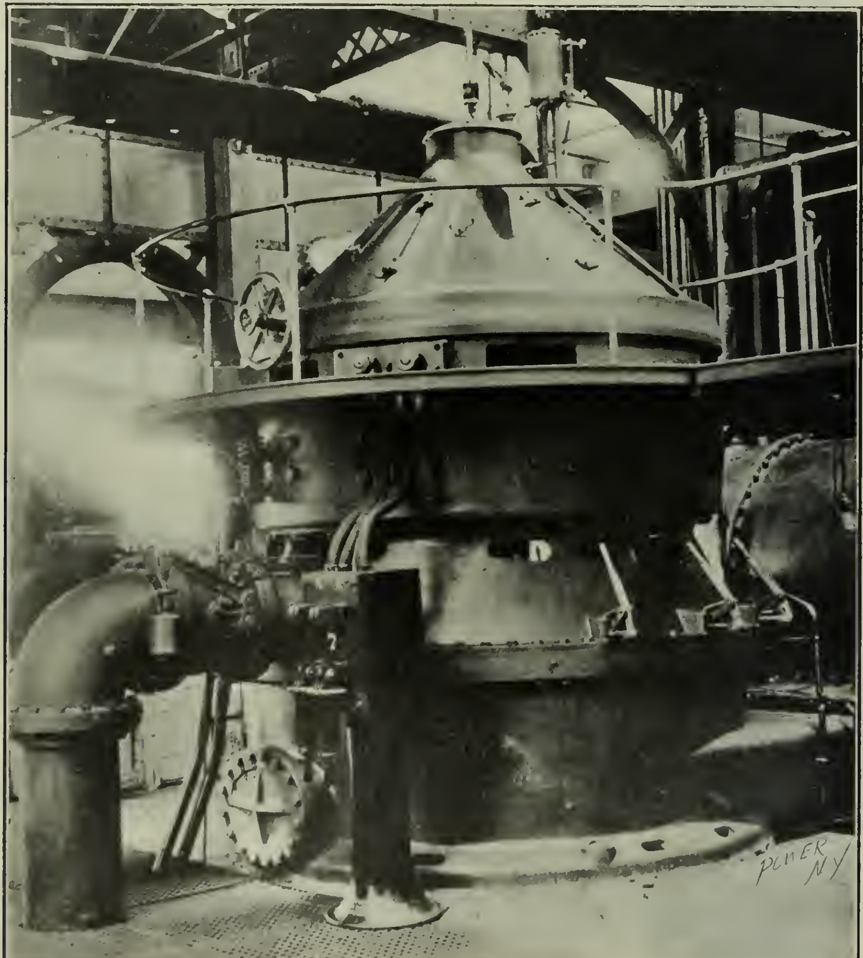

FIG. 2. ADMISSION SIDE OF TURBINE

the plant, under ordinary conditions, operates with an excess of exhaust steam, it was not necessary to place any atmospheric valve on the main exhaust line, there always being sufficient steam going up the exhaust stack to form a seal and so prevent drawing air back from the stack or heaters into the turbine. After the change was made there was no difference whatever in the general operating conditions of the engines, there being no exhaust back pressure and, in fact, if anything, there was a reduction in pressure on the main adjacent to the turbines; at times there has been noted to be ½ inch of mercury below the atmosphere when the station load was comparatively low and the turbine loads heavy. This arrangement gives extremely simple conditions, and the turbines can be put into service, or taken out, by simply opening or closing the throttles, as no other valves are required to be manipulated, the only change in the plant consisting in the amount of steam which is going up the exhaust stack.

Condensing Equipment

The condensing equipment of the plant consists of two 8000-square-foot counter-current Alberger surface condensers, each connected directly to the turbine by means of a short makeup piece. The condenser and turbine are placed on the engine-room [illegible] side valve gear and with Corliss valves on the vacuum cylinder.

The water circulation through the condensers is maintained by means of a [illegible]-inch Kingsford centrifugal pump placed on the outlet side of the condenser, so as to reduce as much as possible the pressure from the towers. This pump is operated by a variable-speed [illegible]-volt direct-current motor, so designed that the pump may be operated at anywhere between [illegible] and [illegible] revolutions. This permits of the adjustment of the circulating water required to give the vacuum under different atmospheric conditions. One pump and motor are provided for each condenser, but no provisions have been made for cross-connecting them, owing to the lack of space for water piping.

On the bottom of each condenser is [illegible] the throttle of the pump and regulates it so as to hold the water at a fixed point in the hotwell, preventing the possibility of the pump running dry and becoming filled with steam.

Water-cooling Plant

As before stated no water was available at this station for condensing purposes and it was necessary to install a plant of [illegible] cooling towers. These cooling towers were located against the north wall of the building and [illegible] on an elevated platform built entirely of reinforced concrete, the floor of this platform being [illegible] feet above the street level and [illegible] feet wide by [illegible] feet long. The structure for supporting the platform consists of eight reinforced-concrete columns, braced by means of a system of struts and tension [illegible]

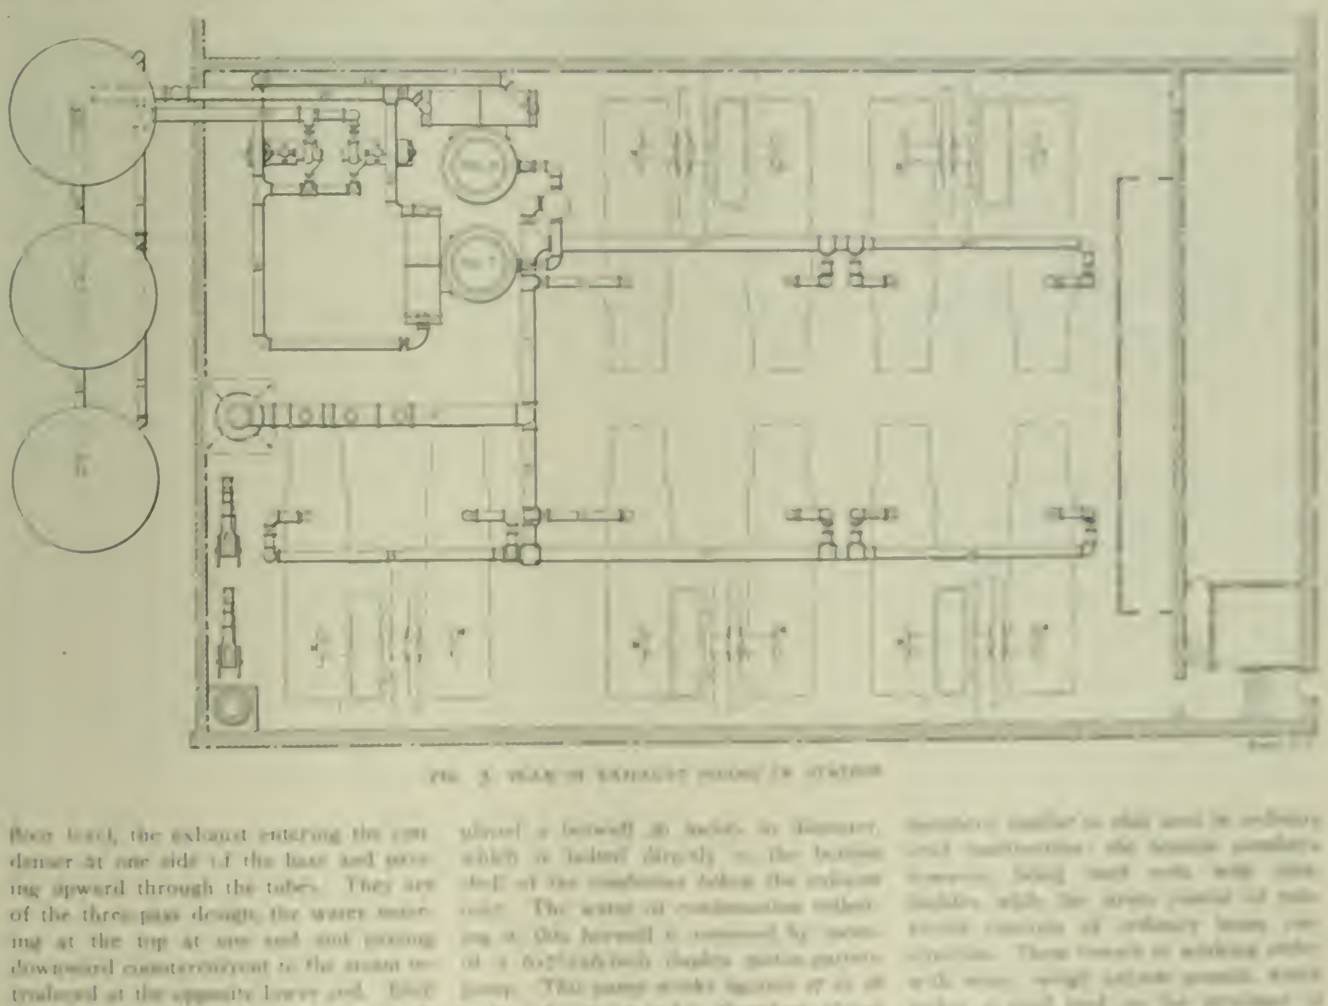

FIG. 3. PLAN OF EXHAUST PIPING IN STATION

[illegible] load, the exhaust entering the condenser at one side of the base and passing upward through the tubes. They are of the three-pass design, the water entering at the top at one end and passing downward countercurrent to the steam, [illegible] at the opposite lower end. Each condenser is equipped with a [illegible]-inch horizontal rotative single-stage dry-vacuum pump. They are, however, cross-connected in such a manner as to permit of interchanging the vacuum pumps on the condensers, or running the two condensers together on one of the pumps. The suction for the dry-vacuum pumps is taken from the top of the condenser and is passed through a moisture separator, preventing any possibility of water entering the vacuum cylinder. These pumps are of the center-crank pattern having slide [illegible] placed a hotwell [illegible] inches in diameter, which is bolted directly to the bottom shell of the condenser below the exhaust inlet. The water of condensation collecting in this hotwell is removed by means of a [illegible]-inch duplex piston-pattern pump. This pump works against [illegible] inches of vacuum and is therefore placed considerably below the bottom of the condenser, thus having advantage of the [illegible] head of water on the suction. As the water coming from the condenser is almost entirely free from oil it is discharged directly into the feed-water heater, the temperature of the water being within one to two degrees of the theoretical steam temperature in the condenser. The pump is controlled by means of a float placed in the hotwell. This float is connected by a system of levers [illegible] [illegible] similar to that used in ordinary [illegible] construction; the [illegible], however, being [illegible] with [illegible], while the [illegible] consists of ordinary [illegible] construction. These towers [illegible] with water, weigh [illegible] pounds, which makes a small load on the [illegible] of [illegible]. The [illegible] floor [illegible] tower [illegible] is covered by a series of [illegible] beams, [illegible] of [illegible] depth, the beams being so placed as to carry the [illegible] load and also to make room [illegible] the [illegible], which [illegible] [illegible] of the [illegible]. The towers are [illegible], being [illegible] feet in diameter by [illegible] feet high. Each tower is equipped with two [illegible]-inch fans, [illegible] and operated by [illegible] shaft. These fans run at approximately 310 revolutions and are driven by means of 40-horsepower variable-speed 550-volt direct-current motors, which are placed on the floor directly beneath the main platform and drive upward by means of belts. The motors are controlled by variable-speed automatic starters placed in the engine room and operated by the remote-control system.

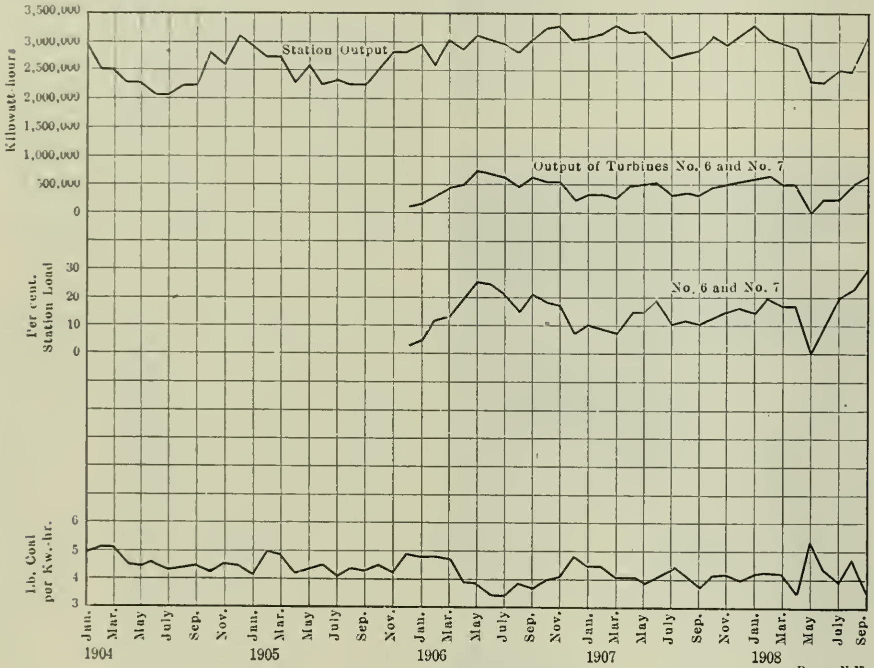

FIG. 4. TOTAL POWER OUTPUT AND PER CENT. OF LOAD CARRIED BY EXHAUST-STEAM TURBINES

The warm water from the condensers is discharged upward through a 20-inch main and is carried along beneath the base of the towers, one connection going up to the top of each tower and supplying the distributor. The distributor consists of an eight-arm revolving spider which is propelled by reaction jets. This distributes the water over the filling of the tower, which consists of a latticework of 1x6-inch boards filling about the middle third of the tower. The outlets from the bottoms of the tower are manifolded together by a 20-inch header and carried down to the engine room, one 14-inch branch going to each condenser.

The feed water for the entire steam plant is taken from the discharge side of the circulating pumps and delivered to the feed-water heaters through regulating valves, which makes it necessary to make up the shortage of water in the towers about once every half hour. This is accomplished continually by means of an automatically controlled variable-speed motor-driven pump. This pump is operated by means of a float placed in the towers. The discharge of this pump is put into the down line from the towers so as to take advantage of the cold water running through the condensers.

Exhaust-steam Turbine Detail

These turbines are of the Curtis vertical type and are of the same general design as the low-pressure end of the high-pressure Curtis turbine. They have, however, only three stages with 10 admission valves controlling the admission of steam to the upper stage. These valves are operated by hand by means of levers placed at the side of the turbine casing. The machine operates without any speed-regulating governor and the load is regulated entirely by the number of admission valves which are open. A safety-stop mechanism is provided automatically to cut the steam off from the turbine in case of the opening of the circuit-breaker. This governor trips a butterfly valve which is closed by a weight. Under ordinary conditions the valve is held wide open by means of a latch. Should the turbine run above normal speed for any reason, the speed-limit governor comes into play, trips the latch and shuts the butterfly valve, thus preventing racing. The generators are shunt wound, but provided with commutating poles between the main field coils; otherwise the generators are of the same design as ordinarily used on direct-current turbine work.

Operation of Turbine

The method of operation of the exhaust-steam turbine is somewhat different from the ordinary high-pressure machine. These particular machines operate at a normal speed of 1200 revolutions and 575 volts without any governor-control mechanism, and the generators are placed directly across the line in a manner similar to a storage battery, and carry a very nearly constant load depending upon the number of admission valves which are open. In these particular machines, each valve opened increases the load approximately 150 kilowatts, and when once set the turbine will hold very close to this load as long as the valve setting remains unchanged. There is a slight fluctuation in the load which is in direct proportion

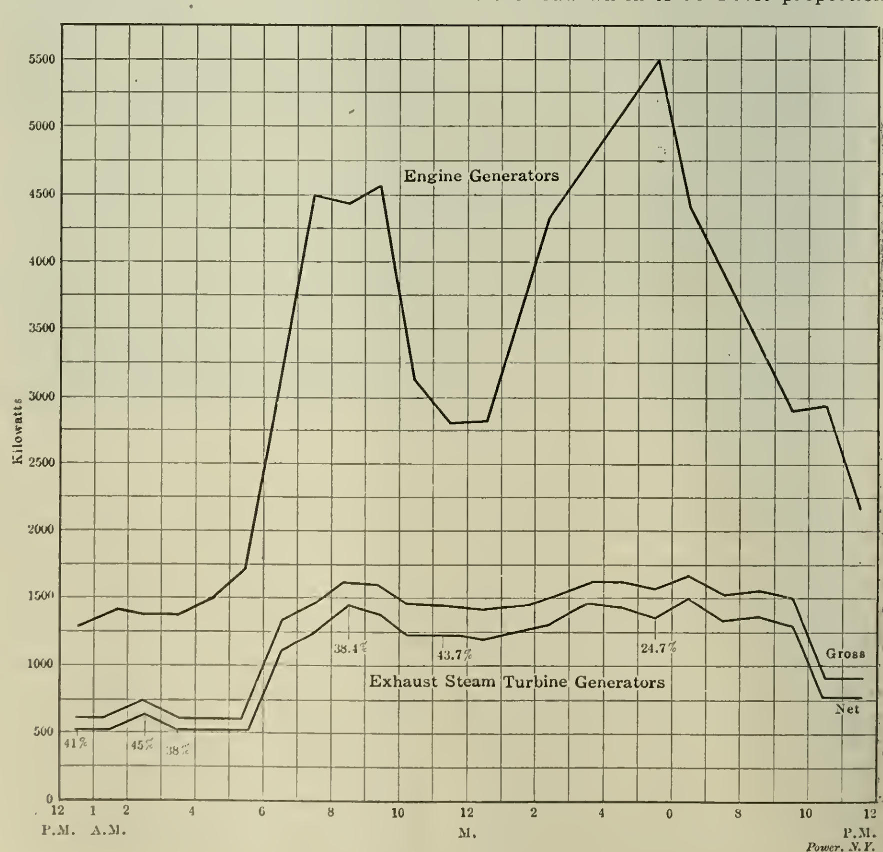

FIG. 5. RELATIVE LOADS OF EXHAUST-STEAM TURBO-DRIVEN AND ENGINE-DRIVEN GENERATORS, SEPTEMBER 4, 1908

to the entire station output, the turbines always holding a very nearly constant percentage of the station load.

One peculiarity in these turbines is the fact that the switchboard operator cannot change the load of the turbine, which is quite contrary to general station practice for high-pressure machines. This is due to the fact that the amount of steam is fixed by the admission valves, which are hand regulated. Should the switchboard operator move the field rheostat so as to increase the voltage of the turbine, this will result merely in a decrease in the turbine speed, and the result in voltage will be the same as before. This condition of affairs seems to be rather peculiar at first sight, but it appears perfectly reasonable after giving the matter some thought. The man at the turbine cannot increase nor decrease the speed, but can only increase or decrease the load by opening the admission valves, and the man at the switchboard can increase or decrease the speed of the turbine by the field rheostat, but he can by no means change the load. These statements are made in a general way, but, of course, there will be some slight variations due to characteristics of the machine, but a discussion on this particular topic will not be taken up at this time.

The method of placing the turbines in service is as follows: After the condensers are in operation and the turbine brought up to speed on the vacuum and the voltage adjusted, the admission valves are opened one by one and the machine picks up its load in proportion to the number of valves open and continues to operate with this load as long as the machine is in service. At times of light load, when the amount of exhaust steam available is lessened, the load is taken off the machine by gradually closing down the admission valves, and it is taken out of service by tripping the automatic stop which shuts the butterfly valve controlling the admission of steam to the machine.

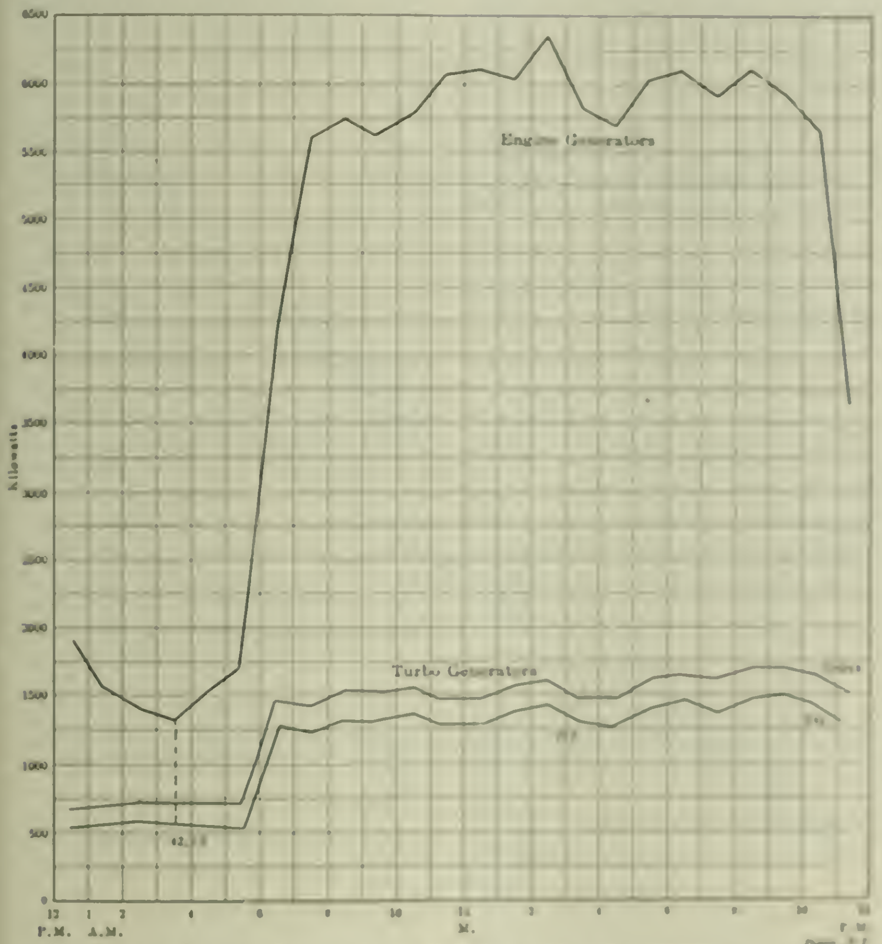

FIG. 6. RELATIVE LOADS OF TURBO-DRIVEN AND ENGINE-DRIVEN GENERATORS, OCTOBER 6, 1908

Operating Record

In the latter part of 1905 the plant was installed in a more or less experimental way, as at that time it was comparatively a new idea and some doubts were expressed as to its success. Everything seemed to be favorable from a theoretical standpoint, so it was decided to take up the matter in a small way at the start. Two machines of 800 kilowatts capacity were placed on one-half of the engine foundation originally designed for the 2600 unit. The first turbine went into service on December 16, 1905, and the second one at a somewhat later date. Fig. 3 shows the record of these machines from that time up to September, 1908. For a considerable period of time some trouble was experienced with the generators of the machines, principally with the commutators, but this is a very common trouble with high-speed direct-current generators. This, together with the fact that the possibilities of these machines had not been fully demonstrated, is responsible for the comparatively poor record which they made during 1906-1907; but even so, there was a considerable increase in the output and economy of the plant during that time. The average output of the turbines during the years mentioned amounted to 14.8 per cent. as much as the engine load. By referring to the curve in the lower part of Fig. 4, the line showing the pounds of coal per kilowatt-hour, a marked decrease can be seen during the period in which the turbines were putting out their maximum power. The best records of the station were always made when the turbines were in service the greater part of the time.

To show what can be done in regular service, a number of charts have been prepared, showing the regular station operating conditions at the present time. Fig. 5 shows the output curve for the Mt. Vernon street station on September 2, 1908, and is a typical output curve for this station during the summer months. Starting at midnight on September 2, the turbine carried a maximum net load of [illegible] kilowatts with 1725 kilowatts on the engine, one engine being in service at this time. Under these conditions, the turbine was pulling 47 per cent. as much load as the engine with no additional increase in steam consumption. As approximately 100 kilowatts are required to drive the auxiliaries of the station, it shows that the turbine is capable of increasing the gross output of the engine approximately 50 per cent. This would be the ideal condition for the station, but by following the output curves, it will be seen that the percentage drops, owing to the fact that there are insufficient turbines to take care of all the available exhaust steam. Through the morning hours, when the station load is comparatively heavy, the two turbines were in service and at that time delivered a net output of 36.4 per cent. as much as the engines, three engines being in service at that time. Following the curve until the noon hour, when two engines and two turbines were in service, it will be seen that the turbines were delivering a net output equivalent to [illegible] per cent. of the engine output, which again approaches very close to the ideal condition. It will then be noted by referring to the peak between 5 and 8 o'clock, that the turbine capacity is again insufficient, two turbines still being in service, and at that time the net output is equivalent to [illegible] per cent. of the engine output, [illegible] engines being in service at that time. By following a similar ber of turbines equivalent to the number of engines, between 40 and 50 per cent. as much load could be carried on the turbines as on the engines; all of this increased power being gained without any increase of coal consumption.

The labor item at this station is increased somewhat by the use of these turbines, but up to the present time this is less than 5 per cent. This is the only increase in the station operating cost. As far as the cost of the turbine installation is concerned, it may be sufficient to estimate that the cost per kilowatt will be about the same as the original boiler, engine and generator equipment; so this need not be considered.

Fig. 6 shows a different loading condition for the same station. It was taken on October 6, and shows the load conditions as the result of the heavy traffic on the streets on that date. In the early morning hours one turbine was in service and gave a net output of 42.3 per cent. of the engine output; one engine and one turbine being in service. From 6 a.m., and all through the balance of the day, two machines were in service, carrying approximately full load. The engine output, however, increased considerably, being in the neighborhood of 6000 kilowatts for the entire day. But even so, the two turbines gave a net output of 24 per cent. of that given by the engines. It can readily be seen by referring to the curves that four turbines could have been operated all through this period.

If it would be possible to operate this station with two engines and two turbines at all times, the coal consumption could undoubtedly be decreased to approximately 70 per cent. of its original figure when noncondensing.

Fig. 4, which showed the records of the turbines during 1906-1907, is somewhat misleading. While the turbines were operating under difficulties they still showed a gain of 14.6 per cent. The records of last year should surpass this in every way. In order to show the reliability of the machines under present operating conditions, Fig. 7 has been prepared. These curves show the record of the machines taken during September of 1908. The practice at this station now is to keep the turbines in the greatest period of time possible; one turbine being in service the entire 24 hours and two turbines being in whenever the load is heavy enough to permit it. This means that two turbines are in service at all times, excepting the hours between midnight and 6 a.m. They are taken out alternately for examination and cleaning the armatures, one machine being taken out of service each night. Fig. 7 shows the record which these two machines have made. The curve for No. 6 machine shows it has been in service 74.9 per cent. of the entire time during the month and No. 7 machine 80.4 per cent. of the time. The maximum line shows the conditions for the 24 hours per day operation. The two lower curves, one for No. 6 and one for No. 7 show the load factor during the period in which they were in service. No. 6 averaged 91 per cent. full load for the entire month and No. 7, 90 per cent. full load for the entire month. By combining these load factors and the operating factors, it will be seen that No. 7 machine developed 72.36 per cent. of its maximum output for the entire month and No. 6 developed 68.16 per cent. of its maximum output. This gives an average of 70.26 per cent. for the two machines for the entire month of September.

This operating record is a good one and is even better than expected, but, under the present conditions, there is no reason why the same record or a better one cannot be maintained for an indefinite period of time. The records of the preceding months of this year are about in accordance with these results, but this one has been selected as giving conditions at the present date.

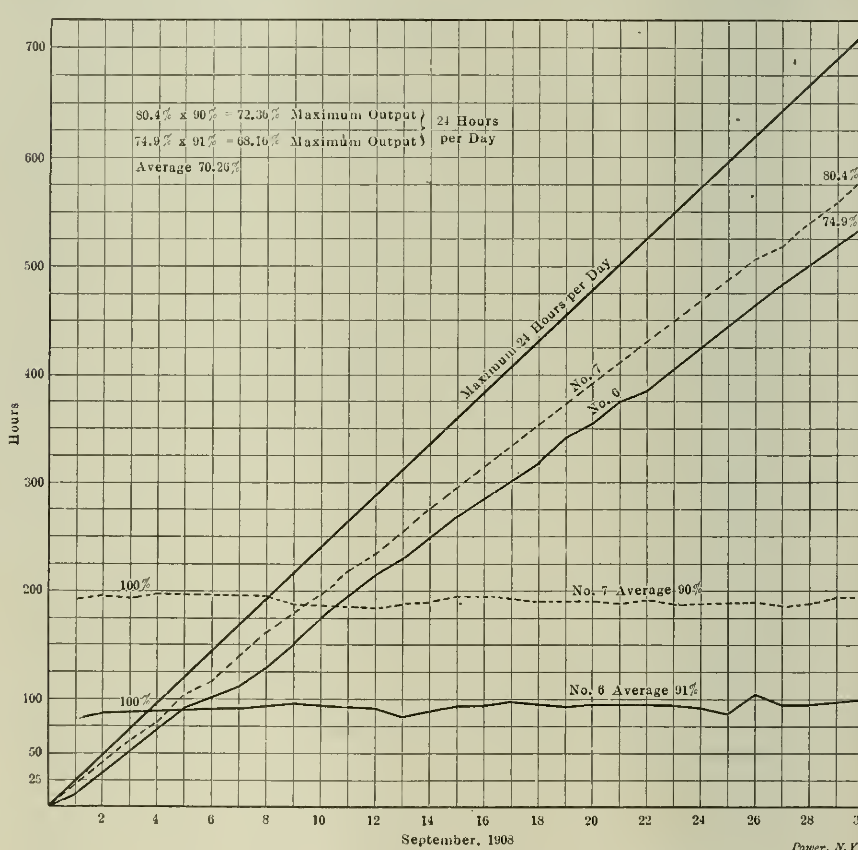

FIG. 7. OPERATING RECORD OF EXHAUST-STEAM TURBINES

Number of Exhaust-steam Turbines Required

In order to get some exact figures as to the performance of these machines with the idea of determining just how many can be used at any given plant, it was decided to make a series of tests with this in view. These tests were carried out last July and the results are gratifying. Complete tests of the entire turbine and condensing plant were made and the results are shown in Tables 1, 2 and 3.

Each of the turbines being equipped with surface condensers, it was very easy to determine the steam consumption. The test was conducted in the ordinary manner, by weighing the water discharged by the hotwell pumps. As the portable tank scales were of insufficient size to take care of the condensation from both turbines, it was decided to make the test on one turbine only, and No. 7 machine was selected for the purpose. Before commencing the test the condenser was overhauled and the glands tightened. The circulation was then started through the condenser, running the pumps at normal speed so as to maintain the same pressure conditions as when operating in regular service. The steam space of the condenser was then exhausted by means of the dry vacuum pumps until 27 inches of vacuum was obtained. The outlet from the hotwell was carefully closed off and a record kept of the rise of water in the gage glass on the side of the hotwell. The rise in inches of water per hour was noted in the hotwell and it was afterward calibrated for the amount which it contained. The scheme of testing out the condenser was carried out before beginning each test and immediately after closing down, the mean leakage being taken as the amount of water which came through from the water space. In most cases this leakage was zero; however, in one or two cases there was a slight leak in the condenser, which at no time amounted to more than 2 per cent. of the water of condensation, but allowance was made for this in figuring up the results.

Several tests were made under somewhat different conditions, the general scheme being to run for a period of eight hours, taking check readings on the wattmeter and amount of water condensed every hour during the run. These results were surprisingly uniform, and as there was so little variation in the steam consumption, some of the tests were stopped at the end of the fifth hour. The results of the tests made on different days were extremely close, and if any variation occurred it was always in the direction

TABLE 1. DATA ON TURBINE.

Average load on turbine (corrected), kilowatts	805.85
Total water from turbine per hour, pounds	31,918
Moisture in steam—0.3 per cent., pounds	92
Water used by step-bearing per hour, pounds	1402
Net steam used by turbine (dry) per hour, pounds	30,424
Steam per kilowatt-hour (dry), pounds	37.75
Steam pressure, pounds abs.	14.53
Barometer, inches	29.16
Vacuum, inches	27.50
Absolute pressure, inches	2.66
Temperature of exhaust steam, degrees F. (2.65 inches abs.)	110.8
Swing of load, amperes	1350-1550

which would naturally be expected from the difference in vacuum or load conditions on the machines.

Test No. 80, the results of which are given in Tables 1, 2 and 3, is a fair sample of the performance of these machines and the results were quite interesting. This test was conducted for a period of eight hours and the turbine carried an average load of 805.85 kilowatts, No. 6 turbine being shut down at this time. These conditions gave the turbine a uniform rating as far as the percentage of the load carried was concerned, as two turbines could have been operated in connection with the station load throughout the entire period.

Table 1 shows part of the results obtained during this test. It can be seen by inspection that the dry steam per kilowatt was 37.75 pounds, the absolute steam pressure being 14.53 pounds, which is slightly below atmospheric pressure. The pressure of the steam was taken at the throttle of the turbine by means of a U-tube filled with mercury, and this at all times was a fraction of an inch below the atmosphere. The absolute pressure in the turbine exhaust pipe was 2.66 inches, which gives a difference in pressure between the inlet and exhaust of 26.6 inches. It will be noted that the load was varying between 1350 and 1550 amperes. The swing was in direct proportion to the total station swing during the period of the test.

Table 2 shows that the total power absorbed by the auxiliaries throughout the test was 172.81 horsepower. This, however, is somewhat large, as atmospheric conditions were such as to require two of the cooling towers to be in service to give the required vacuum, and as each of these was driven by a 40-horsepower motor, it was found that there was about 18 horsepower extra charged against this turbine. Under actual conditions of the test 22.0 per cent. of the output of the turbine was required to drive the auxiliaries, but making corrections for one-half the power of the motor on the second tower brings this figure to 14.6 per cent., which would be the conditions had two turbines and three towers been in service at the time. Referring to Table 2 it will be seen that even with the one turbine in at the time nearly 20 per cent. of the load was carried by this machine as compared to the engines, which amounted to 18.88 per cent. of the entire station load.

Table 3 shows the condenser results obtained during the test. This shows a good performance, as the temperature of the water taken from the hotwell was within 2 degrees of the temperature of the exhaust, thus taking advantage of all the available heat to return to the feed-water heaters. The cooling towers showed a reduction of approximately 11 degrees in the temperature of the water and these conditions remained the same throughout the entire test. Since that time experiments have been conducted to determine the amount of evaporation and loss of water from the towers and to determine the best possible conditions for the speeds of the fans and circulating pumps to reduce the power absorbed by the auxiliaries to a minimum. Progress in this line of work has not advanced sufficiently to make any definite statement in this paper.

Again referring to the tables, it will be seen that the steam consumption of the turbine is 37.75 pounds per kilowatt-hour, which under the conditions of vacuum and steam pressure at the throttle, places this turbine within the guarantee made by the General Electric Company, which is as follows:

TABLE 2. AUXILIARIES.

Power absorbed by motor-driven auxiliaries (estimated horsepower)	128.40
Power absorbed by dry-vacuum pump (horsepower)	8.01
Power absorbed by hotwell pump (horsepower)	5.18
Power absorbed by step-bearing pump (horsepower)	8.12
Total power absorbed by auxiliaries (horsepower)	172.81
Percentage of auxiliaries to total output (2 towers)	22.0
Percentage of auxiliaries to total output (corrected)	14.6
Average load on engines (4 hours), kilowatts	403.7
Percentage of turbine to engine load, per cent.	19.57
Percentage [illegible] load to station load, per cent.	18.88

With atmospheric pressure on throttle, full load, 2 inches absolute pressure, 38 pounds per kilowatt; full load, 4 inches absolute pressure, 45 pounds per kilowatt.

Assuming that the Corliss engines in this station required 15 pounds of steam per indicated horsepower and allowing 1.5 indicated horsepower per kilowatt [illegible], it can be seen that if the entire amount of exhaust steam from these engines was used, 1 kilowatt could be developed on the turbine for each kilowatt output of the engine generators. From this it would seem that the gross station capacity could be nearly doubled by the use of the exhaust steam turbines. [illegible]

[illegible] per cent. of the exhaust steam is required for the feed heaters and [illegible] per cent. of the turbine output is required to operate its auxiliaries. This would cut the net output of the turbines to approximately [illegible] per cent. of the engine capacity. These figures, however, will be modified to a certain extent by the amount of exhaust steam which is available from pumps and other steam-driven auxiliaries. It might be safe to make the general statement that with the above assumptions the net output of

TABLE 3. CONDENSER RESULTS.

Temperature of air, degrees F.	[illegible]
Temperature of injection water, degrees F.	[illegible]
Temperature of discharge water, degrees F.	[illegible]
Temperature of hotwell water, degrees F.	[illegible]
Total head on circulating pump, ft.	[illegible]
[illegible]	[illegible]
Pressure of water on step-bearing, pounds	[illegible]
Speed of circulating pump, r.p.m.	[illegible]
Speed of dry-vacuum pump, r.p.m.	[illegible]
Speed of step-bearing pump, strokes per minute	[illegible]
Speed of turbine, r.p.m.	[illegible]

the station could be increased from [illegible] to [illegible] per cent. by use of exhaust-steam turbines, provided the back-pressure valve was tied and provision made for operating the station-exhaust main at times under a partial vacuum.

The results obtained on the tests of this turbine are exactly in accordance with what was expected from the regular station operating records, and only confirm the belief that the exhaust-steam turbine proposition is worth considering as a means of increasing the economy and output of a noncondensing station.

Rubber Foundations for Steam Turbines

A [illegible]-kilowatt steam turbine recently installed by Willans & Robinson, Limited, of Rugby, for the [illegible] of St. [illegible], has been mounted on special rubber foundations on the Pracht system. The turbine set is bolted to a special slab of concrete, a foot thick, reinforced with a steel grid. This large block rests on a series of circular rubber blocks standing on the ordinary concrete foundations. The upper block is not connected with the engine room floor in any way. A trench is provided round the top slab to permit of the [illegible] of the rubber blocks. Each rubber block is a cylinder about [illegible] inches in diameter and [illegible] inches in height when compressed by the weight of the turbine set. Each rubber block is removable independently of the rest, it being possible to withdraw them for [illegible] by tightening up the jacks, by which they are held by means of screws. These rubber blocks have, however, a life of considerable length, and needed to [illegible]. The turbine in question is said to be the largest [illegible] to rest on the [illegible] system.—Engineering.

Jonathan Hulls and His Steamboat

Sketch of the Inventor and Description of One of the Earliest Patented Systems of Vessel Propulsion by Means of the Steam Engine

BY EDWARD P. BUFFET

If the great-great-great-grandfather of any POWER reader chanced to spend his boyhood at the village of Campden, in Gloucestershire, England, about 170 years ago, he must often have seen plodding along the roads a poorly clad but intelligent-faced clock tinker carrying his box of tools as he went from house to house to seek those little jobs which totaled the means for only a scanty subsistence. It might have been noticed that this man had a more earnest and far-away look in his eyes than is usual for the country mechanic, that he seemed ever to be inwardly wrestling with deep problems, and that he wore the expression of a man who has failed in some great ambition of life, yet who has not broken off, and never could break off, the habit of performing ambitious labors in his head. Shy and diffident in his manner, he would gladly have shunned the sight of passers-by, and well he might, for youths of wanton disposition were relentlessly pursuing him with the refrain:

"Jonathan Hulls, with his paper sculls, invented a machine to go against the stream; but he, being an ass, could not bring it to pass, and so he was ashamed to be seen."

We have recognized in this portrait of Jonathan Hulls the typical unsuccessful inventor. If you are bound to be an unsuccessful inventor and value your peace of mind, by all means be one in some large city, and not in the country among your friends and neighbors.

Jonathan Hulls was born, it is said, at Hanging-Aston, near Campden, in 1699, but his father, Thomas Hull, or Hulls, removed to the latter place and there the boy received his academic training in an ancient grammar school. A man's real education, however, is that which he gives himself by outside study, or, best of all, by interested reading, for it is chiefly what interests us that we remember and that does us good. It is probable that if Jonathan's education had been limited to his perfunctory lessons at school he would have remained through life half illiterate like the other boys of his class; but he had a natural bent for mathematics and in some way made himself fairly proficient in the principles of mechanics. He was also able to write in a decent English style.

The trade of "clockmaker" which he took up was in reality that of an itinerant clock mender. He was accustomed to make a circuit through a certain district curing the ailments of any farmhouse or church timepieces that chanced to be under the weather. Hulls married early and removed to the hamlet of Broad Campden about 1729. His studious habits and mental ability, far superior to that of his neighbors, readily won him a local reputation for intelligence. That particular work of genius which has earned him belated fame in the world is said to have seethed in his imagination from his youthful years. To realize so ambitious a project as a steamboat, either in the water or in print, was an audacious attempt for a country clocksmith of those days, with a family to support. He therefore did what aspiring authors of his time were accustomed to do and sought the aid of a patron. This was a Mr. Freeman, of Batsford park, near Aston, who was so much impressed with Hulls' invention that he put up the money for a trip to London to embody it in a patent and a pamphlet.

That monograph appeared in 1737. Its publication was the high-water mark of Hulls' success, for there is no record that anyone ever took enough notice of tne work to build a steamboat on the lines suggested. Mr. Freeman was reasonably loath to support any additional venture for exploiting the invention, and Jonathan was abandoned to his fate of failure and ridicule.

For a long time no more is heard of him, but a real inventor, especially an unsuccessful inventor, is insuppressible though he live a thousand years, and the bee of ambition continued to buzz in Hulls' bonnet. Eventually he cropped out in print with new products of his brain.

His final known attempt was in 1754, when, in partnership with two fellow-townsmen, R. Darby and William Bradford, schoolmaster, he had patented a "Statistical and Hydrostatical Balance" and a "Sliding Rule for Artificers." The former was "an instrument for detecting frauds by counterfeit gold, which gives the weight and shews the alloy of that metal in coin and all utensils made thereof, and if adulterated, the nature and extent of the alloy." This instrument displayed much ingenuity and at least one actual specimen of it has survived to our day. The sliding rule, which probably was not a logarithmic slide rule, is described in a pamphlet entitled: "The new Art of Measuring made easy by the help of a new Sliding Rule. Coventry: Printed by T. Brooks in Broadgate, 1754."

Little or no financial return was destined to attend any of Jonathan Hulls' efforts and, finally, unable to meet the gaze of his neighbors, he hid himself in the London crowds. At a date which is unknown, he died the death of an inventor.

Down to comparatively recent times his descendants have remained in his own village, mechanics, like himself, and with his modesty if not with his genius. The widow of their last survivor in the district died in 1865, not long after which the family cottage at Broad Campden in which Jonathan Hulls had dwelt, was torn down.

It would be too much to claim for Jonathan Hulls that he was the first man who ever designed a steamboat. The idea seems to have been a favorite one for inventors in the first part of the eighteenth century. Neither can he receive the credit which attaches to one who has made the invention commercially practical. But assuredly he deserves always to be remembered as one of the most important forerunners of steam navigation. There is no telling what would have resulted from his efforts could he have secured the pecuniary coöperation of a Boulton or a Livingston.

Of the book published in 1737 by Jonathan Hulls, a few copies are still extant and from one of them, or rather from a fac-simile, extracts are here reproduced.

It will be noticed that Hulls did not invent a marine engine, but merely the application of power from a Newcomen engine to propel a towboat. (See illustration.) Most of this 48-page pamphlet is taken up with demonstrating mechanical and hydrostatic principles involved in his mechanism. Like Euclid, he seems to take nothing for granted, but to develop, step by step, even the simpler and more obvious propositions in his theory. This part of the work shows that he had put himself through a pretty good mathematical training.

But let Mr. Hulls tell his own story:

Extract from Jonathan Hulls' Pamphlet

In some convenient part of the Tow-Boat, there is placed a Vessel about two 3ds full of Water, with the Top close shut, this Vessel being kept Boiling, rarifies the Water into a Steam, this Steam being

ORIGINAL APPLICATION OF JONATHAN HULLS' PATENTED METHOD (1737) OF STEAMSHIP PROPULSION

convey'd thro' a large Pipe into a Cylindrical Vessel, and there condens'd, makes a Vacuum, which causes the weight of the Atmosphere to press on this Vessel, and so presses down a Piston that is fitted into this Cylindrical Vessel in the same manner as in Mr. *Newcomen's* Engine, with which he raises Water by Fire.

Vid. fig. 30.

P. The Pipe coming from the *Furnace* to the *Cylinder.*

Q. the *Cylinder* wherein the Steam is condensed.

R. the Valve that stops the *Steam* from coming into the Cylinder, whilst the Steam within the same is condensed.

S. the Pipe to convey the condensing Water into the Cylinder.

T. A Cock to let in the condensing Water when the Cylinder is full of Steam and the Valve *P* is shut.

U. a rope fixed to the Piston that slides up and down the Cylinder. *Note,* This Rope *U* is the same Rope that goes round the Wheel *D* in the Machine.

It hath been already demonstrated, that a Vessel of 30 Inches Diameter, which is but two Foot and a Half, when the Air is drawn out, the Atmosphere will press on it to the Weight of 4 Ton 16 Hundred and upwards; when proper Instruments for this Work are applied to it, it must drive a Vessel with a great force.

Note. The Bigness of the Machines must be proportioned to the Work that is to be performed by them; but if such a Force as is apply'd in this first Essay be not sufficient for any Purpose that may be required, there is room to make such Additions as will move an Immense Weight with tolerable Swiftness.

In my Opinion it will not be found Practicable to place the Machine here recommended, in the Vessel itself that is to be taken in or out of the Port, &c. But rather in a separate Vessel, for these Reasons:

1. This Machine may be thought Cumbersome, and to take up too much Room in a Vessel laden with Goods, Provisions, &c.

2. If this Machine is put in a separate Vessel, this Vessel may lie at any Port, &c. to be ready on all Occasions.

3. A Vessel of a small Burthen will be sufficient to carry the Machine to take out a large One.

4. A Vessel will serve for this Purpose the more, Tho'ry, after she is thrown off and is not able to be taken far Abroad.

THE EXPLANATION OF THE MACHINE:

1. Represents the Chimney coming from the Furnace.

2. The Tow-Boat.

3. 3. Two pieces of Timber framed together to carry the Machine.

4. 4. At each end are three Wheels of one Axis to receive the Ropes, *M F E* and *&c.*

Note. *M* is the same Rope that goes into the *Cylinder*, *Vid.* &c.

H a and *H b* are two Wheels on the same Axis with the Fans *I I I I I* and move alternately in such a manner, that when the Wheels *D a, D D b* move backward or forward they keep the Fans *I I I I I* in a direct Motion.

F b is a Rope going from *H b* to *D b*, that when the Wheels *D a, D* and *D b* move forward, moves the Wheel *H b* forwards, which brings the Fans forward with it.

F a is a Rope going from the Wheel *H a* to the Wheel *D a*, that when the Wheels *D a, D* and *D b* move forward the Wheel *H a* draws the Rope *F* and raises the weight *G*, at the same time as the Wheel *H b* brings the Fans forward.

When the Weight *G* is so raised, while the Wheels *D a, D* and *D b* are moving backward, the Rope *F a* gives way, and the Power of the weight *G* brings the Wheel *H a* forward and the Fans with it, so that the Fans, always keep going forward notwithstanding the Wheels *D a, D* and *D b* move backwards and forwards as the Piston moves up and down in the Cylinder.

L L, are Teeth, for a catch to drop in from the Axis, and are so contrived that they can catch in alternate Manner, to cause the Fans to move always forward, for the Wheel *H a* by the power of the weight *G* is performing his Office, while the other Wheel *H b* goes back in order to fetch another Stroke.

Note. The weight of *G* must contain but half the weight of the Pillar of Air pressing on the Piston, because the weight *G* is raised at the same time as the Wheel *H b* performs its Office, so that it is in effect two Machines acting alternately by the weight of one Pillar of Air of such a Diameter as the Diameter of the *Cylinder* is.

If it should be said that this is not a New-Invention, because I make use of the same power to drive my Machine that others have made use of, to Drive theirs for other Purposes, I *Answer*, The Application of this power is no more than the Application of any common and known Instrument used in Mechanism for new invented Purposes.

Answers to some Queries that have been made, concerning the Possibility and Usefulness of this Undertaking

Query I. *Is it possible to fix Instruments of sufficient Strength to move so prodigious a Weight, as may be contain'd in a very large Vessel?*

Answer. All Mechanicks will allow it is possible to make a Machine to move an immense Weight, if there is Force enough to drive the same, for every Member must be made in a proportionable Strength to the intended Work, and properly braced with Laces of Iron, *&c.* so that no part can give way and break; if the Braces, *&c.* necessary for this Work had been put in the Draught, it would have been so much crowded with Lines that the main Instruments could not be so well perceiv'd.

Query. II. *Will not the Force of the Waves break any Instrument to Pieces that is placed to move in the Water?*

Answer. First, it cannot be supposed, that this Machine will be used in a Storm or Tempest at Sea, when the Waves are very Raging; for if a Merchant lyeth in a Harbour, *&c.* he would not choose to put out to Sea in a Storm if it were possible to get out, but rather stay untill it is abated.

Secondly. When the Wind comes a Head of the Tow-Boat the Fans will be protected by it from the violence of the Waves, and When the Wind comes Sideways, the Waves will come Edge-ways of the Fans, and therefore strike them with the less Force.

Thirdly. There may be pieces of Timber laid to swim on the Surface of the Water on each Side of the Fans, and so contriv'd as they shall not touch them, which will protect them from the Force of the Waves.

Up in-land Rivers where the Bottom can possible be reach'd, the Fans may be taken out and Cranks placed at the hindmost Axis to strike a Shaft to the bottom of the River, which will drive the Vessel forward with greater Force.

Query III. *It being a continual Expence to keep this machine at Work, will the Expence be answered?*

Answer. The work to be done by this Machine will be upon particular Occasions, when all other means yet found out are wholly Insufficient: How often does a Merchant wish that his Ship were on the Ocean, when if he were there, the Wind wou'd serve tolerably well to carry him on his intended Voyage, but does not serve at the same time to carry him out of the River, *&c.* he happens to be in, which a few Hours work of this Machine wou'd do: Besides, I know Engines that are driven by the same Power, as this is, where materials for the Purpose are dearer than in any navigable River in *England*; therefore Experience demonstrates that the Expence will be but a Trifle to the value of the Work perform'd by those sort of Machines, which any Person that knows the Nature of those things may easily Calculate.

Repairing a Damaged Armature Winding

By R. H. Fenkhausen

Although there are still many motors in use with ring-wound armatures, this style of winding is fast becoming obsolete due to its high internal resistance, high armature reaction and poor speed regulation, and nearly all armatures are now made with some form of drum winding, the coils of which are usually form-wound. There are two general types of winding in use, the lap-connected winding (Fig. 1), which necessitates cross-connection of the commutator when two brushes are desirable on a four-pole motor (Fig. 3), and the wave-connected winding (Fig. 2), in which the coils are connected so that external cross-connections are not required, and also serve to neutralize the effects of an unbalanced field due to worn bearings, etc.

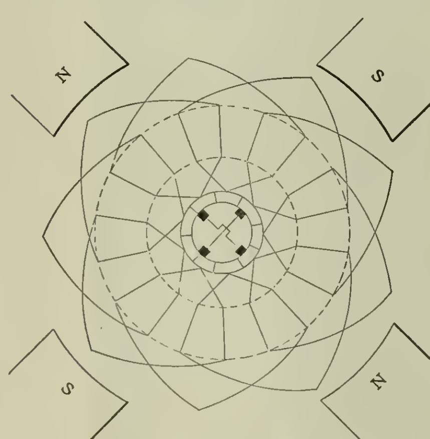

FIG. 2. WAVE-CONNECTED WINDING

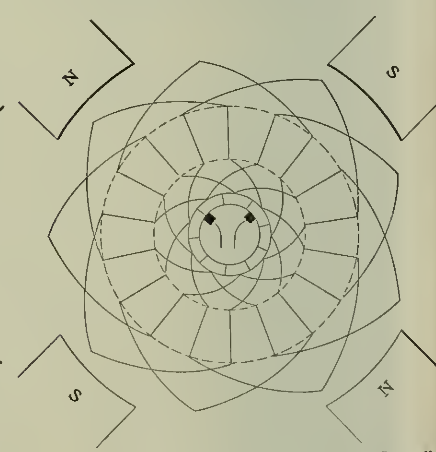

FIG. 3. WAVE-CONNECTED WINDING

The rewinding of a coil on a ring armature can be accomplished without disturbing its neighbors, but in drum windings in which the wire is wound directly in the slots it may be necessary to remove any number of coils up to the entire winding, depending on the manner in which the coils are arranged with reference to the damaged one.

Most modern armatures are of the general type shown in Fig. 4, in which the coils are wound on forms and insulated before being placed in the slots. Fig. 5 represents a coil for the armature shown in Fig. 4, and Fig. 6 shows a bar-wound coil of the type used in larger machines. These coils span several teeth of the armature core and each slot contains the bottom half of one coil and the top half of another coil some slots from it, the span or "throw" of the coil varying with the teeth per pole of the armature. Fig. 7 shows the core, and Fig. 8 a partly wound view of the armature in Fig. 4.

When it becomes necessary to replace a formed coil the binding wires must first be cut, or the fiber wedges holding the coils removed, and the connections to the commutator unsoldered. The top half of the injured coil should then be raised by slipping two pieces of ¾-inch linen tape under the extended ends of the coil and gently raising it from the slot. In order to remove the lower half of the coil it will be necessary to lift the top halves of as many coils as the injured coil spans. When the damaged coil has been removed it should be repaired if possible by re-insulating the burned spot, but if this is impossible a new coil should be put in. As a general rule it does not pay to make coils except in a shop having special facilities, and even then the coils can be purchased cheaper in many cases from the manufacturer of the motor, and the machine is not kept idle while coils are wound and dried.

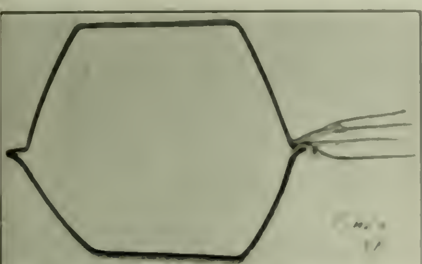

FIG. 5. A COIL WIRE

FIG. 3. CROSS CONNECTIONS

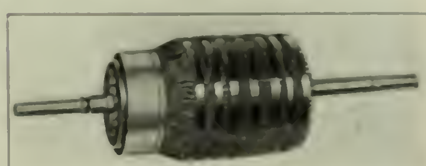

FIG. 4. A COMPLETE ARMATURE

FIG. 6. A BAR OR STRAP COIL

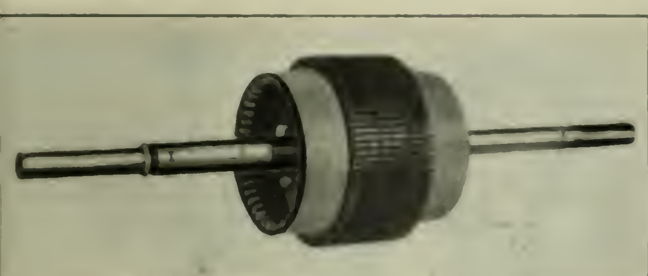

FIG. 7. ARMATURE CORE

FIG. 8. PARTLY WOUND

To Make Coils in the Shop

Spare coils for every size of armature should be kept on hand, but in case it is necessary to make coils in the shop the following procedure will give satisfactory results. Obtain two pieces of hardwood about 1 inch longer and wider than the coil desired and about ½ inch thicker, and lay out half the coil on each, as shown in Fig. 9. Then cut out to shape and bolt the two together with a distance piece between equal to the offset of the coil. The completed form is shown in Fig. 10. Start the coil in one of the holes E or F, depending on whether a right- or left-hand coil is desired, and wind on the surfaces X Y of the form, being careful to keep the wire tight until the required number of turns are wound. Most coils have two layers, but these layers should be separately wound and afterward rested together and connected.

When a layer is completed it should be held by wire loops at the points A B C D on the form to keep it in shape, after which the form should be taken apart and the coil removed. As soon as all the coils are made they should be dipped in an insulating varnish which will hold them in shape while being taped, as well as improving the insulation. After dipping, the coils should be baked, but if no oven is available an air-drying varnish should be applied. Common shellac will serve the purpose if no other varnish is on hand.

When the coils are perfectly dry the layers may be taped together, with paper between and a layer of "Empire" cloth or [illegible] tape applied. This should be followed by a layer of plain white tape to prevent abrasion of the cloth layer and the coil bent to the exact shape required, after which it should be dipped again and the layers connected in series or parallel as required. Before the final taping is applied, sleeving should be slipped over the terminals of the coil and if the winding is at all intricate it is advisable to place different colors of sleeving on the two terminals in order that they may be readily identified.

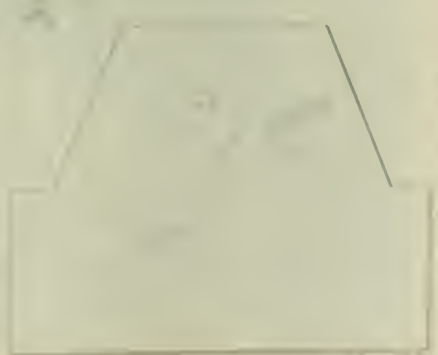

FIG. 9

While it is not claimed that the form described will make perfect coils, they will be accurate enough for practical use, and the form can be made by anyone of [illegible] [illegible], whereas the [illegible] accurate forms would take much longer and would be more expensive.

Before the coils are placed in the slots, the insulating troughs should be examined and renewed if damaged, and the [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] [illegible] of the [illegible].

[illegible] will [illegible] it into place.

[illegible] coils are [illegible] they should be wedged into place [illegible] [illegible] [illegible] vibration will [illegible] which may damage the insulation.

[illegible] all the coils are in place the [illegible] minals should be separated and each coil tested for continuity grounds or crosses with other coils, after which the bottom terminals may be carried to the commutator and soldered in.

The top connections should now be arranged in the proper order and the first lead tested and soldered to the proper bar, after which the other top leads are connected one at a time in proper sequence until all are in place.

Great care must be used in soldering the top leads that they are connected in the proper order, because in some types of windings two short-circuits and four open-circuits can result from the interchange of two adjacent leads.

After all the coils are connected the winding should again be tried with the testing set and if found all right the armature should be placed on knife edges and balanced with lead strips placed in the

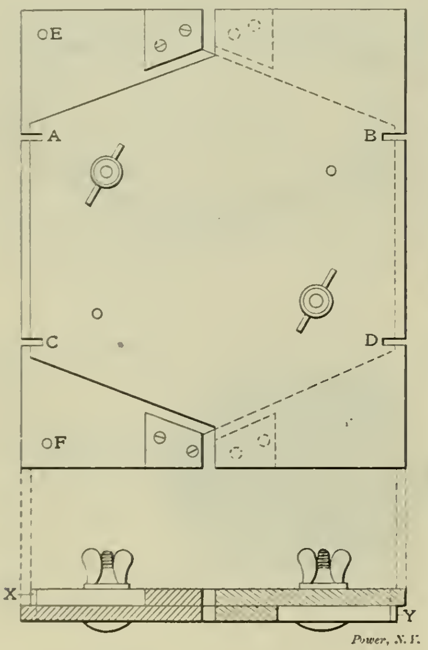

FIG. 10. COIL FORMER

slots over the coils on the light side. The binding wires may then be replaced and the armature put into service again.

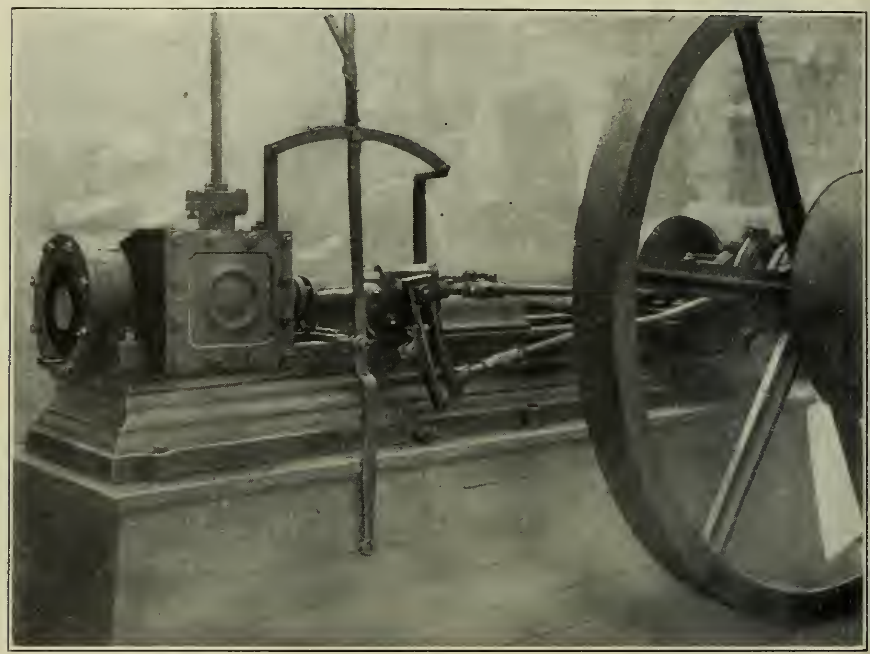
In a paper read by Prof. J. A. Smith before the Victorian Institute of Engineers it was shown that with a condenser temperature of 120 degrees Fahrenheit the amount of heat transmitted through each square foot of condenser surface was diminished 50 per cent., when air corresponding to 0.63 of an inch of mercury was introduced into the condenser. In other words, to obtain the same vacuum as when no air was present would require a condenser twice as large, or else a great deal more or colder circulating water.

At least 10,000,000 tons of peat is made and used to advantage in foreign countries every year.

An Historic Engine

Herewith are shown photographs of the engine used in the original packing plant of Armour & Co., which was located at a point that is now the very center of the immense union stockyards at Chicago. Built in 1866 by the old Columbian Iron Works, the engine practically had been in constant use until about one year ago. It was first installed on a high brick foundation behind three horizontal return-tubular boilers, and furnished the power for all the operations in the plant as then conducted. Due to the growth of the industry the engine was replaced by a larger one and was successively employed in hoisting ice, running the canned-meat department and the machine and pipe shop.

Finally, in 1901, when its 35, or so, effective horsepower could no longer be used to advantage elsewhere, it was exiled to Round lake, Ill., where it was put to a peculiar service. The company here harvests natural ice, and there is much trouble with a variety of long stiff grass or weed growing up from the bottom and interfering with the quality of the ice. Mounted on a flatboat, it was the duty of the engine to operate a device of special design for cutting this grass. During its sojourn here it was fitted with the link motion shown in the photograph.



TWO VIEWS OF AN HISTORIC ENGINE IN THE ARMOUR PLANT, CHICAGO STOCKYARDS

Recently the engine was replaced by a motor, shipped back to the stockyards and erected in the engine room of the company's power house, alongside a 600-ton ice machine, the latest piece of power machinery to be installed, representing the first and the last in power development of the company.

As shown in the photographs, the engine has the old box type of engine bed, locomotive guides and slide valve. The cylinder is about 12x16. Key adjustments are provided at the connecting-rod ends, but there is no gib-and-key arrangement as commonly understood; the key alone being used, held by a set screw.

The flywheel is cast in one piece, with the spokes loose at the inner end and fitting on a bushing keyed to the shaft. The whole is fastened securely by two rings of square iron shrunk on each end of the hub. This construction enables the flywheel to be used with any reasonable size of shaft, by varying the bushing, which doubtless was a desirable feature in the old days.

Electrolysis and Corrosion

By F. L. Johnson

While sitting at my desk one day, idly wondering why nearly everyone who had any work to do felt drawn to some kind of a city in order to do it, I was pleasantly surprised by the entrance of my young friend Sawyer. As he seated himself and looked around with his usual keen glance, I noted, in a subconscious way, that his appearance had improved. His trousers were freshly creased and several conventional touches in his dress showed that even in his strap-hanging moments he had kept up his habit of noticing things and profiting by what he saw.

After a few general remarks had been exchanged, he said:

"You probably have not forgot about that case of troublesome electrolysis I told of not long ago? Well, last week I had to go to the city where that happened and I took time to visit the plant to see if I could learn anything new about electrolysis of pump parts. I met the engineer, who at once told me of some things that had happened.

"This particular plant is operated differently from any other that I ever saw. No one man is responsible for its operation, successful or otherwise. On the part of the engineer, it is expected that he will keep the motive power in first-class running order all the time and have any unit that may be called for ready for immediate service.

"Of the electrician, it is expected that he will see that such units as will generate the required current in the most economical manner will be used. Coöperation between the steam and electrical departments is expected, but there is no provision for the preventing of friction between the two branches of the service. That friction did occur at times is evident from the fact that the engineer was never able to arouse any interest on the part of the electrician in the destruction of pump cylinders by what was believed to be electrolysis.

"New pump cylinders and parts were charged up to the steam plant and were no part of the operating expense of the electrical department.

"One day the engineer thought that perhaps the current that was destroying the pump came from the generator itself, and determined to try to find out if his guess was a fair one. At once the pump was overhauled and every part that showed any signs of electrolysis was replaced by a new part. The electrician was then notified that the engine was out of repair and could not be run.

"Then, while imaginary repair parts for the engine were being waited for, the pump was run night and day for a week, at the end of which time the pump was opened and found to be in first-class condition. The electrician was called in and shown the condition of the pump and informed of what had taken place. He was skeptical and wanted another week's run of the pump under the same conditions. It was given, and at the end of the second week, during which things were carefully watched by the electrical department, the pump was again examined and found in perfect condition.

"All imaginary repairs on the engine having been completed, it was started and run for four days, when it was necessary to shut down because the studs, nuts, valve seats and springs left their proper places in the pump and went floating away with the overflow, in company with the electric current which came from somewhere and took away with it all the metal it could carry.

"During the second week of running the pump independently a connection was made from the rail of a street-car line, half a mile away, to the pump. A flow of current of from 7 to 10 amperes was measured at the pump. But the engineer could not learn whether the flow was to or from the pump, nor the voltage of the current. Connections were also made to other pumps where no wasting away had taken place, with the result of a still larger amount of current flowing, and one of these pumps had been in use for years and never showed any signs of wasting by electrolysis nor anything else except wear where wear would be expected.

"Now, this matter has interested me considerably because I cannot understand why one particular pump in a system having common suction and discharge mains should be affected by electrolysis unless there is a leak from the generator of the engine which this particular pump serves. Now, as I understand the several periods of the story, [illegible] a problem of this kind expends his energy in trying to prove that certain factors do not enter into the problem, instead of seeking to find all of the factors.

"However, I did not start in here to moralize over the tendency of the man who takes no interest in finding leaks or removing their cause, simply because the cost will not be charged up to his department, but to have a little talk with you and ask if you could suggest any way of solving this particular problem."

I said that I had heard engineers say that before the introduction of the electric light little or no trouble had been experienced from the wasting of condenser tubes, even at sea, where nothing but salt water was used for condensing. He replied:

"I have heard the same story, but it is so hard to prove it that I have given up. Before the introduction of electricity, condensing plants were few and far apart, while now they are everywhere, but the practical engineer who operated condensing plants at that time has almost disappeared. I have met only one of the old school and all that he would say on the subject was, 'Young man, you will have to get your information just as I did, by experience.'

"I had heard about a man who had made electrolysis and corrosion a study, and I went to see him, asking about the destruction of pumps and condensers, and for a possible remedy. He went to the bottom of the subject for me. He said that while he would not say that wandering currents did not contribute in a measure to corrosion, he emphatically claimed that corrosion is going on where no extraneous currents can be held responsible for the damage. Then he talked about solution-tension, osmotic pressure, porosity of metals, molecular oxygen, ferrous ions, ferric condition and polarization by hydrogen.

"I left him with my head in a whirl and dizzy from the effects of the close-to-date use of the appalling depths of my ignorance of the subject.

"Some day a man who does not know enough to know that these things are beyond his reach will come along and, because he does not know, he will find out, and everything will be so plain that the engineer who does not even know the difference between passive resistance and depolarized hydrogen can touch a button or close a switch and read as easy as a chart the exact condition of his condenser tubes and the quality of the water passing through them, and running a condensing plant will seem like going on a vacation.

"I've been there, assisted a [illegible] who had designed a boiler which takes so much of the heat out of the furnace gases [illegible] the boiler, and [illegible]

Use Cylindrical Flywheels for Safety

Widening Rim and Shortening Radius of Flywheel Will Obviate Explosions without Sacrificing Convenience, Cost or Efficiency

BY A. L. HODGES

As the flywheel is one of the most important subjects in the mechanical world just now, it is the duty of every engineer to investigate all its properties and endeavor to conceive a way to change its makeup, in order to eliminate the big element of danger always lurking therein. The purpose of this article is to prove by mathematics and experiment how this can be done, the final product having very few disadvantages compared to the present-day affair, and a great many advantages over it.

The determining factor in the worth of a flywheel is its moment of inertia. This is a peculiar property of a rotating body and can be defined as the resistance offered to rotational motion, or, if already in motion, the resistance encountered in stopping it. It is both of these that makes the flywheel of use in machinery, by making the machine run smoothly, no matter how the load varies. Now the moment of inertia depends on several things. It is expressed by the formula,

$$I = M K^2,$$

where

I = Moment,
M = Mass of the body,
K = Radius of gyration.

This radius of gyration is found for different bodies by calculus. For a uniform and homogeneous disk it is ½ R, or one-half of the radius. For a ring with the mass concentrated in the circumference, it is R, or the radius. Now the flywheel is of this latter type, its mass being mostly on the periphery. In the ensuing argument the mass will be considered as being concentrated on the circle half way between the outside and inside diameters of the rim, and while this will be in error slightly it does not vitiate the argument at all, as will be presently seen.

Why Flywheels Explode

As the moment of inertia, then, depends directly on the mass and as the square of the radius, if we have two flywheels weighing the same, and one having a radius equal to twice the other, it will have a moment of inertia four times as great. This has caused the tendency in manufacturing flywheels to get greater efficiency by making the radius longer, and oftentimes with disastrous results. To see why flywheels disintegrate the forces acting to pull them apart and to hold them together must be investigated. The centrifugal force is the disintegrating force. It is expressed by the formula,

$$F = \frac{M V}{R},$$

where

F = Force,
M = Mass of each rotating particle,
V = Velocity,
R = Radius.

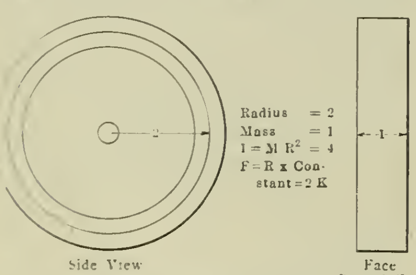


FIG. 1. PRESENT FLYWHEEL

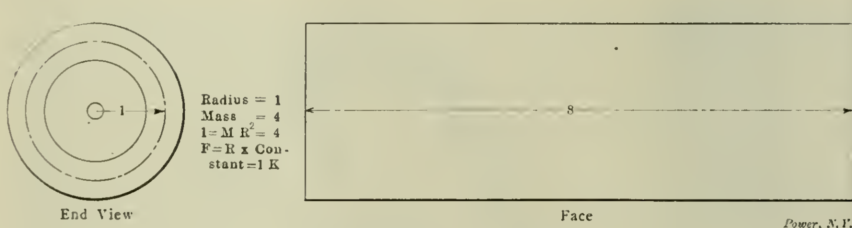

FIG. 2. PROPOSED FLYWHEEL

Now the velocity of a particle on the rim of each of two flywheels going the same number of revolutions per minute varies directly as the radius. But suppose the expression is reduced to terms of the radius. The velocity is certainly the number of revolutions in a given time multiplied by the circumference of the circle, which is, of course, $2 \pi R$. Let N stand for the number of revolutions per unit time. Then

$$F = \frac{M (N 2 \pi R)^2}{R} =$$

$$\frac{4 M N^2 \pi^2 R^2}{R} = 4 M N^2 \pi^2 R.$$

Now the proposition was to let all these terms be constant for the two flywheels except R. The number 4 is a constant, so is π^2, it is given that the N^2 is constant and the M, or mass, also. So that for two flywheels having the same mass and the same number of revolutions per unit time, it is seen that the disintegrating force varies directly as the radius. It must be remembered that the moment of inertia, the property desired, varies as the square of the radius.

Widen Rim and Shorten Radius

What is the force, then, preventing disruption of the wheel? It is that of cohesion only, or the attraction of the molecules for one another. This force acts only through small distances, yet it is sufficient in the case of steel wire to hold up 150,000 pounds per square inch. To return, then, to the original proposition. The idea is to increase the mass of the wheel's periphery considerably by widening its rim and necessarily the hub, but to shorten the radius, so that although the amount of inertia will be the same as before, the force tending to disintegrate will be very much less, so much less in fact that it would be practically impossible for the wheel to explode. The appearance of such a wheel would be that of a cylinder more than a wheel, but right here comes the practical side of it. For such a wheel no pit would have to be dug and no ceilings cut through to give it room. It would take up slightly more floor space, but as its hight would not be great, a frame could be built around it and steps over it.

Another item is that of friction. On account of the increase in mass, the friction would be somewhat greater, but as it would allow of greater speed it is at once seen that the difference would not be very great in the long run. As to the element of danger, that would be absolutely eliminated, as the periphery of the wheel could stand as great a speed as the big one, being made from the same material, but it is smaller and would allow a greater number of revolutions per minute. So in case the machinery, through accident or carelessness, attains a speed above normal, there would be absolutely nothing to fear from the improved flywheel.

In the accompanying sketches are given comparative drawings of two wheels having the same moment of inertia, but the element of risk very different, as shown by the ratio of velocities for the same number of revolutions per minute. The velocities vary as the radius, so the unit radius would have only one-half the velocity of the other, and consequently one-half of the disintegrating force as the other. The mass, however, must be four times as great. This would merely make the rim eight times as wide, using the same thickness of rim in both cases.

It must be remembered that as the rim of the wheel gets thicker, the wheel itself more nearly approaches a disk, and the gyration radius would be ½ *R* instead of *R*. Therefore it is necessary to keep the rim as thin as possible. The figures following are only true on the assumption that the mass is concentrated in the middle circle. Of course, for any desired flywheel all these can be easily worked out. The purpose of this article is simply to show that exploding flywheels are not necessary and can be rendered impossible without sacrificing in the least any convenience, cost or efficiency.

It is possible that the above reasoning is not quite clear to those students who have used Kent's handbook entirely, for here it is claimed that the tensile stress per unit cross-section of the rim is expressed by the formula

$$S = C\ R^2\ r^2,$$

where

C = Constant,
R = Radius of wheel,
r = Number of revolutions per minute.

But it must be noticed that this is derived from the previous formula

$$S = C_1\ W\ R\ r^2,$$

where

C_1 = Another constant,
W = Weight or mass of the rim,
R = Radius of wheel,
r = Revolutions per minute.

How, then, is the variable W omitted from the formula which contains only R? Because W is considered a variable which, as it is the weight of ring of unit cross-section, will vary as R. Consequently, the constant is changed and the form varying as R^2 in the final formula is obtained. Right here comes in the agreement in reasoning with the first part of this article. One of the conditions was that the mass being constant the force varied as R alone. This is at once clear, for if M is constant, form of the cross-section can vary. The rim would merely become thinner. Also that the M is not the mass of a unit cross-section, but of the whole rim or one particle in the rim. The crux of the whole thing is that the mass can be increased without increasing the radius by merely widening the rim.

THE BALL BEARINGS TO REDUCE FRICTION

As to the friction of the cylindrical flywheel, it is known that friction does not depend on area, but merely on the weight and a constant for any two given surfaces. So the shaft or axle of the new flywheel could be made of as large a diameter as desired, and it could be supported in as many places as desired to prevent vibration of the shaft, without increasing the friction. Now as this is so, the more area in contact the less would be the pressure per unit area. This would allow for the use of any bearing metal now used for that purpose. Referring to Fig. 2, in that particular case four supports of the same dimensions would be needed as for Fig. 1, or two supports of twice the dimensions. Either would give the same pressure per unit area on the bearings. To have more than two supports, the cylinder could be made into separate wheels on a rigid shaft, which would not lessen its efficiency and would only lengthen the shaft by a distance equal to the width of the extra bearings.

As the number of supports, then, does not increase the friction and lessens the pressure per unit area, ball bearings ought to find an immediate application. A great improvement in ball bearings has been made in recent years. Their sphericity and accuracy in size have been improved and their ability to resist crushing has been more than doubled by the use of special alloys of crucible high-carbon steel. Consequently, smaller balls can now be used to do the work of larger ones, which would have been used before had the space been available.

Another improvement is the recent introduction of the annular ball bearing, where the balls are placed in a groove between two rings, which thus give a larger bearing surface and consequently allow for a greater pressure on the balls. The pressure on a sphere is a rather interesting problem. If it were possible to have two spheres each of an absolutely incompressible material, the place of contact would be a geometrical point and no matter what the weight, the pressure exerted would be infinite. But as this is impossible the hardness of both the ball and the shaft allow of such flattening out according to the pressure, and thus a considerable area is subjected to pressure.

As a result, [illegible] has been found, possible to decrease the friction to [illegible] over the former bearings. Thus it can be seen that by the use of ball bearings the new flywheel can be brought down to almost as low a friction as the old type, although it does contain several times the amount of [illegible].

The Turbine and Reciprocating Engine for Naval Purposes*

By LOUIS W. [illegible]†

It has been fairly well proven that for land purposes and for merchant vessels of high power and speed the turbine has given satisfactory results from an economical standpoint. A turbine under these conditions runs at maximum speed and maximum power. A passenger ship leaving port starts out under full-power conditions and remains under the same conditions until the arrival at the next port, time of passage meaning money to the owners.

For naval purposes the installation of turbine machinery is an entirely different proposition. A ship is built to fight, and should be able to maintain the greatest speed possible if called upon under the best conditions. A ship built may never be called into a naval fight, but no one can tell when the day will come when the machinery may be called upon to perform its greatest power. It may be only for an hour or two, but this hour may mean victory or defeat.

If run at maximum speed the turbine may be the best available. The question, however, arises, which would be the better for all-round work, both at low and high speeds and give as good results in cases of emergency? It may be admitted that for maximum speeds the turbine has a little the better of the argument, but for all-round cruising, and taking into consideration the installation of machinery, I think the reciprocating engine up to the present time is the better installation.

If two shafts are installed in the ship and on each shaft one turbine of a large unit, the economy is sure to drop when the speed drops, and at low power the economy will be greatly decreased because a large unit cannot be satisfactorily designed to give economical results at all speeds. The maximum peripheral speed at the buckets is neither week in some vessels, much less than usually [illegible] of a turbine employed for electric lighting, and if the most general design were followed in the two-shaft [illegible] turbine should be at least [illegible] as long if equal economy were to be obtained. In order to give a low peripheral speed at a satisfactory number of revolutions, the diameter of the turbine has to be increased, which means a material increase in the weight of the machinery. If two turbines are placed on each shaft, with a high-pressure and a low-pressure on each shaft, the economy [illegible] will be much, but it is sure to fall [illegible] at the lower speeds and greatly exceeds that of a correctly designed reciprocating [illegible]

*Abstract of paper read before the American Society of Naval Engineers. [illegible]
†Assistant [illegible]

engine at low powers. If three or four shafts are installed, or even with two shafts, combinations may be made whereby cruising turbines are installed, and the economy may be obtained at the lower speeds which will correspond closely to that of the reciprocating engine. As these economical results are obtained, what is done to obtain them? More turbines of smaller units have to be installed, more shafting, more piping, with joints, and increase of valves, and the whole equipment has to be increased and complicated. It becomes a question whether, to obtain this economy at the lower speeds equal to that of a reciprocating engine (it is doubtful whether it is obtained), this increase of machinery and complications will offset any gain which is claimed by the turbine. The less the amount of machinery on board and the less complicated it is, the easier will it be to handle and care for. The machinery on board a man-of-war at the present time is complicated enough without adding any more complications to it.

For naval purposes under ordinary conditions a ship rarely cruises at maximum speed. The ordinary cruising is around 10 or 12 knots, which is, say, 15 per cent. to 20 per cent. of full power. At this speed the cruising turbines would be practically the only ones in use and the others would run idly. With the reciprocating engine the economy can be regulated by using the cutoffs so that no change is necessary by making any change in the combination of the motive power. For these lower powers the economy of the reciprocating engine is decreased but slightly. For maximum speed the reciprocating engine could be built to make the speed required and at the same time be economical. If all possible refinements in design that tend to economy are made, the reciprocating engine could be nearly, if not quite, as economical as the turbine. These refinements consist in the reduction of clearances, proper proportioning of the sizes of the cylinders, care in providing smooth exits through ports and passages, longer stroke, if possible, better condensing apparatus and the use of superheated steam. With high-class land engines, owing to the use of Corliss and drop types of steam valves, the clearance spaces have been much reduced. I do not see why Corliss valves, or something on that style, could not be used for marine engines. They might be placed in the tops of the cylinders. If as many experiments as are being made at the present time on the turbine were made on the reciprocating engine, I think an increase in the economy would be shown with the reciprocating engine.

Working out the water rates of about ten ships in the United States Navy, the average gives about 17.2 pounds of water per indicated horsepower for main engines only. This is at maximum power under service conditions. Assuming that the water consumption was greater than this, say 19 pounds (which is quite high and perhaps ought to be about 17.5 to 18 pounds), this would give for a 20,000-indicated horsepower engine a water consumption per hour of 380,000 pounds. Assuming that the boilers evaporated 9.5 pounds of water per pound of coal, then the amount of coal burnt per hour for the main engines would be 17.8 tons. Now assume that the turbine installation of 20,000 gives a water consumption *under service conditions* of 15 pounds, this will mean a water consumption per hour of 300,000 pounds, which, assuming as before the same evaporation per pound of coal, would mean a consumption of 14.1 tons of coal per hour. With the increase in auxiliaries required for the turbine this would be brought a little higher. This will show an increase in economy on the side of the turbine at the high speeds, but how long is either going to run at those top speeds? The reports of the economy of the turbine show the gain at the maximum speeds, but reliable information is not obtained, as a general rule, for the lower speed, and it does not appear that the turbine has beaten the reciprocating engine in *overall efficiency*—that is, taking into consideration the engine and screw together. The degree of economy of the turbine in marine practice must compete on the largest scale with that of a quadruple-expansion engine expanding saturated steam with 210 pounds fifteen times into a vacuum of 25½ inches, with an economy of 13.6 pounds of water per indicated horsepower per hour.

Another question to enter into the installation of a turbine or reciprocating engine is that of the relative propeller efficiencies. It is claimed by some that the high-speed turbine will give a smaller screw and thereby get deeper immersion of the blades and less draft to the ship. This may be well enough for torpedo boats and vessels with shallow draft, but for larger vessels larger screws are needed. With propellers for turbines running at high speeds it is just a question how fast the water will flow to the screw. In a small turbine the revolutions have to be high in order to get the peripheral-blade speed. As soon as the revolutions increase above that designed the efficiency of the screw decreases and cavitation losses may also enter. It is a difficult question to design a screw that will meet all the demands of a naval vessel. The thrust may be divided among three screws, but this will increase the machinery installation and complicate matters. The larger the screw, the greater the efficiency. If a blade of standard width gives insufficient surface, to prevent cavitation then either the blades have got to be made wider, other things remaining the same, or a larger pitch ratio must be chosen, which will mean an increase in the diameter of the screw and reduction in the revolutions, which means an increase in the diameter of the turbine and an increase in the weight. For marine turbines the vane speed can hardly exceed 200 feet without great sacrifice to the propeller efficiency, and is generally from 140 feet to 100 feet. If the revolutions are, say, 250 per minute, then the corresponding turbine diameter would be 10 feet 7 inches, and if the revolutions were decreased to 200, then the diameter of the turbine would be 13 feet 4 inches. A screw may be designed for a turbine with a certain speed, but as the speed decreases the economy is lost in the turbine, and the screw will also lose its efficiency when the revolutions for which it is designed vary to any great extent. At high speeds of revolution the propeller efficiency drops very materially and, as a general rule, the gain in economy is counterbalanced by the loss in propeller efficiency.

In land service an arrangement is now being tried with a low-pressure turbine working in conjunction with a reciprocating engine, the low-pressure turbine being placed so as to use the exhaust from the reciprocating engine. This is giving satisfactory results and has secured great gains in the economy of steam. With the reciprocating engines as now used in the naval service, at high speeds, the vacuum does not have a great deal of effect in the power of the engine. This is due to the small size of the ports and the quick opening and closing of the valves. To get the full effect of the vacuum it would mean increasing the size of the valves to such an extent that it would be impracticable. If a low-pressure turbine was placed so as to take the exhaust from the main engines the vacuum would have its full effect in the turbine, which would mean more work being done and more economy. By using this low-pressure turbine in conjunction with the main engines some complications would arise, and it is a question whether for the increased economy the installation of the low-pressure turbine would be worth while. This combination is spoken of in Lieutenant Dinger's article in the *Journal* of the American Society of Naval Engineers, November, 1908.

A good many foreign navies, in fact, nearly all, have tried, and are still trying, the installation of the turbine, but the results have been kept a secret and their economical and practical results are still a question of doubt. All reports, as a general rule, of the ships having turbine installation show a better economy at the maximum speed than the ships fitted with the reciprocating engine, but the results at lower speeds are not so well reported, and the average result is not very satisfactory for any authentic information.

Many things are claimed for the turbine, among them being a saving in weight and a saving in space. The saving in weight *seldom* shows an advantage of 5 per cent. over that of the reciprocating engine. The tendency now is to increase the weight without any gain in economy. The turbines installed in the first battleship in the British navy averaged about 40.4 pounds per indicated horsepower, now the average is about 43.2 pounds. When one takes into consideration that a turbine installation requires high vacuum, which means an increase in the cooling surface at the condensers and a more complete condensing apparatus, the weight of the turbine will not be so very much under that of a reciprocating engine for the same power. In order to get the greatest efficiency out of the propeller for general work, and at varying revolutions, the propeller must be increased in size. When this is done the speed of rotation of the shaft must be reduced. The general tendency is to decrease the revolutions, which, as a general rule, means increasing the diameter of the turbine rotor in order to obtain the proper vane speed. Any increase in the diameter of the rotor means, of course, an increase in weight and space. The average weight, including main-engine cylinders, shafting, main-engine framing and bearings, reciprocating parts of main engines, main-engine valve gear, main condensers, main air and circulating pumps and propellers arranged for the "Louisiana," "South Carolina," "Michigan," "Washington," "Tennessee," "West Virginia" and "Maryland" is 68.5 pounds per designed indicated horsepower. If we take out the main condensers, main air and circulating pumps and propellers, the average weight per designed indicated horsepower will be 52.35 pounds. Should we take out the weight of the shafting aft from the engine this would bring the weight per indicated horsepower still less. When one takes into consideration the turbine combinations that are being made to increase the economy and the increased diameter in the turbine it will not be astonishing to note that the weights will not differ much. There is not so much space saved in the turbine installation, and the space used by the turbine and condensers will not be much less than the space used for the installation of a reciprocating engine. The head room may be less in the turbine, but if proper facilities are made for removing the turbine casing and removing the exhaust pipes the head room will not be reduced much. When the combinations of turbines are installed for economical purposes the space saved is very small, if any, over that occupied by the installation of a reciprocating engine.

Another one of the claims of the turbine might be added here, and that is the reduction in the engine-room staff. This is true, but if forced lubrication were used on the reciprocating engine (it is being installed on some at the present time), this engine-room staff might be reduced somewhat.

The adjustment of the rotor in a fore-and-aft direction should be very exact. When it is taken into consideration that the clearance is from 1/16 inch to [illegible] inch between the stationary blades and the rotor, it will be readily understood that there is not very much chance for a longitudinal movement of the shaft. When the turbine is going ahead and is suddenly thrown to full astern, there is bound to be a great strain set up in the thrust, which would, if there was the slightest give to the thrust, allow a play in a fore-and-aft direction. After running for a time the shaft collars are bound to wear the shoes in the thrust, and any slight play in the thrust will have to be closely watched. In case the shaft does change an amount equal to the clearance, it would mean that the shrouding of the blades would be badly cut, and in case the blades were not shrouded it might mean the destruction of the blades and the motive power of the ship. Cases have occurred where the shrouding has been cut, and in some cases where the blades have gone.

Nearly every ordinary case of breakdown in a reciprocating engine at sea can, with a little ingenuity on the part of the engineering personnel, be repaired and the ship be able to get to port. The parts of the reciprocating engine are easily accessible and can be temporarily repaired in some way or another. Spare parts can also be carried to cover any ordinary breakdown. It is different with a turbine; if any of the moving rotors are disabled there is no easy way to repair the defects unless the casing is taken off and proper facilities given to do the work, and if the blades are gone there is no way to repair the defects. Ordinarily, most of the merchant ships now fitted with turbines run between two ports, and are at one time of the run close to the works where they were built or may be within easy reach of the works. With a man-of-war this is entirely different. She may be ordered at any time to any part of the world, and if easy and feasible methods of repairs are not given for the work then the ship should not be ordered to any place outside of close communication with the shops where she was built. No spares can easily be carried for the rotor of the turbine, and if this rotor should be disabled there is no easy method to repair it. A turbine ship might be on a foreign station for years at a time or might be on blockade duty or performing special duty in time of war. If anything should go wrong in the interior of the turbine it is a much more difficult operation to repair than with a reciprocating engine.

In accepting the turbine for naval purposes all the above points must be carefully considered to cover all conditions of speed and general work. The specifications for turbine ships should [illegible] ing service conditions than at full power, and any tests made with the turbine should be made with the installation on board and under service conditions. The comparison should then be made with the reciprocating engine. When the grand average shows a decided advantage in favor of the turbine for all-round work for naval purposes over that of the reciprocating engine then, but not until then, should the turbine installation supersede the reciprocating engine in the ships which are to be built in the future, whose speed is not much above about 21 knots.

In writing this article I am not at all against the use of the turbine, but I think up to the present time it has not shown, taking everything into consideration, a great enough advantage in all-round work to warrant its taking the place of a reciprocating engine. I think that if some refinements were made in the reciprocating engine, this form of motive power would, for naval purposes, keep at equal pace with the turbine installation.

Government Bulletin on Smokeless Combustion of Coal

A bulletin on the smokeless combustion of coal in boiler plants, with a chapter on central heating plants, will soon be issued by the technologic branch of the United States Geological Survey, giving in detail a study of the conditions found in industrial establishments in thirteen of the largest cities of Indiana, Illinois, Kentucky, Maryland, Michigan, Missouri, New York, Ohio and Pennsylvania, between 400 and 500 plants having been inspected. Sufficient information was collected to make the data from 284 plants of value for this report.

The bulletin, prepared by D. T. Randall and H. W. Weeks, not only shows that bituminous coals high in volatile matter can be burned without smoke, but that large plants carrying loads that fluctuate widely, where boilers with banked fires must be put into service quickly and then forced to the capacity of their units, can be operated without producing smoke that is objectionable. Proper equipment, efficient labor and intelligent supervision are the essential factors.

The burning of coal without smoke is a problem which concerns the Government directly because of the advantages of smokeless combustion both in public buildings and on naval vessels. To publish [illegible] experiments as a factor in [illegible] the fuel economy of the United States, therefore, is a part of its general investigation of the best methods of utilizing the [illegible] of this country. The United States Geological Survey has made a careful study to determine the conditions necessary for the smokeless combustion of [illegible] coal in boiler plants.

The general conclusions of Messrs. Randall and Weeks are as follows:

Smoke prevention is possible. There are many types of furnace and stoker that are operated smokelessly.

Credit is to be given to any one kind of apparatus only insofar as the manufacturers require that it shall be so set under boilers that the principles of combustion are respected. The value of this requirement to the average purchaser lies in the fact that he is thus reasonably certain of good installation. A good stoker or furnace poorly set is of less value than a poor stoker or furnace well set. Good installation of furnace equipment is necessary for smoke prevention.

Stokers or furnaces must be set so that combustion will be complete before the gases strike the heating surface of the boiler. When partly burned gases at a temperature of, say, 2500 degrees Fahrenheit, strike the tubes of a boiler at, say, 350 degrees Fahrenheit, combustion is necessarily hindered and may be entirely arrested. The length of time required for the gases to pass from the coal to the heating surface probably averages considerably less than one second, a fact which shows that the gases and air must be intimately mixed when large volumes of gas are distilled, as at times of hand firing, or the gas must be distilled uniformly, as in a mechanical stoker. By adding mixing structures to a mechanical-stoker equipment both the amount of air required for combustion and the distance from the grates to the heating surface may be reduced for the same capacity developed. The necessary air supply can also be reduced by increasing the rate of combustion.

No one type of stoker is equally valuable for burning all kinds of coal. The plant which has an equipment properly designed to burn the cheapest coal available will evaporate water at the least cost.

Although hand-fired furnaces can be operated without objectionable smoke, the fireman is so variable a factor that the ultimate solution of the problem depends on the mechanical stoker—in other words, the personal element must be eliminated. There is no hand-fired furnace from which, under average conditions, as good results can be obtained as from many different patterns of mechanical stoker; and of two equipments the one which will require the less attention from the fireman gives the better results. The most economical hand fired plants are those that approach most nearly to the continuous feed of the mechanical stoker.

The small plant is no longer dependent on hand-fired furnaces, as certain types of mechanical stoker can be installed under a guaranty of high economy, with reduction of labor for the fireman.

In short, smoke prevention is both possible and economical.

During 1904 to 1906 coals from all parts of the United States were burned at the Government fuel-testing plant at St. Louis, in furnaces which were in the main of the same design. Most of the tests were made on a hand-fired furnace under a Heine water-tube boiler. The lower row of tubes of the boiler supported a tile roof for the furnace, giving the gas from the coal a travel of about 12 feet before coming into contact with the boiler surface. This furnace is more favorable to complete combustion than those installed in the average plant. A number of coals were burned in this furnace with little or no smoke, but many coals could not be burned without making smoke that would violate a reasonable city ordinance when the boiler was run at or above its normal rated capacity.

In 1907, the steaming section of the St. Louis plant was moved to Norfolk, Va., where subsequent tests of this nature were made. The plant at Norfolk was equipped with two furnaces—one fired by hand and the other by a mechanical stoker.

In the course of the steaming tests some special smoke tests were made and the influence of various features in smoke production was noted. As the tests were made as far as possible under standard conditions with a minimum variation in boiler-room labor the results bring out the importance of other factors, such as character of fuel and furnace design.

A brief summary of the general conclusion is as follows:

A well-designed and operated furnace will burn many coals without smoke up to a certain number of pounds per hour, the rate varying with different coals, depending on their chemical composition. If more than this amount is burned, the efficiency will decrease and smoke will be made, owing to the lack of furnace capacity to supply air and mix gases.

High volatile matter in the coal gives low efficiency and *vice versa*. The highest efficiency was obtained when the furnace was run at low capacity. When the furnace was forced the efficiency decreased.

With a hand-fired furnace the best results were obtained when firing was done most frequently and with the smallest charge.

Small sizes of coal burned with less smoke than large sizes, but developed lower capacities.

Peat, lignite and subbituminous coal burned readily in the type of tile-roofed furnace used and developed the rated capacity with practically no smoke.

Coals which smoked badly gave efficiencies 3 to 5 per cent lower than the coals burning with little smoke.

Briquets were found to be an excellent form for using slack coal in a hand-fired plant. They can be burned at a fairly rapid rate of combustion with good efficiency and with practically no smoke. High-volatile coals are perhaps as valuable when briquetted as low-volatile coals.

A comparison of tests on the same coal washed and unwashed showed that under the same conditions the washed coal burned much more rapidly than the raw coal, thus developing high rated capacities. In the average hand-fired furnace washed coal burns with lower efficiency and makes more smoke than raw coal. Moreover, washed coal offers a means of running at high capacity, with good efficiency, in a well-designed furnace.

Forced draft did not burn coal any more efficiently than natural draft. It supplied enough air for high rates of combustion, but as the capacity of the boiler increased the efficiency decreased and the percentage of black smoke increased.

Most coals that do not clinker excessively can be burned with from 1 to 5 per cent. greater efficiency and with a smaller percentage of black smoke on a rocking grate than on a flat grate.

Air admitted freely at firing and for a short period thereafter increases efficiency and reduces smoke.

As the CO in the fuel increases the black smoke increases; the percentage of CO in the flue gas is therefore, in general, a good guide to efficient operation. However, owing to the difficulty of determining this factor, combustion cannot be regulated by it.

The simplest guide to good operation is pounds of coal burned per square foot of grate surface per hour.

None of the problems of combustion has received more experimental treatment than the burning of coal in hand-fired furnaces. Hundreds of devices for smokeless combustion have been patented, but almost without exception they have proved failures. This record may be explained by the fact that many of the patentees have been unfamiliar with all the difficulties to be overcome, or have begun at the wrong end. Numerous patents cover such processes as causing the waste gases to reënter the furnace, and schemes for collecting and burning the soot are legion. So many manufacturers who have been looking for some cheap addition to a poorly constructed furnace to make it smokeless have experienced inevitable failure that the work of educating the public to rid cities of the smoke nuisance has been hard, long and only partly successful.

The total number of steam plants having boilers fired by hand is far greater than the total of plants with mechanical stokers, but if the comparison is based on total horsepower developed the figures show less difference. Particularly is this true in sections of the central West, where mechanical stokers are generally used at large plants. As a rule, hand-fired plants do not have proper furnaces, and methods of operation are far from conducive to good combustion. Coal is usually fired in large quantities, and little opportunity is given for the air and gases to mix before the heating surface is reached and combustion is arrested. In all the hand-fired plants visited success in smoke prevention has been obtained chiefly by careful firing. The coal was thrown on often in small quantities, the fire was kept clean, enough ash to prevent the passage of air through the fire never being allowed to collect on the grate; and more air was supplied at firing than after the volatile matter had been distilled. Even with such precautions the plants might have made objectionable smoke at times but for the fact that usually some method was employed for mixing the gases and air before they reached the heating surface.

Some general conclusions from the facts set forth in the bulletin are as follows:

The flame and the distilled gases should not be allowed to come into contact with the boiler surfaces until combustion is complete.

Firebrick furnaces of sufficient length and a continuous or nearly continuous supply of coal and air to the fire make it possible to burn most coals efficiently and without smoke.

Coals containing a large percentage of tar and heavy hydrocarbons are difficult to burn without smoke and require special furnaces and more than ordinary care in firing.

Briquets are suitable for use under power-plant conditions when burned in a reasonably good furnace at the temperatures at which such furnaces are usually operated. In such furnaces briquets generally give better results than the same coal burned raw.

In ordinary boiler furnaces only coals high in fixed carbon can be burned without smoke, except by expert firemen using more than ordinary care in firing.

Combinations of boiler-room equipment suitable for nearly all power-plant conditions can be selected, and can be operated without objectionable smoke when reasonable care is exercised.

Of the existing plants some can be remodeled to advantage. Others cannot, but must continue to burn coals high in fixed carbon or to burn other coals with inefficient results, accompanied by more or less annoyance from smoke. In these cases a new, well designed plant is the only solution of the difficulty.

Large plants are for obvious reasons usually operated more economically than small ones, and the increasing growth of central plants offers a solution of the problem of procuring heat and power at a reasonable price and without annoyance from smoke.

The increasing use of coke from by-product coke plants in sections where soft coal was previously used, the use of gas for domestic purposes and the purchase of heat from a central plant in business and residence sections all have their influence in making possible a clean and comfortable city.

The Alberta (Can.) License Law

On May 9, 1906, the legislative assembly of the Province of Alberta, Canada, passed its first engineers' license and inspection law, entitled, "The Steam Boiler Act."

This act, with the amendments passed in 1907 and 1908, clearly defines the terms "boiler," "owner," "engineer," "inspector," etc., prescribes the duties of all persons connected with the operation and inspection of steam boilers, and provides for the enforcing of the act.

The act provides for obtaining a certificate of qualification as engineer in three ways:

First, any person who holds a certificate of qualification as an engineer from any incorporated body authorized to grant such certificates of qualification for operating steam boilers and engines, or from the Dominion or any provincial government, or from any competent authority in any other portion of the British Empire, or the United States of America, shall be entitled, upon making application to the minister accompanied by such evidence of his qualification as may be required by the minister and upon payment of a fee of $5, to obtain a certificate of qualification as an engineer in the class determined by the minister.

Second, those who have had over one year's experience in charge of and operating steam boilers and engines outside of this province, upon furnishing evidence of the fact and passing an oral examination before an inspector, can obtain provisional certificates which entitle them to act as engineers to operate steam boilers and engines of any capacity not exceeding 75 horsepower for one year, and at the expiration of such certificates, if the holders desire to continue to act as engineers, they have to undergo a written examination for first-, second- or third-class certificates, as may be determined by the inspector. The fee for a provisional or final certificate is $5.

Third, persons who have had no experience in operating steam boilers and engines, but who desire to become engineers, can do so by serving as apprentice for one year to an engineer or engineers who are registered as holders of first-, second- or third-class certificates for the province, and at the expiration of such time passing an examination before an inspector.

Examinations for final certificates are held from time to time at various points throughout the province by the inspectors, and persons desiring to undergo an examination should notify the inspectors or the deputy minister so that they may be informed of the next date of examination.

The names and addresses of the inspectors are: Joseph Bruton, Calgary; David Tyson, Strathcona; F. W. Dickens, Red Deer.

Persons undergoing a written examination are examined as to their knowledge of the construction, care and operation of steam boilers and engines; also a carefully [illegible] list of theoretical and practical questions. Any candidate through lack of education may be allowed to secure the services of a person who will write answers to questions, or interpret only as instructed by the candidate, but such person or interpreter must not be an engineer.

Candidates writing for a first-class certificate must obtain 70 per cent. of the total number of marks allotted, those writing for second- must obtain 60 per cent., and for a third- 50 per cent., in order to pass. Those who fail for first-, but make 60 per cent. of marks allotted, may be granted a second-class certificate, and those making only 50 per cent. on the second may be granted a third-class certificate. Candidates failing to pass may not again write for the same or a higher class of certificate until after the expiration of one year.

For the guidance of those who may desire to present themselves for examination for certificates as engineers, the following information is given regarding the subjects of examination:

(a) Questions relating to the origin of steam and its uses.

(b) Questions relating to the different kinds of boiler to generate steam, and manner of constructing them, including the strength of materials used in building boilers, and the proper proportions in size and thickness of material to be used to boilers with proper areas of grate, etc.

(c) Questions regarding the different kinds of safety valve for controlling the pressure in steam boilers and other necessary fittings.

(d) Questions regarding the proper methods of caring and maintaining steam in boilers and the care necessary to keep them in good order, and when repairs are necessary the method of making them.

(e) Questions regarding the kind, construction and operation of the different appliances used to feed and supply boilers with water during operation.

(f) Questions regarding the different kinds of engine used in developing steam, including their construction, and the methods of calculating their power and the proper methods of timing and operating such engines.

The questions are made as clear and concise as possible and every effort has been made to make the questions cover such theoretical and practical knowledge as should be possessed by every engineer charged with the care and operation of steam boilers and engines.

Candidates desiring to qualify for examination can obtain the necessary theoretical information to enable them to answer the questions by studying any recognized textbooks on the boiler and steam engine.

Forms of application and any additional information may be obtained by addressing John Stocks, Deputy Minister.

Practical Letters from Practical Men

Don't Bother About the Style, but Write Just What You Think, Know or Want to Know About Your Work, and Help Each Other

WE PAY FOR USEFUL IDEAS

Courtesy Due the Engineer

The engineer often enters into correspondence with different manufacturers in order to find out what is most suitable for his plant, considering the conditions under which he has to operate. He uses his firm's letterhead to show who he is; but many times the dealer will write the firm in reply, with the result that the letter promptly reaches the waste basket, causing at least delay and perhaps trouble for the engineer. It is the engineer's duty to find what is needed, then to advise his employer. Then when a manufacturer or dealer receives word from that employer it is time enough to write him and not before. This consideration is due the engineer.

The writer has within a short time sent orders to a firm to the amount of $10,000, yet it is possible that that firm does not know to whom to credit that business. This goes to show that while the employer pays the bills, the engineer may have to furnish the brains. In fact, that is what he is paid for. As a rule manufacturers and dealers are courteous to and assist the engineer in many ways, seeming to appreciate the fact that he is "the man behind their machines," yet there are others who persist in working against their own interests.

Timing Gas Engine Valves and Ignition

Mr. Tilden in his letter on page 416 of the March 2 issue comes to conclusions which do not seem to "jibe" with my experience, and I should like to point out the reason why I am strongly of the opinion that it is better if the valves do not close and open on the dead-center points. I made several tests on vertical gas engines and I found that a proper adjustment for the valves is as follows:

For vertical engines (Fig. 1): Inlet valve to open 30 degrees ahead of the dead-center point; to close 6 degrees after the dead-center point. Exhaust valve to open 40 degrees ahead of the dead-center point; to close 30 degrees after the dead-center point.

For horizontal engines (Fig. 2): Inlet valve to open 20 degrees ahead of the dead-center point; to close 20 degrees after the dead-center point. Exhaust valve to open 40 degrees ahead of the dead-center point; to close 10 degrees after the dead-center point.

This adjustment will give better results than when the valves open and close at the dead-center point.

It is true that a gas engine acts during two strokes as a pump and that the valves of a pump should close at the end of the stroke. But it is a well known fact that in a gas engine it is important that the mixture is, as far as possible, free from exhaust gases, or else there will be slow combustion, which may cause backfiring if the cylinder head is not free from dead spaces. By adjusting the valves as mentioned herewith there will be a better clearing of the cylinder, if the engine is well constructed, which means a better mixture, and this is of more importance than the very small loss of mixture, if any, produced by opening and closing the valves a little earlier and later.

As mentioned by Mr. Tilden, it is important that the time of ignition may be changed while the engine is running. It should be possible to ignite the mixture from 50 degrees ahead to 20 degrees after the dead-center point, the latter adjustment being used for starting the engine.

Harry A. Meixner.

Brooklyn, N. Y.

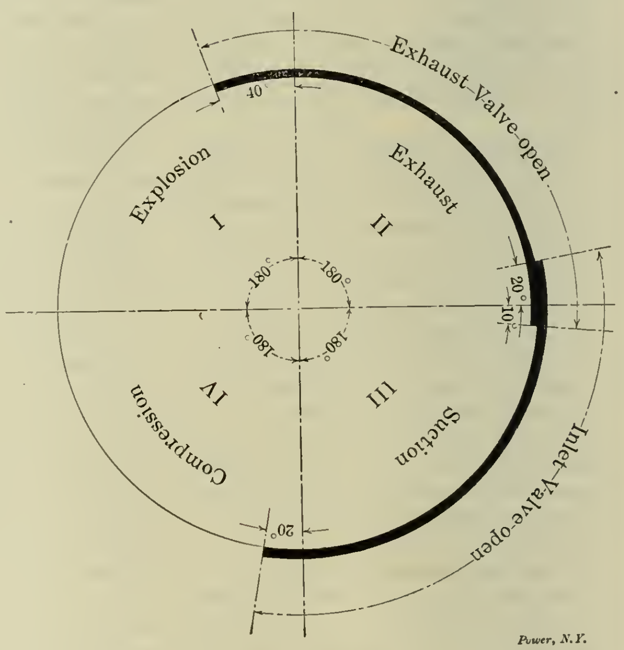

FIG. 2

Improvement on Low Water Alarm

The low water in the storage tanks located on the roof of the factory was rather difficult to account for when the insurance inspectors made their visit. After promises had been made to keep a closer check on the actual amount of water in reserve, a careful inspection of the low-water alarm was made, with the idea that the trouble came from this source.

A construction similar to Fig. 1 was in use. This consisted of a float connected to a stem, to which was secured a brass disk *A* which made contact with the two springs *B B*, when there was an absolute

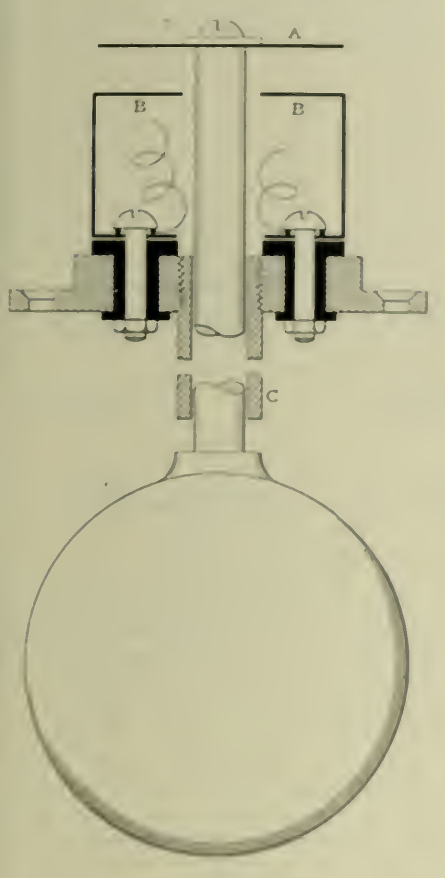

FIG. 1

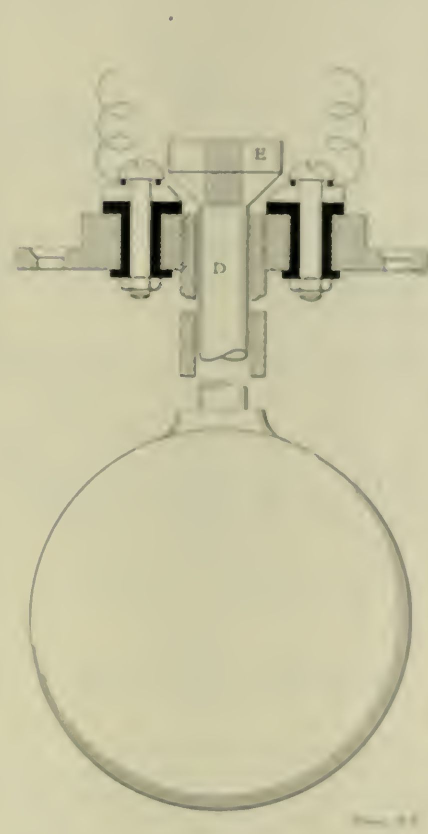

FIG. 2

alinement of the top of the springs. The guide pipe *C* was supposed to make contact probable and if one of the springs had not become bent the scheme would have worked intermittently, with fair results.

However, the design seemed so hopeless that a few changes were made, as shown in Fig. 2.

The rod *D* was threaded at the upper end and a brass cone *E* attached. The two springs *B B* were discarded and two segments of a circle were made of brass and attached to the fiber cross shown in the section in black. The action now became much more positive, as the cone *E* wedged into position and made contact with both of the segments, and there was no possibility of any of the parts getting out of order.

The scheme has given perfect satisfaction and the inspectors have since found a tank full of water on their rounds of inspection.

Lubricants for Cylinders

In reference to John M. Sewell's article on the above subject, I should like to make a few remarks, partly as a friendly criticism and partly to enlighten his views.

A few years ago the chemist dominated the lubricating-oil trade, and oils were judged by certain physical tests made on them. The tests were usually made for gravity, flash, viscosity, acid, etc. Actual results on engines so constantly contradicted the chemists' ideas that Henry M. Wells and myself began an investigation and were fortunate in obtaining the assistance of scientifically trained men in the Manchester University engineering department, where a system of research work was carried. Some extremely interesting results were obtained.

One important factor was made clear in this research work, viz., the chemists' tests were useless in selecting a good oil or the best oil out of a number designed for any given purpose. Of course, gravity had no value at all, and when viscosity was found for high temperatures, practically all cylinder oils had the same viscosity at, say, 400 degrees Fahrenheit. At 600 degrees Fahrenheit they all became thinner than water.

The flash point also appeared a poor factor for classing oils as to quality. The flash is found under ordinary atmospheric conditions and pressure, but when an oil is placed under considerable pressure and in the presence of steam at a high temperature, conditions are changed and consequently the flash point becomes of exceedingly doubtful value. It was found, on examining oil and deposits taken from steam engines using high-pressure and superheated steam, that no cylinder oil decomposed, even at over 700 degrees Fahrenheit. This is not the place to go thoroughly into these or other factors, and they are merely mentioned to show that the chemists' ideals are not the engineers'.

In regard to Mr. Sewell's claim that pure mineral oils are best for cylinder lubrication, I believe I am correct in stating that practically all the best cylinder oils are mixed with oils that are not mineral. Pure hydrocarbon oils have had a fashion, in name at least, but I thought it had completely died out, for oil manufacturers enjoyed the joke too much. The acid bogey crops up now and then, but there are bad workmen in most trades. Further, I ventured to state that practically all mineral oils contain acid and no inconsiderable quantity of it, either. I have certainly seen more damage done by such acid than is done by badly compounded cylinder oils containing decomposed animal or vegetable fats.

In conclusion, I would point out a slight oversight on the part of Mr. Sewell, when he mentions that a gas-engine oil must have a high fire test and be a pure mineral oil. The temperatures in a gas engine are enormously higher than in a steam engine, and yet we use on the gas engine what is really only an engine-bearing oil with a flash point considerably lower than any steam-cylinder oil. A steam-cylinder oil with a high flash point would be useless on a gas engine, and the gas-engine oil with its low flash point, as compared to a steam-cylinder oil, would be useless on a steam engine. Flash point, therefore, has no influence. As regards gas-engine oil being pure mineral, it is quite possible that such oil is used, and probably successfully, in some cases, but the great majority of gas engines use a compounded oil containing other ingredients than mineral oil. Experience seems to point to the fact that such mixtures are a necessity for successful lubrication of a gas-engine cylinder.

Kerosene as a Scale Remover

Mr. Mellen set forth his views regarding the use of kerosene for removing scale from steam boilers. Evidently, Mr. Mellen did not go very deeply into the properties of kerosene, or he would not have assumed that the "150 degrees" on a barrel of illuminating oil implies that that is the point at which it will vaporize. If the barrel contained gasolene the "150 degrees" would mean the point at which it would vaporize, but for kerosene the vaporizing point is 338 degrees Fahrenheit and upward, so that Mr. Mellen's conclusion that kerosene in a boiler passes off in the form of vapor long before any steam is used from it is not true, unless the pressure in the boiler exceeds 100 pounds. As the pressure on the boilers in the case he had in mind was only 20 pounds, it is quite evident that the kerosene did not pass off in the form of vapor.

I also think that Mr. Mellen is inclined to condemn kerosene too strongly as a scale preventive. Where used with intelligence it seems to give excellent results. The first application of the oil should, if possible, be made while the boiler is idle, by inserting from 3 to 6 quarts of oil, then filling the boiler with water, heating it to the boiling point and allowing the water to stand in the boiler a week or two before removal. The oil should then be added in small quantities (2 to 4 quarts per week) when the boiler is in actual use.

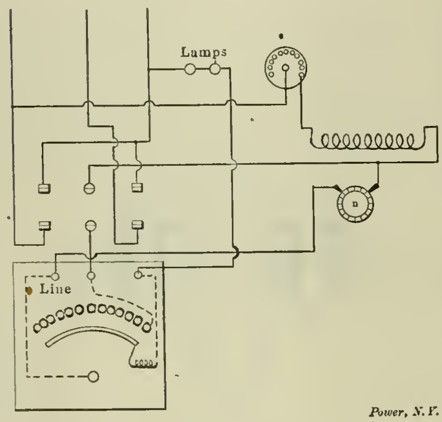
Mr. Hull's Emergency Motor Connections

Referring to Fig. 1 of C. V. Hull's interesting article on page 763 of the April 27 number, I should like to suggest that the seriously objectionable feature of connecting his field winding directly to the line could easily be avoided by making the connections as shown in the accompanying diagram. This not only compels the operator to open the field circuit every time the armature is disconnected, but it causes the lamps to indicate which voltage the motor is running on, by burning dimly or brightly, and it eliminates one of the wires from the field winding to the main line, one terminal of



MR. MALCOLM'S DIAGRAM

the field winding being connected directly to one armature terminal on the motor, as usual.

George W. Malcolm.

Brooklyn, N. Y.

Gas Engine Back Firing

In making tests, in the works, of four-cylinder vertical gas engines considerable trouble was experienced with back-firing. This would occur at no load just the same as when the brake was on up to 100 horsepower. It did not occur on the compression stroke, as they often do, but on the suction stroke. If it had occurred on the compression stroke it would not have been heard in the air pipe; at least, not so loud, as all the valves are shut.

As the engines were only just erected, the trouble was not due to incandescent carbon deposit, but it was thought it might be due to burs on sharp corners getting red hot. Care was therefore taken to clean everything and round off the holes to the indicator cocks, etc. We started up again, but things were no better, the back-firing occurring with annoying regularity. Just then the producer was put out of commission owing to a damaged lining. We turned the town gas over to the engine and it ran as nicely as could be desired; no back-firing occurred at all.

By the time the end of the test was due the suction producer was all right, so we turned the gas on to the engine again. Back-firing occurred, however, as loud and as often as before. This showed that either the mixture or the gas was at fault. We twisted the air cocks to all positions and got a very slight improvement by more air. Next I turned off the steam a little at the producer and the improvement was considerable. I then turned it off by degrees still more, taking care that the generator did not heat up abnormally, and soon the back-firing ceased altogether.

Now, from what I have read of the theory of the production of gases, I remembered seeing it stated that there are some mixtures of oxygen with hydrogen that are explosive at comparatively low temperatures. So I think that when I turned off the steam the gas that was coming through before was modified so that these mixtures were not in it. I should, however, like to read another opinion about this. If it is so, then the hot gases remaining over from the exhaust stroke would easily light back the fresh gas when the inlet opened.

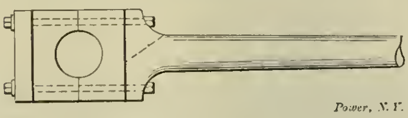
As this case cannot be unique the cure may be of use to others.

John S. Leese.

Manchester, Eng.

Cause of an Engine Wreck

One morning recently a 400-horsepower tandem compound engine, belted to a generator and running noncondensing, with full load and a gage pressure of 135 pounds, was running smoothly, when the top lug on the connecting rod next to the crank brasses broke as shown in the illustration, wrecking the engine. When the lug broke, the brasses pulled apart at the top when the engine was taking the pull, allowing the connecting rod to



CAUSE OF ENGINE WRECK

drop to the floor, after bending the lower bolt in a segment of a circle.

When the connecting rod dropped to the floor the piston hit the cylinder head of the low-pressure cylinder, cracking the low-pressure piston. The crosshead shoes were detached from the crosshead and shot out on the floor. After the load had been taken off, the flywheel and generator ran for about 25 minutes.

Kerosene Oil in Boilers

I have taken charge of boilers which were badly coated with a hard-lime scale and have removed it very effectually by the use of kerosene. I would not, however, recommend the use of kerosene indiscriminately, for if the water to be treated carries a quantity of vegetable matter it is liable to be muddy. Other boiler solvents would be better, but a hard-lime scale that cannot be removed by other solvents can be moved by an intelligent use of kerosene. If a boiler is excessively scaled there is some danger from the use of kerosene, as it will undoubtedly find the weak places in the shell and tubes and is liable, in removing the scale, to start a leak. In order to obtain the best results it is necessary to put the kerosene into the boiler before filling it, as the oil will then float on the surface of the water, the entire surface of the shell and tubes will be covered and if there is any scale, the oil will work underneath and detach it from the iron. A practical demonstration of this can be obtained in the case of an old bolt, the nut of which, however rusty, can readily be removed after a liberal use of kerosene. The usual grade of kerosene oil will vaporize at approximately from 115 to 125 degrees, the difference being relative as to whether the vaporizing is carried on in an open or closed vessel. Taking the average point as 120 degrees, it is certain that feeding kerosene, drop by drop, into the feed water is useless, especially if a heater is placed between the feeder and the boiler, as it would be a very poor heater which would not heat the water to more than 120 degrees, and as steam at even 80 pounds pressure, absolute, would have a temperature of 292 degrees, there remains 172 degrees in excess of the vaporizing point of kerosene. So it appears that the only method of obtaining satisfactory results is by putting the oil into the empty boiler.

CHARLES H. TAYLOR.

Bridgeport, Conn.

Arranging a Water Column

A short time ago the writer had occasion to visit a fellow engineer and, while being shown through the plant, noticed a little feature that may be of interest. Everything was in order and the engines running nicely, but the water glasses on the boilers were in the wrong place, and it was necessary to keep a light hanging near them all the time. I suggested the remedy shown in the accompanying sketch.

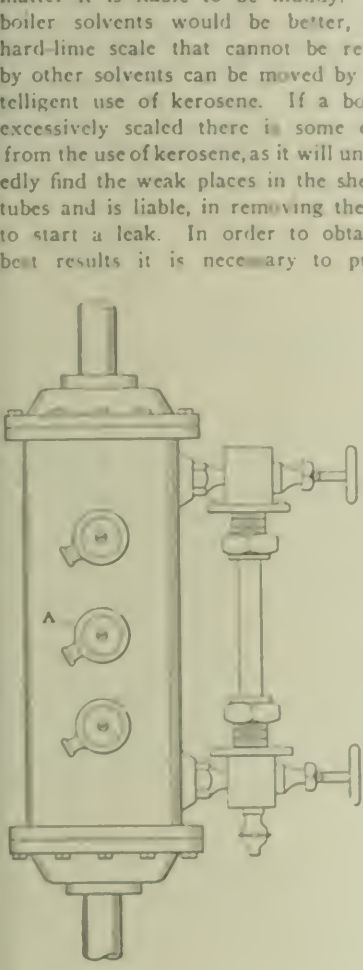

FIG. 1

FIG. 2

In Fig. 1, the water column is shown with the try cocks in front at A, also the water glass, which could not be seen at a short distance from the column to the left. Fig. 2 shows the same water column turned one-quarter around to the left, bringing the glass to the front, but putting the try cocks B too close to the breeching door of the boiler. By disconnecting the water column from the piping and turning it upside down, it changed the position of the try cocks shown at B to that shown by the dotted lines, at C. It will be noticed that they are in an inverted position. They were given one-half turn each, which put them in the correct position. In making this change it was necessary to transfer the water-glass shut-off valves so as to have the gage valve J at the bottom.

C. W. DUNLAP.

Depew, N. Y.

Increase of Salary

In answer to the question propounded by Mr. Mitchell, I should most certainly ask for an increase of salary, as the employer shows by his actions that he will not give it until asked. My way would be to show him where and how I had saved him money and then ask him if I was not entitled to at least part of the amount I had saved him. If he were the right sort of a man he would grant it; if not, there is only one way to do, and that is to look for another situation where your work will be better appreciated, and when secured, leave in a square and fair way. The only argument one can use with some employers is more pay or a new man, but I do not believe in the use of it until peaceful persuasion has failed.

It is a hard matter to decide this question when all the facts are not known, but it looks to me from those given, that if the company mentioned could pay its former engineer $15 per week the present one under the circumstances ought to get that amount, or more, without asking for it.

There are a large number of employers who know very little about a steam plant or what is going on there, and as long as the wheels keep turning and the bills for fuel, supplies and repairs are not too high, will never give it a thought. This class of employer will not give an increase of salary unless it is brought to his notice with good, strong arguments and facts. I take it from the information given that the engineer has kept a record of his plant and knows somewhere near the cost of operation, and if so he has one good, strong, convincing argument in his own hands.

Most employers, if approached in the right way and the matter is put up to them in a business-like manner, will meet you more than half way and will either grant your request or give good reasons for not doing so, in such a way that there will be no hard feelings. But walking into a man's office and informing him that "I have saved you so much money, or, the plant has cost you less money to run under my charge than under my predecessor, and I want the same or more salary than he got, or you can get another engineer tomorrow morning," is not the right way to go about it, and will lead to hard feelings and cost you your situation.

Present the facts of the case as you see them, give him to understand that you think it is right you should get an increase, and also that there will be no hard feelings, only disappointment, if you do not get it, and then you will know the road open for a second attack if needed. Use diplomacy, for it pays in the end.

W. E. Sargent.

Franklin, Mass.

I should say that the engineer referred to certainly had the right idea about "showing his employers by his work that he was worth all they could afford to pay," but unfortunately he was the right man in the wrong place, as he was receiving $200 per year less than a former man, while saving his employer $2400 per year in expenses.

Few employers are willing to increase a man's pay voluntarily, however good he may be, but let him hang on as long as he will, and when he tires of the conditions under which he is working, and desires to leave, he is told that he is a good fellow, along with a lot of other "gush," and perhaps if he can be persuaded to stay, a little "satisfier" is attached to the pay check, and he blushes when he gets it. He is a good fellow, though, and he stays. It seems to me that the man who really knows and does things is the man who gets the little plum, although we desire to believe the reverse.

Some time ago an engineer was told by the superintendent that since he had taken charge "things had been going 100 per cent. better;" but a short time afterward, when this same good engineer asked for an increase in salary, he was told that there was no chance for any raise. This engineer was making a good saving, but he didn't get any of it.

If a man can better conditions or save his employer dollars, I see no reason why he is not entitled to a portion of the saving, and if he cannot get it without the asking, he should ask. He will be turned down enough at that. My experience has been that I never get what I do not ask for.

Some large manufacturers give their employees a portion of what they save the concern. This is based on the premium system, but the giving of a portion saved could be carried to practically every department where capital and labor meet.

Yes, ask for more salary if you conscientiously think you deserve it, and know the reason why, even if you do not get it. Hold up for your just dues, for no one respects a weakling. The good man too oft gets the flowers after he is gone

L. Earle Brown.

Ensley, Ala.

The question of requesting an increase in salary seems to me to be one not rightly classified by the word "proper." An engineer, or anyone else, in fact, is employed on the basis of his being able to produce results. If he can do this, his employment may be considered "proper," if you please, but there is no real significance in such a designation.

In the case of the engineer who had shown an operating saving of $50 per week over his predecessor, there should not only be no hesitancy in his asserting his right to an increase of salary, or an amount at least equal to that of the other engineer, but rather he should receive an even better salary than the other engineer, in proportion to the increased savings. The employer who does not appreciate an engineer who can save $50 per week over the operating cost which obtained previous to his taking hold will never give an increase unless it be asked for, and probably then only when he sees that he cannot otherwise hold the engineer. Again, an operative who can show such saving does not have to work at a lower salary than one who cannot, and if his salary does not increase as a natural result, it will be increased by someone else. Wide-awake employers are on the lookout for efficient engineers.

It is a modest principle not to ask for an increase of salary, but a dollar is a dollar, and the man who does not sell his labor at its highest market value, but conscientiously keeps quiet and wonders why his employer does not raise his salary, may be a long time waiting. The employer who wants real live men is not hunting cheap ones.

F. E. Lister.

Brooklyn, N. Y.

As a rule, a man will always work for the same wages he started out at, if he does not ask for more. I have always made it a point to earn more for the employer than I was receiving in wages, and I have gained my point, as I have never been refused a raise when I asked for it. I think before a man asks for an increase in salary he should consider very closely whether he is worth enough to his employer to warrant the raise. No man with ordinary intelligence can work at the same business any length of time without being worth more to his employer.

Employers will hire just as cheaply as possible, no matter what you are worth to them. I think it every man's duty to himself and family to ask for a salary to the extent of their actual worth to their employer, and if the employer does not then concede to what the employee asks, the employee should be prepared to quit his job and go where he can get what he is worth. Most employers know pretty nearly what you are worth to them after you have worked for them awhile.

The most important point is, to be sure that you are fully worth to your employer what you are asking for, and if you get the raise, bend every energy to make good and prove to him that it is a good thing for him that he conceded to your wishes.

Monroe Johnson.

Emmetsburg, Iowa.

I should say that the engineer has good grounds to ask and expect to receive pay even greater than the former engineer had been getting. I think it is a mean business to pay less to a good engineer who does better work than the former engineer.

Edward Anderson.

Stevensville, Mont.

By all means ask for an increase in salary. The average engineer piles up fortunes for men who never toil at productive labor, and yet imagines he is in duty bound to work for just what salary his boss may choose to give him. Try to get an increase in salary, and lay it aside, for the day will surely come when the "boss" will say: "I don't need you any more, you are too old."

Astoria, L. I.

Exhaust Release Valves

Is there a Corliss valve gear which releases the exhaust valves from the control of the eccentric? If not, would there be any gain, instead of connecting the exhaust-valve rods directly to the crank, by connecting them to the dashpots by a bell crank and rod, similar to the way the admission valves are connected, with a fixed trip that will detach the hook after the valve has come to the end of its travel, and immediately upon the release of the exhaust valve, the dashpot would bring the valve back to its open position, thereby getting quicker release later in the stroke than is practicable without the release?

Would the small gain in efficiency be offset by the increased first cost and maintenance? I should think that in a large slow-speed Corliss engine these few extra complications would be offset by the increased efficiency.

W. A. Fullgraf.

Ottumwa, Ia.

What Knocked the Cylinder Head Out?

Under the heading "What Knocked the Cylinder Head Out?" W. A. Hamlin reports in the January 19 number, page 168, an accident to an Atlas automatic engine and gives as the probable cause the catching of the "outer" piston ring in the head-end counterbore of the cylinder.

I wish to take exception to this diagnosis of the case, as the design of the piston and cylinder make it untenable, as I will show.

Mr. Hamlin says that the packing rings consisted of three sections, and according to that the piston must be 11 inches or less in diameter, as larger piston rings have four sections. These small pistons f the Atlas make have only one packing ng, ¾ inch wide, and Mr. Hamlin's eference to the "outer rings" must therefore be taken as the outside, that is, head nd lap or tongue of a ring section.

The sections of the ring are arranged s shown in Figs. 1 and 2. There are no rass bushings, but radial holes are drilled to the piston head to receive the spiral rings and brass keepers. To hold the ston ring below the surface of the pisn head, while the piston is being entered to the cylinder, ¼-inch holes are drilled r retaining pins, going through the head d flange, the center of the ring section, d ending in the crank end flange of the

FIG. 1

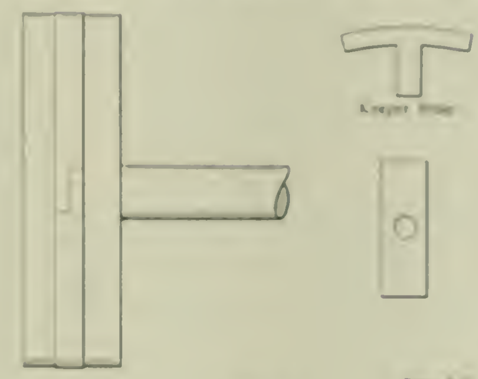

FIG. 2

ston head. These pins are removed hen the piston is in place to allow the g to bear against the cylinder bore. he ring is kept from turning by small ns, which are driven into the inside face the ring sections and engage the epers.

Suppose the ring is placed so that the epers are in the centers of the sections, Mr. Hamlin states, then the length of e keepers, viz., 2 inches, and their being ld in a radial position would prevent e sections from rocking. The distance tween the inside edges of the two counterbores is ⅛ inch more than the stroke the engine, and a ¼-inch ring can avel only 3/16 inch over the edge of the unterbore on each end, making it impossible for the ⅛-inch tongues of the ng sections to catch, however the ring ight have been placed.

Mr. Hamlin says that the velocity of the wheel pulled the wrist strap apart, rrying the crank and connecting rod ound, the connecting rod striking the osshead, knocking it through the crankd cylinder head and piston through the ad-end cylinder head.

I think the steam sent the disconnected osshead and piston much faster and with ore force through the cylinder than the nnecting rod could. The inertia governor certainly gave full steam as soon as e disconnected shaft slowed down, but e connecting rod, besides being too short ithout a strap, was much too slow to do

There must have been another cause of the accident. A liberal dose of water is the nearest I can think of.

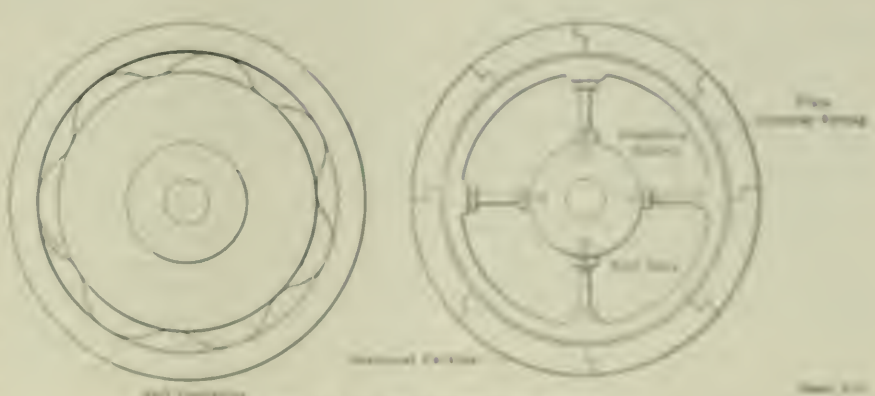
Self Centering Pistons

I recently had an experience with a salesman who was introducing what was claimed to be a self-centering piston, for which great claims were made regarding the economical use of steam; in some particular cases as high as 10 per cent. was guaranteed.

This piston appeared to be nothing more or less than one of the old types with the packing rings somewhat revised, the idea being that the piston was centered and the rings held to the walls of the cylinder by means of a crimped spring extending around the bull ring and underneath the packing rings, as shown.



DETAILS OF SELF-CENTERING PISTON

While this method may hold the packing rings out to the walls of the cylinder it appeared to be far from a self-centering piston, owing to the fact that the spring at the bottom was compelled to carry the entire weight of the piston. This weight undoubtedly compressed the spring, thereby allowing the piston to fall so that it was not exactly centered, and it also would allow the piston to lift up and down at each stroke, possibly not to any great extent at first, but pistons that are running in this condition very rapidly wear and conditions become worse.

A short time ago I had an experience with one of these so-called self-centering steam-expansion kind of pistons, in which the rings were let out by the steam pressure. While this method may work quite successfully when first installed, it very soon becomes otherwise. In this case the steam was admitted to the under side of the rings, thus forcing them to the under side of the cylinder.

If the load is always kept the same and the cutoff at one particular point, it might work, but suppose that after six months or a year of running the load should be decreased, this would make an earlier cutoff, and as the cylinder had become worn larger on each end, owing to the action of the steam, the result would be a serious leakage. When the cutoff was at one particular point the rings were subjected to the full pressure of the steam until this point of cutoff was reached. After this point had been passed the rings were simply held to the walls of the cylinder by the expansion of the steam which was rapidly becoming less as the end of the stroke was neared. This inequality of pressure resulted in the wear of each end of the cylinder becoming larger, and as no provision had been made for centering the piston it necessarily was down on the bottom all the time. Of course this wear in effects also allowed the piston rod to ride on the bottom side of the packing in the stuffing box, thus destroying it, causing frequent packing.

It also caused a poorly running crosshead, as when the piston is out of center, and in some cases I have known it to be as much as 3/16 inch low. In such a case it is impossible to insure a good running crosshead, owing to the fact that the rod is continually out of line, and any attempt at these adjustments must inevitably result disastrously to the crosshead or the guides.

A good sectional packing with facilities for adjustment, combined with a good intelligent engineer, are to my mind the best combination obtainable.

Will the Load on the Bolts Change?

In the March 30 number, page 609, G. A. Glick submits a problem entitled: "Will the Load on the Bolts Change?" Mr. Glick's Figs. 1 and 2 are reproduced here. Fig. 1 represents a steam cylinder and cover having no gasket between them, the joint being ground and made up metal to metal. Fig. 2 represents the same cylinder and cover, the joint being made up with a gasket between the two faces, as shown.

The area of each cylinder is 120 square inches and each cylinder cover is fastened on by 12 stud bolts and nuts. Each nut is screwed down tight, until each of the 12 studs is under an initial tension of 1000 pounds.

The question asked is this: If steam is admitted to the cylinder under a pressure of 100 pounds per square inch, will the tension in the stud bolts in either case increase, decrease or remain the same? And in each case what is the total tension in pounds on each stud due both to screwing up the nuts and to the internal fluid pressure in the cylinder?

From the foregoing we get: Number of bolts times the tension in each bolt equals

$$12 \times 1000 = 12,000$$

pounds, which equals the total tension in the 12 bolts, or the pressure tending to close the joint.

In Fig. 1 this 12,000 pounds represents the total compression on the metal at both faces of the joint, and in Fig. 2 the compression on the gasket between the two faces.

The total internal fluid pressure in the cylinder tending to open the joint in each case will be the area of the cylinder times the pressure per square inch, which equals

$$120 \times 100 = 12,000$$

pounds.

Some engineers are of opinion that when the pressure is in the cylinder the bolts are stretched to an extent sufficient to relieve the compression in the gasket or packing, thus relieving the bolts of the initial tension caused by the elastic thrust of the gasket against the two faces of the joint when screwing down the nuts.

Where rubber or any elastic gasket or packing is used between the flanges to make a tight joint, the gasket is compressed or flattened to some extent and the bolts may or may not be elongated or stretched, depending on their rigidity and the tension in each bolt when tightening up.

Any farther extension or elongation of the bolts due to the internal fluid pressure may not affect the initial tension to any great extent, as the pressure within the cylinder may not be great enough to cause an extension or elongation in each bolt sufficient to relieve the compression in the gasket; or, in other words, if the extension of the bolts due to the internal fluid pressure is small compared with the compression of the gasket, the ultimate load on each bolt may approach the following value, namely: The initial tension due to screwing up plus the tension caused by the internal fluid pressure in the cylinder.

In Fig. 2 a tension of 1000 pounds is produced in each bolt by screwing up. When steam at 100 pounds pressure per square inch is turned into the cylinder an additional load of

$$\frac{120 \times 100}{12} = 1000$$

pounds is produced in each bolt (the area of the cylinder being 120 square inches and there being 12 bolts).

The total or ultimate tension in each bolt is, then, somewhere in the neighborhood of

$$2 \times 1000 = 2000$$

pounds, provided, of course, that each

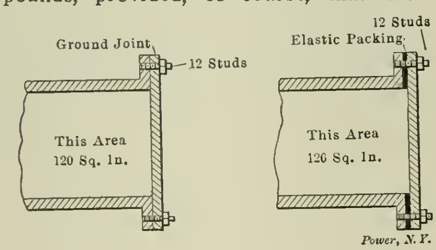

FIG. 1 FIG. 2
(Reproduced)

bolt does not stretch sufficiently under the pressure in the cylinder to relieve part or all of the outward elastic thrust of the gasket, or, as it is called, the compression of the gasket.

If, however, in the case cited the extension of each bolt diminishes in part the compression in the gasket, the exact ultimate load per bolt cannot be determined without first knowing the exact outward thrust in pounds exerted by the gasket at the time the pressure is in the cylinder.

This, it seems, would be a very hard matter to determine with any degree of accuracy. Then, again, it is reasonable to assume that most gaskets after having been subjected to high compression and heat for any length of time would attain a permanent set, thus necessitating the going over and tightening up of the nuts several times after renewing a gasket, in order to keep the joint tight against the internal pressure. This is absolutely necessary at times, until the gasket becomes permanently set, and at first thought may give rise to the idea that the pressure within the cylinder has caused a permanent set in the bolts or studs, when in reality the gasket is at fault.

Where rigid flanges are bolted together metal-to-metal, using no gasket, as in Fig. 1, the conditions are somewhat different.

In this case it is very probable that any slight extension of the bolts due to the pressure within the cylinder would relieve the initial tension due to screwing up, and the ultimate load per bolt would be either the tension due to screwing up, or the tension produced by the internal steam pressure, according as the former or the latter is greater. In Fig. 1 these forces are equal, therefore the ultimate load per bolt should be in the neighborhood of 1000 pounds, provided the internal fluid pressure causes a slight extension of the bolts relieving the initial tension.

Any additional pressure in the cylinder over and above 100 pounds per square inch would thus add to the tension in the bolts.

Where the connecting flanges are deflected by the bolts the case would be similar to Fig. 2, where a gasket is used between the faces of the parts to be connected, the deflection of the flanges acting in a manner similar to the compression in the gasket, exerting an outward thrust against the bolts.

In any case, to determine to just what extent the bolts are strained in each of the foregoing cases, the relative rigidity of the bolts and the parts they connect must be known, as well as the elasticity of the gasket or packing.

William F. Fischer.

New York City.

Worn Dashpot Repair

The dashpot on the low-pressure sid of one of our engines was badly wor and would pound when the receiver pres sure changed. I persuaded the chief t let me send it to a local machine shop along with Mr. Ferguson's sketch, whic was published in a recent number. H gave me permission, provided I paid th bill if it did not work. In a week i came back, with what looked to be a goo job. I connected it up and started th engine. The noise was bad before, but i was a hundred times worse with the ne ring. When the valve was opening th plunger would grind and chatter an when unhooked the plunger would nc drop until it was forced down by the clo ing shoulder.

I took out the ring and filed the shar edge off the top. That helped some, b letting down a little oil, but it would n close the valve, no matter how the a valve was regulated, and as it pounde so that I was afraid I might have to pa for a new jim-crank lever, I took it ou

The chief ordered a new plunger. came and we fitted it, and everything we nicely. The laugh is on me, as I had pay $2.80 more for the repair than t new plunger cost. I am a little poor but a whole lot wiser.

Thomas Sheehan.

Pittsfield, Mass.

Setting the Slide Valve

Every engineer believes he knows how set the simple slide valve, but few can ll at what point of the stroke the exhaust opens or closes. I have found many ide-valve engines using more steam than ey should, although in each case the lve was set by the stereotyped rule of: Place the engine on one of its dead cenrs with the eccentric rolled 90 degrees advance of the crank and enough rther to get the required lead. Then roll e engine over to the other center and if e lead is the same the valve is properly t." Easy, isn't it? We are often told at it is not practical to advance the centric to obtain a cutoff earlier than or ¾ stroke, on account of the excesve compression.

It is the writer's experience that the ily way to set the slide valve properly r highest economy is to remove the lve from the steam chest and, taking a nall try square, place one leg of the uare on the valve seat near the edge of ch port, in turn, and draw a mark forard on the bottom side of the steam est with a sharp scribe, so that the exact sition of the ports can be seen after the lve is back in position. Before putting e valve back in position, however, take e try square and, beginning with the ce of the valve, square around to the ck, making marks so that the position the edges of the hollow steam passage in be seen when the valve is in position.

Next give the valve, say, ⅛ inch lead, ith the engine on one center, and then rn to the other center, when if the lead the same the eccentric rod and valve em are of the proper length. After aking a mark on the crosshead, roll the igine in the direction it is to run and by oking at the marks in the steam chest id on the back of the valve it is easy to ll the exact point of exhaust closing id opening. By marking the slide where ie mark on the crosshead stands when ie exhaust is just closed, and turning the igine over on the return stroke, and aking another mark on the slide when ie exhaust is just shut, one can tell by easurement if the compression is equal.

The eccentric should be set with as uch regard to the exhaust opening and osing as to the outside lead. The writer as greatly improved the economy of veral slide-valve engines by cutting out me of the excessive inside lap. It is not hard thing to do and can be done best a milling machine or planer, although can be done with a common chipping hisel. Care should be taken not to take ut too much at a time if the engine is to e run condensing, as a condensing enine should have an earlier exhaust closre than a noncondensing engine.

Readsboro, Vt.

Cost of Treating Boiler Feed Water

I wish to make a tardy correction of an error of mine in connection with an article that appeared in the number of March 23 on "Proper Treatment of Boiler Feed Water," page 555, column 1. The cost of treatment for 70,000 gallons, instead of 1000 gallons, at the present market price of lime and soda ash is 66.5 cents. This would make the cost per 1000 gallons 0.95 cent, which is more reasonable. Our tanks are of 70,000 gallons capacity and I neglected to reduce the cost to the 1000-gallon unit in spite of the fact that I was reminded that the cost of treatment was excessive.

A. J. Boardman

Indianapolis, Ind.

Boiler Efficiency

The letter of A. Bement, in the issue of March 16, shows that he uses the term "boiler efficiency" in a different sense than it has been used by all the authorities on steam boilers for the past forty years, and in a sense that is not in harmony with the meaning of the word "efficiency" as applied to other things than boilers. The general meaning of the word is a fraction denoting "output divided by input," and generally it is not so much a function of a machine itself as of the conditions under which it is used. It is therefore not a constant quantity for any particular machine, but a variable quantity. Thus in a centrifugal pump working under different heads, it ranges from zero, when the head is too great for the pump to overcome the static resistance, up to possibly 75 per cent., when the head is something less, and down to zero again when the head is zero, the variation of efficiency being represented by a curve. In an electric generator the efficiency also varies with the load.

In a steam boiler the efficiency is zero when the rate of combustion of coal is sufficient to provide only for the loss by radiation; it rises to a maximum when the rate of driving is in the neighborhood of three pounds of water evaporated per square foot of heating surface per hour, and usually falls off rapidly when the rate is above four pounds.

Mr. Bement says "the efficiency of a boiler as a heat absorber cannot be altered without changing the design of the apparatus." If he will consult the records of the tests of 13 boilers at the Centennial exhibition in 1876 he will see that a change in the rate of driving changed the efficiency in every case. In Donkin and Kennedy's book on boiler tests he will find vast differences in the efficiency of one shape of boiler, viz., the Lancashire. The efficiency of a boiler is not a constant depending on the design, but a variable depending on the quality of the coal, on the method of firing, on the rate of driving, on the air supply per pound of carbon and on the loss by radiation. The Geological Survey is, therefore, perfectly right in its use of the term "efficiency."

W. Kent

Sandusky, Ohio.

Bridgewalls in Theory and Practice

In the March 9 number, W. H. Wakeman has an article about bridgewalls in theory and practice. In my opinion the bridgewall, no matter how constructed, cannot prevent smoke or hot gases from going up the stack. As to smoke formation, much depends on how coal is fired and how it is worked after it has started to coke.

The way I fire my boilers produces the least work, very little smoke at any time and an even steam pressure, simply because I never put on green coal with low steam. If the steam gets down I use the bar or a three-pronged hoe and break the fire up, which will soon bring up the steam. Then I lightly cover the fire with green coal. I never use the hoe or slice bar on a green-coal fire.

If a fireman or an engineer wants to make as little smoke as possible, he should not disturb a thick fire of green coal.

William Murray

Philadelphia, Penn.

State Supervision of Boilers

The editorial in the March 2 number on State supervision of boilers treats both sides of the question in a very impartial manner, but one in my place would have leaned just a little toward the manufacturer's contention.

We got a new boiler, and it was needed the "worst way." After it was set up and connected to the main, as per law, that is, with a gate and a globe valve between the main steam pipe and the boiler, we were all ready to start it, when along came the State inspector and condemned one of the valves, because it was not of the outside-screw-and-yoke pattern.

We have the same valve on all the other boilers. It is an automatic stop valve and has always given satisfaction. The company that made this valve did not make one with the outside screw and yoke, but it is making them now, and our new boiler had to lay cold until it got one made.

Now the point is: was the original valve detrimental to the boiler's safety? If so, why don't the inspector make us change all the rest?

Perhaps there is something against the outside-screw valve that I know nothing about, but any information on the subject will be gladly received.

Pittsfield, Mass.

Some Useful Lessons of Limewater

Chemistry of Lime Further Studied by Experiments with Shavings, the Flame of a Candle and with Gasolene, and by Making Acetylene

BY CHARLES S. PALMER

In the last lesson we laid out some work on the chemistry of carbon, and now we will get busy and put some life and meaning into the dead bones of the table, by the simple device of making a few tests that we can see and handle. You remember that the table began with the hydrogen compounds of carbon, on the left and "reduced" extreme, going from the various hydrocarbons through carbon itself; and so on to carbon one-oxide ("monoxide") and, finally, to carbon two-oxide (dioxide), carbonic-acid gas or carbonic anhydride, at the extreme right or "oxidized" end of the table. The typical hydrocarbon to study is methane or "marsh gas," CH_4, and it is a pity that there is no simple and handy method of making this thing in the pure form; but you can get so near it that the difference need cause little worry.

The name "marsh gas" means just what it says. Now that you stop to think of it, you will recall that you have often seen much queer bubbling on the surface of ponds where last year's vegetation is rotting at the bottom. If you should take the trouble to go to such a pond armed with a common fruit jar and a few matches, you could easily stir up some of this gas from the bottom of the pond with a stick; and, if you should collect some of the bubbles in your jar, by the simple trick of displacement in the jar full of water and mouth downward, using the pond as a large pneumatic trough, just as you collected the oxygen and hydrogen as shown in the earlier lessons, if you should do this, you would undoubtedly get a gas which would burn with a faint and almost colorless flame, but with much heat. The gas so collected, and so burnt, is mostly methane or marsh gas, CH_4; and, if you should happen to take along with you a small bottle of filtered limewater, you could pour some of it into the jar, after burning some of the marsh gas, and you would note the white precipitation of your old friend, plain carbonate of calcium, which would tell you that the burnable gas from the pond is something that contains some carbon, just as the formula says, CH_4; that is, the gas is not pure hydrogen, but also contains some carbon, because it gives, on burning, carbon two-oxide (dioxide), the oxidized extreme of carbon. Now, it is interesting to know that when you find a gas that burns with an almost colorless flame, it probably contains some hydrogen, just as marsh gas does, and, just as its formula (CH_4, i.e., C-H-4) says that it does, four atoms of hydrogen. Incidentally, it is interesting to note that this marsh gas or methane contains in each molecule, or in a definite volume, say a pint, more hydrogen than pure hydrogen, H_2 (H-2), does itself.

We have already noted that the carbon-hydrogen compounds, or the "hydrocarbons," are so many that their systematic study is almost beyond the grasp of the beginner; but we can get this one fine clue and guide to them, that is, that in their first acquaintance they are all very much alike in being able to burn. Furthermore, they all tend to burn to carbon dioxide (two-oxide), and this last gas can always be tested by limewater, giving the plain white carbonate of lime. So we will turn at once to several ways of getting and studying these hydrocarbons.

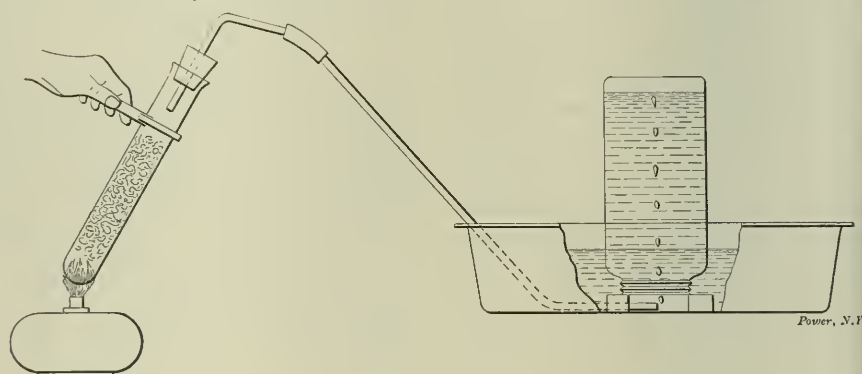

FIG. I

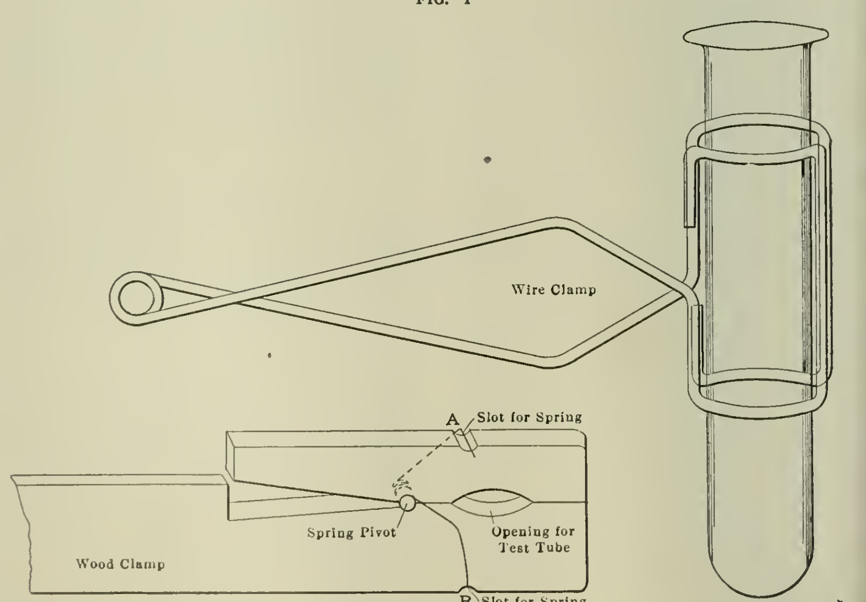

FIG. 2

Getting Gas from Shavings

Suppose that we start with some common wood shavings. Prepare the apparatus shown in Fig. 1. This consists of a common test tube fitted with a cork and a delivery tube leading over to the bottom of your pneumatic trough, with its jar filled with water and inverted, to catch the gas that will come over. Fill the lower three-fourths of the test tube with soft-wood shavings, packed moderately tight. Heat the test tube over any handy source of heat, such as an alcohol lamp, or even over a common lamp—for in this rather dirty experiment, you will not worry if the outside of the bottom of the test tube should get sooty. You can hold the test tube, while heating it, by simple wire or wood clamps, Fig. 2, or you can hold it by a strip of paper, as shown in Fig. 1. If you use the paper clamp or holder, you will naturally grip the test tube at the upper end, for you are going to heat the tube hot enough to get off some wood gas, and the bottom of the tube will naturally get quite hot. Some of this heat will come to the top of the test tube, of course, for it has to pass over, through the delivery tube, to the pneumatic trough.

In this experiment, you do not have to throw away any gas at the start, as you did in making hydrogen, because in this case the amount of air in the whole test tube is so small in comparison with what is to be given off by heating the wood that you can collect every bit of what comes over. But be sure and remember, in this and in every similar experiment where you lead gas off from a hot tube, to *take the delivery tube out of the water before you take the flame from the hot test tube, or before you take the hot test tube away from the flame*, so that the water will not be sucked back to the hot tube by the natural cooling of the hot gas inside. Natural gumption will tell you how to work the experiment, always noting that time is an important factor, and that some things will work in 10 or 15 minutes that might not work in the same number of seconds.

As you heat the tube of shavings, as shown in Fig. 1, about the first thing that you will note is the collection of water from the charring of the shavings. Some of this water will go over through the delivery tube and if it makes the common "water hammer" of condensing steam, you will not be frightened at that, it could not very well do anything else. You will also note the gradual charring of the wood, and pretty soon some gas will begin to collect in the inverted jar in the pneumatic trough. Now, all of this gas is not marsh gas, but enough of it is, and the rest of it is so closely related by birth to marsh gas, that you can think of all of it as being a mixture of several things much like marsh gas. You will also want to note the considerable quantity of water which collects at various parts of the apparatus, testing for it by a test that I will note later. You will also want to save the test tube of charred shavings, to examine it later for the strong acid reaction that it will probably show.

By this time you will have collected quite a jar of the gas from the heated shavings. If the wood is all charred before the jar gets full, remove the delivery tube from the water, take another test tube of shavings, and go on as with the first until you do get a full jar of gas. This gas you will remove from the pneumatic trough, with a card covering the jar and holding it mouth downward, just as you did in the case of the hydrogen. You will burn the gas, noting that it burns in the air, but that the splinter itself is put out in the jar of gas. You will also note the test for limewater at the end of the burning of the gas. The gas will probably not work the "cannon" test, with the small pursuy jar, as in the case of hydrogen, very well, because it is not all hydrogen, nor even all marsh gas, but contains some heavier gases, like ethane, and other things heavier than hydrogen, and perhaps heavier than the air. But collect enough of this wood gas to get at some of its main points. Of course, you

FIGS. 3 AND 4

could make some gas from coal, the yellow bituminous or cannel coal, and there you will have your trials and your surprises, too, so you cannot help learning something. In all these cases you will get some tar, some creosote, and perhaps some acid, as in the case of the wood (acetic acid, or "wood vinegar"). You may also get the odor, at least, of wood alcohol.

THE WONDERS IN A CANDLE FLAME

The next step is to study the candle and here I wish that every reader of POWER could get that matchless sound, clear and sensible book of Faraday's, "The Chemistry of a Candle," and read it. Indeed, it would be worth your while to buy a copy for yourself and put it in your own private library of chemistry. That little book tells you how to study the candle flame; how to examine the different parts of a flame; how to dissect the flame; and how to test the different parts separately. But you can do these things even without the book. First, you want to look at the flame of a common candle. You want to draw the flame, noting its several parts, as shown in Fig. 3.

You will soon see that a candle is a miniature gas factory; that the wick is the retort, where the candle stuff is distilled into gas by the heat of the flame. You will note the elegant and simple way in which the wick melts a little pool of oil about the lower part of itself to furnish itself with a continuous supply. You will also note the neat way in which the candle wick is braided so that, as it burns away, the top curls over to one side, perhaps so well that it does not have to be "snuffed," but burns off its own top. You will note that the top and sides of the wick are surrounded by a small reservoir of unburnt gas, which passes upward and outward to the air to be burnt.

You will also note the strong contrast between the colors of the different parts of the flame. At the bottom and sides of the flame you will see a bluish tint, where the gas, carbon monoxide (one-oxide), is burning, with the hydrogen. You will also note that the excess of carbon (and in such flames there is a great excess of carbon, compared with the available amount of oxygen at hand in the surrounding air) gets left in the first grab for the oxygen, and it has to wait until it gets to the top and outside parts of the flame before it can find its supply to go over to its destiny, carbon monoxide, and then carbon dioxide.

You can show that there is this central part of cool and unburnt gas about the wick of the candle, by holding a piece of common white paper right down flat onto the flame for a moment, when you will get a black ring of charred paper, where the hot outside ring of the flame attacked the paper. The untouched and still white center inside of the black ring on the paper is proof that this cool central reservoir of unburnt gas is there. But, more than this, you can take a short bit of fine glass tubing, as shown in Fig. 4, and actually pipe off some of it, burning it at the top of the glass tube by lighting it with a match or splinter. This gas in the core of the candle flame is worth some time and study, for it holds some secrets of flame that you want to know about.

If you get some of the old-fashioned candles, those that are made from tallow, the kind that smell dreadfully when put out and which smolder for some minutes after the flame is extinguished, you can perform some "stunts" worth doing. For instance, you can not only pipe off this central gas from the core of the flame, and burn it, but you can also see the core of gas and burn it in the open. To do this, let the tallow candle get to burning well and blow it out, noting the stream of unburnt gas which persists in coming off long after the flame has gone out. Now, if you do this in a room where the air is still, so that this current of unburnt gas from the tallow candle is not thrown about but ascends in a quiet, even column of gas, smoky gas that you can see, you can light this column of gas at the top with a burning splinter and the flame will run down the ascending column of gas to the wick, actually re-igniting the extinguished candle. If you have a real tough sample of the genuine old-fashioned candle, so that the ascending column of unburnt gas is so thick that it can be almost cut with a knife, you can make the flame run down as far as several inches from the wick. I have seen the flame run down 4 or 5 inches, and once or twice I have seen candles with such heavy tallow that in a quiet room the flame will run down to the wick as far as 10 or 12 inches. This statement looks like a fish story; but try it and give the tallow candle a chance to see what it can do. The books may try to decry the reality and genuineness of the experiment, and they may say that the column of ascending gas is not pure gas, that it contains much liquid and solid matter in "suspension" in the current of unburnt gas. All that may be; but at the same time, the "fat" column of unburnt gas from the tallow candle may represent very well some of the conditions found in actual experience, where flames seem to travel vast distances, i.e., relatively vast, along gases which are only waiting to be lighted to get in their work.

But there is another side to the study of the candle flame which we must note: The inside of the flame is full of unburnt gas, waiting to seize hold of any oxygen that may be available; hence this part, the inside and the lower parts of the flame, is called the "reducing" flame, because it wants oxygen, and will have it if it is given half a chance. But, the upper and outside parts of the flame have taken on all the oxygen that they want, and still they have the greatest amount of heat, and hence these parts of the flame are called the "oxidizing" parts. I will return to this subject later when we take up some of the points of simple blowpipe analysis. But keep your memory eye fixed on the inside reducing part and the outside oxidizing part of the candle flame. You can catch some of the unburnt carbon in the middle of the flame, or at the top, by holding a cold saucer in it for a few moments.

The Power of Gasolene

There are several, indeed many, other sides to this study of combustible gases, and the subject of gasolene is one of them. If you have not studied this, you will be surprised to learn what a chance for dreadful mistake and accident lies in this simple question of the amount of air that it takes to burn gasolene. Now gasolene is only a mixture of several hydrocarbons, all close cousins to methane and ethane. But in the molecules of the volatile liquids that make up what is sold as gasolene there is so much carbon and so much hydrogen snugly packed away that it is no simple matter to select the

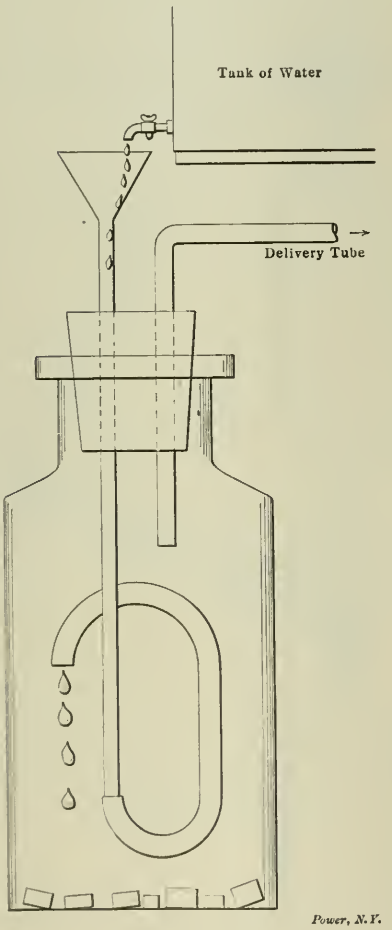

FIG. 5

right amount of air wherewith to burn them and then to mix them well.

Thus, you can pour out a teaspoonful of gasolene in any safe place and light it. when it burns quietly, if lighted at once. But take a common empty tin can, holding about a pint, and pour in the can some five to ten drops of gasolene. Try five drops at first, and gradually feel your way along. Put the cover back on the can, and let it stand for some few minutes, so that the slight amount of gasolene can well evaporate and get well mixed with the air in the can. Now, you want to have a small hole in the side of the can for a "touch hole," to which you will apply the flame when business is ready to commence. You will be surprised to see how much force you will get in this simple explosion. Then, you will go over to the corner, light your pipe of reflection and do some good thinking.

You will begin to have a great respect for those simple formulas that told you all about this sort of thing; only we did not realize what we were tampering with when we read that gasolene, for instance, is made up of C_7H_{16} (C-seven-H-sixteen). Seven atoms of carbon and sixteen atoms of hydrogen tucked away in one molecular handful, no bigger, though much heavier, than H_2 or O_2. You will see that one has got to stop and digest some of these things. You ask: How does it happen that so much carbon and hydrogen can be put in such a small space? How does it happen that such small molecular parcels of gasolene can take care of the oxygen in so much air? For you will find that a very few drops of gasolene will make all the air in the can frightfully explosive; and, still, the teaspoonful of pure gasolene which is unmixed with air will burn quietly. The point to note is, not why it all happens, but what it is that happens. That is what we all need to keep our eyes fixed on, the actual fact. When gases burn with each other, it is not only actual *weights* which unite with each other, but it is also definite proportions by *volume* which control the reaction.

Making Acetylene

Among the many other possible illustrations of hydrocarbons there is one which you really ought to study, both for the fact that it shows the nature of a class of hydrocarbons which are called "unsaturated" and also for the fact that it is made in the rather unusual method of treating a certain substance with water. I refer to the making of acetylene by treating what is called calcium carbide with water. As mentioned in the last lesson, this is used in making the brilliant gas for the powerful searchlights on automobiles and the like. You can easily get some of this substance, but you will have to study a bit to devise and construct a simple form of apparatus in which to make the gas. You cannot use large quantities of water recklessly; nor can you let the whole process take place in the open air; for we want to collect the acetylene as fast as it comes off, and yet add the water in *small* and continuous quantities.

A simple form of apparatus is shown in Fig. 5. This is merely a pickle bottle, with a funnel, and with the lower end of the funnel bent so that it is water-sealed from the outer air. The delivery tube is of the common make. You can get the water seal by putting a short piece of rubber tubing on the stem of the funnel in the bottle, long enough to make a complete bend (Fig. 5). Then you will put several pieces of the calcium carbide, which is a grayish, earthy-like substance, in the bottle, closing the bottle with the cork and setting over the funnel a can of water so arranged that water will drip into the funnel in a set of drops, not a stream, for that would be too much. You can easily control the dropping by making a small hole in the lower side of the can and plugging it with a match, which can be drawn out or pushed in as desired. The gas is collected in the jar in the pneumatic trough in the usual way. But be sure and drive out the air from the bottle, first, as you did with hydrogen. You will test the burning of this acetylene, C_2H_2, by burning, and the residual gas in the jar after burning with limewater.

But the most interesting thing about this gas is that it is made from water acting on calcium carbide. This substance is one of the later additions to our supply of interesting chemicals, and is usually made in an electric furnace. Just why water should be such an active agent in making this gas, acetylene, is more than we can fully explain at this time, but an inkling can be imparted. This substance, water, is a kind of "bank of chemical exchange." Look at the formula of water. It is H_2O. It contains both hydrogen and oxygen. Now if we pay into this "bank" hydrogen, we get back reducing action, but if we pay into this "bank" oxygen we get back an oxidizing action. Farther, if we pay into this "bank" of water both hydrogen and oxygen, we can back both reducing and oxidizing actions. Note the following equation for the reaction of water on calcium carbide:

H_2O Water	+	CaC_2 Calcium Carbide	=	CaO Calcium Oxide Lime	+	C_2H_2 Acetylene

Really, the calcium carbide is a kind of chemical "salt," and a kind which is decomposed by water. So, when the water acts on the "salt," calcium carbide, we get the base anhydride, lime, CaO, and the weak "acid," acetylene, C_2H_2. No one would ever guess that acetylene is an acid, unless he had the advantage of comparison with many other reactions; for acetylene does not act on litmus as the common strong acids do when they turn litmus red. But you can begin to see by comparison that the more one goes from the reducing or hydrogen end of a series of compounds toward the oxygen end, the nearer he gets toward acid properties.

And so as we go from the extreme reduced end of the carbon table, and long before real active acid properties are shown, as we go toward the oxygen end of the table, we begin to get some indications of acid properties. We will consider this strange chemistry more in the next lesson, but this is only a sample of what the chemistry of carbon has to teach us.

One thing that you must do, to clinch some of this, is to test the residue in the acetylene-making bottle with litmus, and you will find that lime is there and can be used just as was the lime in the barrel that you were using several weeks ago. You have got well started on the chemical study of lime, but we shall find that it holds up continually. Make some limewater from this residual lime from the calcium carbide in the pickle bottle, and test it every way you can, for it is the same old friend, to pilot you a bit farther.

The Ambiguous Term "Gallon"

As the liquid measures of the United States unfortunately bear no direct relation to those of England, much confusion is occasioned by the careless use of the term "gallon." Only recently in these columns confusion arose in regard to the amount of circulating water used in a certain plant by a failure to distinguish between the imperial gallon used in Great Britain and the United States standard gallon. For this reason it may be of interest to define the two standard gallons and trace their origin and variations from the early days of English history.

From as far back as the thirteenth century the gallon has been variable. Originally it was intended to be a measure of weight and not of bulk. To carry out this intention to its full extent would have required that every commodity measurable in bulk should have its own gallon, each holding the same weight, with the bulk varying inversely as the specific gravity. This would, of course, have caused endless confusion and early usage led to the adoption of two standard gallons related to each other in capacity as the inverse ratio of the specific gravity of wheat and wine, the latter standard being the wine of Gascony, which at that time, 1225, was a British province. These two standards were supposed to represent the average of the two classes of exchangeable commodities, wet and dry, the ratio referred to being assumed as [illegible].

In 1266 Henry III declared by statute that "an English silver penny, called a sterling, round and without any clipping, shall weigh 32 wheat corns in the midst of the ear, and 20 pence do make an ounce, 12 ounces one pound, 8 pounds a gallon of wine, and 8 gallons of wine a London bushel." In [illegible] a statute of Henry VI gave the gallon a different value, which was based on the weight of water. A ton was the weight of 32 cubic feet of water and the eighth part of a cubic foot, or 216 cubic inches, was taken as a gallon of water. Hence the wine gallon, being enlarged to hold the same weight of wine, became [illegible] cubic inches, and the wheat gallon [illegible] cubic inches.

In the latter part of the fifteenth century (1496), Henry VII provided that a new standard gallon measure be constructed to hold 8 pounds of wheat of 12 Troy ounces each, and in [illegible] the wine gallon was declared by law to contain 231 cubic inches. This is the present United States standard gallon for liquids.

In 1700 the old trouble with the excise officers broke out and led to two legal acts. First, the statute of William III, [illegible], establishing the Winchester bushel and vaguely defining its capacity as 2150.4252 cubic inches, and, second, a statute of the [illegible] Anne, [illegible], which in like manner established the Winchester gallon, specifying it to contain 268.8 cubic inches. Elizabeth constructed the standard gallon of 282 cubic inches, or nearly 8 pounds avoirdupois of wheat, which became the old ale gallon. The Irish gallon, which from 1430 to [illegible], had contained eight pounds Troy of wine, was at the latter date settled at [illegible] cubic inches, but in 1735 was again changed to 217.1 cubic inches for all purposes. The Scotch gallon was no less than 830 cubic inches.

Finally, in 1818, a royal commission was appointed to recommend standard measures, and as a result a bill was introduced in parliament and passed June 17, 1824. This bill was put into operation January 1, 1826, and fixed the capacity of the gallon by requiring that it should contain 10 pounds avoirdupois, or 70,000 grains Troy, of distilled water at a temperature of 62 degrees Fahrenheit and with the barometer reading 30 inches of mercury, stating at the same time the capacity thus determined to be 277.274 cubic inches. This is the value of the imperial gallon now in use in Great Britain, and is the only legal gallon in that country for both wet and dry measure.

In the United States no standard of measure was ever established, the gallon being inherited from Great Britain. Instead of using the British temperature of comparison of 62 degrees Fahrenheit, a temperature of 39.83 degrees Fahrenheit (taken as temperature of maximum density) was proposed by F. R. Hassler of the Coast Survey. The stated legal capacity of the gallon was to be 231 cubic inches and of the Winchester bushel 2150.42 cubic inches. On account of the change in temperature a further adjustment of these capacities was proposed, making the gallon contain [illegible] grains of distilled water at its maximum density at 39.83 degrees Fahrenheit, and the Winchester bushel [illegible] grains. This adjustment made the Winchester bushel of the United States and Great Britain slightly different, and on June 14, 1836, Congress gave legal sanction to these values and passed a joint resolution directing a complete set of all weights and measures adopted as standards to be delivered to the governor of each State.

If this were all and there were only one standard gallon in the United States, as in Great Britain, it would be an easy matter to distinguish between the two, but in this country there are not only the wine gallon containing 231 cubic inches, but also the ale, beer or milk gallon containing 282 cubic inches, and the dry gallon, besides the proof gallon for internal-revenue taxation. The proof gallon is a wine gallon of spirits containing half its volume of nearly pure alcohol at 60 degrees Fahrenheit and is the basis for computing the United States internal-revenue tax. For example, a gallon of spirits containing 40 per cent. alcohol would be 80 per cent. proof, and the number of proof gallons is computed by multiplying the per cent. of proof by the number of wine gallons.

New Hampshire and Minnesota definitely retain the ale, beer or milk gallon of 282 cubic inches; Wisconsin and Connecticut the dry gallon of 282 cubic inches as the legal standard, and Maine definitely mentions the milk gallon as among its list of State standards. The milk gallon is 51 cubic inches larger than the standard gallon used more generally throughout the country. There are thus three standard gallons: the dry gallon derived from the Winchester bushel; the liquid gallon derived from the wine gallon, and the liquid gallon derived from the beer or milk gallon.

In addition to the capacity measurement by volume the legal weight of a gallon of certain commodities has been fixed by statute in some States and in several cases by Congress for certain purposes. Thus in Nebraska 12 pounds of strained honey is a legal gallon. In Kansas 6½ pounds of kerosene and 8 pounds of castor oil, in Ohio 7½ pounds of kerosene and in Indiana 11 pounds of sorghum molasses are all legal gallons of the products named. These legal weights differ among themselves and do not accord with the true volume of one gallon of 231 cubic inches.

In dry measure the standards used have no direct relation to the liquid measures of this country or Great Britain. The fundamental unit is the Winchester bushel, a unit abandoned by England in 1824, but still retained in general use in this country. As previously stated, it contains 2150.42 cubic inches and is about 69 cubic inches, or 3 per cent. smaller than the imperial bushel of Great Britain. The United States dry gallon contains 268.8025 cubic inches, or 1.16365 liquid gallons. Here again conflicting State laws render an adequate statement of the standard of the bushel difficult. Although the standard Winchester bushel contains 2150.42 cubic inches, Nebraska has established 2150 cubic inches as the volume of a legal bushel for that State, and other States have made similar changes. Also several States have adopted the old ale or milk gallon as the capacity of the dry gallon, this being about 5 per cent. larger than the corresponding unit derived from the Winchester bushel, and special bushels have been established in the various States for different products.

In brief, this is the history of the gallon with its various legal values, but as far as engineering data are concerned, it will be safe to distinguish only between the United States gallon containing 231 cubic inches and representing the volume of 8.33 pounds avoirdupois of pure water at a temperature of 39.83 degrees Fahrenheit and the British imperial gallon containing 277.274 cubic inches and representing the volume of 10 pounds avoirdupois of distilled water at 62 degrees Fahrenheit weighed in air of the same temperature with the barometer reading 30 inches of mercury.

Recent Ice Jam at Niagara Caused Serious Damage

By James J. Jenkins

The power interests at Niagara Falls have had the most astonishing experience in their history, all caused by the greatest ice jam that locality has seen in more than 50 years. On Wednesday, April 7, the Lake Erie and Niagara regions were swept by a fierce gale. The effect was a general breaking up of the lake ice field, which was driven into the entrance of the Niagara river channel at the foot of the lake. The discharge of ice from the lake to the river was tremendous, and from shore to shore, in both of its great channels, the river carried the ice night and day until the Niagara river, from Lake Ontario to the falls of Niagara, full 14 miles, was coated with the frozen mass, which had gathered to a thickness of from 25 to 50 feet or more.

FIG. 1. IN FRONT OF THE NIAGARA FALLS POWER COMPANY'S TUNNEL PORTAL AND THE HYDRAULIC COMPANY'S POWER HOUSE

FIG. 2. THE TRACKS OF THE GORGE ROAD ARE BURIED UNDER THE ICE ALL ALONG THE SHORE TO THE RIGHT

The spectacle thus created was astonishing, but the effect was more so, for the river rose to an unusual hight, breaking beyond all previous high-water marks, while the ice was carried to the greatest hight and was sent crushing, with the full force of the current, against everything within 40 feet of the normal level of the river. Up to the coming of this ice jam and high water, all available data indicated that the lower river had never risen higher than 28 feet, which in itself is a remarkable hight considering the rapidity and freedom with which the lower Niagara discharges into Lake Ontario.

Situated very close by the foot of the Horseshoe fall, at the water's edge on the Canadian side, is the power house of the Ontario Power Company, in which the development is made on horizontal shafts. When the site for this power house was selected, all available data then at hand were closely studied, and the conclusion of the engineers was that it would be safe to build the power house where now located. The conditions that developed during the April jam have demonstrated an error of judgment, considering the fact that the Niagara river and its possibilities are unknown factors. For although this great power house is situated a number of feet above the normal level of the river, and beyond the previous high-water mark, the ice and water burst into the station through windows and door, making it necessary to shut down the plant to dry out the machines. The full extent of the damage had not been announced at this writing, other than in the following statement issued by the company:

"During the night the unprecedented accumulation of ice below the falls, extending for nearly nine miles to Lewiston and beyond, caused the water to rise about 40 feet above normal. The maximum record for high water in the past, covering a period of 70 years, is about 28 feet above normal. The power house is designed with its windows about 7 feet above the highest previous known hight of water. Last night, however, the water exceeded this previous record by about 12 feet, and the water and ice poured through the windows and south door of the power house, at once causing a stoppage of the machinery. Temporary connection is being made, through the courtesy of the Electrical Development Company, with that company's works, and the steam-reserve plants at Rochester, Syracuse, West Seneca and elsewhere are being used to supply a portion of the load in this State of New York. The intention is to supply the public-service corporations first, such as railroads and lighting companies, and, afterward, the manufacturers and private users.

"No permanent damage is done to the power house or its machinery. As soon as the water is pumped out of the power house, it will be necessary only to clean and dry the machinery before resuming full operation. The money loss is extremely small, but the inconvenience to customers is, of course, serious.

"A recurrence of the accident is impossible, as the windows will be built up solid to a hight above any possible rise of water in the future, and the south door, which is not necessary to the operation of the works, will be closed with masonry."

FIG. 3. ONTARIO POWER COMPANY'S POWER HOUSE ALMOST BURIED UNDER THE ICE

FIG. 4. [illegible]

The enormous hight to which the ice advanced in front of the power house is well portrayed in one of the accompanying illustrations, in which the broken edge of the ice jam will give a pretty fair idea of the thickness of the mass of ice in the river in front of the station. It should be borne in mind, too, that there is more ice below the water line than above it. From this point in front of the Ontario Power Company's station the ice field extended in an unbroken mass to the whirlpool rapids. Usually, the giant stream that bursts from the portal of the tunnel of the Niagara Falls Power Company, close by the New York abutment of the upper steel-arch bridge, has strength enough to open a wide channel in any ice field that may gather there, but it was different with this April jam, for the tunnel torrent had little or no effect on the gathered ice, simply losing its identity under the broad white surface that stretched for miles down the gorge.

Out in front of the power houses of the Niagara Falls Hydraulic Power and Manufacturing Company the mighty ice was unbroken and rough. The night the Ontario Power Company's station was flooded, the water entered the basement of one of the power houses of the Niagara Falls Hydraulic Power and Manufacturing Company to a depth of a foot, but this point was about 8 feet below the turbine installation. Taking into consideration the known drop of the river between the base of the Horseshoe and the foot of this station, it would appear that there must have been a backing-up of the water to effect the damage to the Canadian station. Between the two points there was a great mass of ice, and it is not strange if all the water and ice that plunged over the Horseshoe fall was unable to pass down the gorge without backing up.

So great was the jam that the whirlpool was bridged from shore to shore, while the river from the outlet to Lake Ontario was a whitened pathway. So high was the water that the ice was lifted over the tracks of the Niagara Gorge Railway, the roadbed of which was buried for miles under from 10 to 20 feet of icy cakes, and the poles and wires were torn down. Until the ice is off the roadbed, it will be impossible accurately to judge the extent of the damage. However, it is generally felt that it will be very heavy, quite sufficient to delay the early spring operation of the scenic line.

On the Canadian side of the river, below the Devil's hole, great damage was done to the steel towers of the aluminum power-transmission line over which the Ontario Power Company supplies current to the Niagara, Lockport & Ontario Power Company for transmission to Rochester, Syracuse and other places in the interior of New York State. This transmission system was interrupted, not only by the damage at the power house, but also by the damage to the towers, the center one of three towers being tipped over to the north onto one of the others. All about their bases there was ice, notwithstanding that they had been placed so high that it was felt they were above the danger line. Boathouses, fish traps, docks, private pumping stations and other structures near the water's edge were swept away for miles, and at Lewiston two fair-sized hotels, normally far removed from the river, were guarded for fear they would be crushed by the ice, which there reached an elevation of about 50 feet and touched the rear verandas.

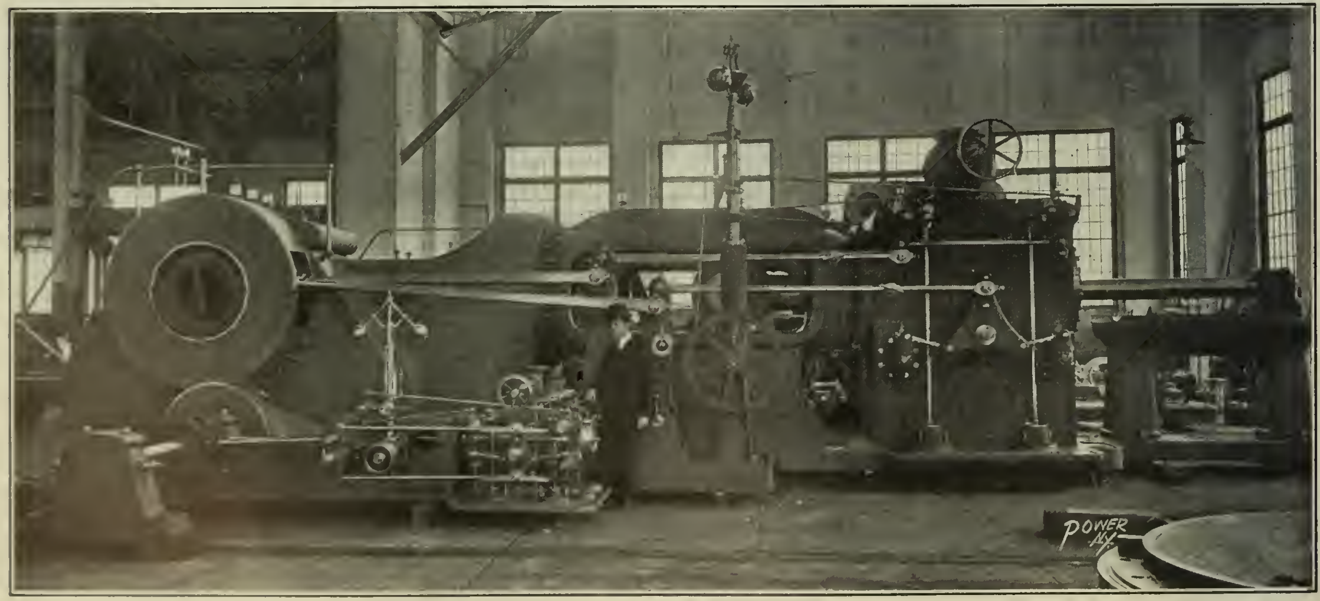
On April 20 it was possible to touch the floor of the Lewiston suspension bridge while standing on the ice. The belief prevailed that the ice was resting on the river bed between Lewiston and the mouth of the river, causing the water to back up.

Previous to April 20 estimates placed the damage at more that a million dollars. Now it is believed that it will be weeks before accurate figures are obtainable by any of the main interests affected. Generally speaking, it may be accepted as fact that it was the unexpected that happened, and all engineers who have to do with great works know what this means. The flooding of the station of the Ontario Power Company may cause a notable change in extensions of that plant, while the ice-jam effects will go down in history as making new records for the mysterious-acting, uncontrollable Niagara when it is under the terrific influence of a wind storm, particularly in winter, when any hour a million tons of ice may be swept into the gorge from the higher level above the falls. The use of dynamite and the warm weather broke the jam on April 25.

FIG. 5. SHOWING THE ICE JAM IN THE LOWER NIAGARA

Large Engine for Tennessee Coal, Iron and Railroad Company

The accompanying photograph shows the high-pressure side of a 42 and 78 by 54-inch cross-compound, condensing Cooper-Corliss engine on the erecting floor of the C. & G. Cooper Company, Mount Vernon, O. It was built for the Tennessee Coal, Iron and Railroad Company's plant at Ensley, Ala., and fifteen heavy steel cars were required for its transportation. The shipment was made forty days before the expiration of the four months stipulated.



LARGE ENGINE FOR THE TENNESSEE COAL, IRON AND RAILROAD COMPANY

This engine is practically a duplicate of the unit placed in operation at the Carnegie Steel Company's Duquesne works a year ago. It will drive a 2500-kilowatt Crocker-Wheeler alternator and is designed to carry heavy overloads. Alongside it is shown, for purpose of comparison, a 50-horsepower simple engine built for the Franklin Foundation, of Boston, Mass. A similar engine to that shipped to Alabama is being built for the Packard Motor Car Company, Detroit, Mich., to drive a 2500-kilowatt Western Electric Company direct-current generator.

Rate of Timber Consumption

It has been estimated that the amount of wood annually consumed in the United States at present is 23,000,000,000 cubic feet, while the growth of the forest is only 7,000,000,000 feet. In other words, Americans all over the country are using more than three times as much wood as the forests are producing. The figures are based upon a large number of State and local reports collected by the Government, and upon actual measurements.

The State forester of Connecticut, in a recent report, has given figures on growth and use for New Haven county, which give many more valuable details than are generally to be obtained, and well illustrate how the forest is being reduced by over-cutting. In this county a very careful study was made on each township of the amount of forest, the rate of growth, and the amount of timber used. For 1907 the timber used was 120,000 cords, in the form of cordwood, lumber, ties, poles and piles. The annual growth on all types of forest land, including the trees standing on abandoned fields, for the year, reached a total of 70,000 cords. Thus the amount cut yearly exceeds the growth by 50,000 cords.

The amount of standing timber considered as merchantable and available for cutting within the next few years was found to be 1,200,000 cords. Each year the annual growth increases the supply on hand by 70,000 cords, while the use decreases it by 120,000. The net reduction is therefore 50,000 cords a year. If the cut and the growth remain at the present figures, the supply of merchantable timber will be exhausted in about twenty years. At the end of that time there will be a large amount of forest standing in the county, but it will be in tracts under forty years of age, containing wood below the most profitable size for cutting. Cordwood could still be cut, but supplies of the most profitable products, like ties and lumber, would be practically exhausted.

Connecticut's case illustrates what is meant when the exhaustion of the timber supply is spoken of. It does not mean that every tree will be cut and that the ground will be bare. It means, on the other hand, that year by year the people of the country are cutting more timber than the forest grows, and that within a comparatively short time the continued loss will have so reduced the forest that it will be difficult and expensive to obtain timber of useful size in sufficient quantity.

Testing Coal at an Electric Railway Power House

There is a growing inclination on the part of electric-railway companies to determine accurately the value of fuel used in power stations. G. H. Kelsay, superintendent of power of the Indiana Union Traction Company, is making frequent tests of fuel used at the company's Anderson power station, to determine the evaporation of water with various kinds of coal. Adjoining one of the boilers in the station he has erected apparatus to weigh the coal and take the temperature of the water as fed to the boiler, the temperature of the steam and the quality of steam as delivered by the boiler during a 12-hour run. In making the test the supply water to the boiler from every connection is shut off, except the water as fed through an independent pump at the base of the testing tank. The water for feeding the boiler is obtained from the feed line header, and from this feed line header is passed to a carefully calibrated tank with tapered top and reduced neck, so as to hold a definite and exact quantity of water when full. The tank has been carefully calibrated for various temperatures of water, and a thermometer is inserted in the tank at midway to get the temperature, and from curves plotted from temperatures and weights the weight of each individual tank of water is determined. Water is then discharged to a lower tank and pumped into the boiler. Coal is discharged from the bunkers over the boiler into a portable hopper mounted on a set of calibrated scales. From each hopper of coal a small sample is taken and at the end of the day's run these samples are carefully mixed and quartered so as to obtain a sample sufficient to fill a quart fruit jar, giving the nearest possible average coal used during the day's test. From this sample of coal B.t.u. determinations are made by means of a Parr calorimeter. During the test of 12 hours the men conducting the test endeavor to keep the fires in a uniform condition, so that the results of all coal tests will represent the merits of coal for each test.—*Electric Traction Weekly.*

The joint annual convention of the Southern Supply and Machinery Dealers' Association and the American Supply and Machinery Manufacturers' Association will be held at Chattanooga, Tenn., May 5, 6 and 7.

Canadian General Electric Company

The annual meeting of shareholders of the Canadian General Electric Company, Ltd., was held at Toronto on March 29. The report of the directors for past year of a highly satisfactory character, showing profits to the amount of $[illegible], leaving $[illegible] after providing for depreciation and interest on borrowed capital. Of this, $[illegible] was paid in dividends and $[illegible] carried to the credit of profit and loss account, bringing it up to $[illegible]. The reserve fund stands at $[illegible], making a total surplus of $[illegible]. The report states that notwithstanding the continued industrial depression, the company had been fortunate in securing several important contracts, which will ensure their works would keep them fairly busy during the current year. As an indication of the improvement in conditions it was noted that during the past three months more orders had been secured than during the previous six months, leading the directors to look forward to the future with more confidence than at any time during the preceding year.

The Gas Engine in Blast-Furnace Practice

On Tuesday evening, April 20, George A. Orrok, secretary of the Gas Power Section of the American Society of Mechanical Engineers, delivered an illustrated lecture before the members and guests of the [illegible] Science Club of Brooklyn, on "The Gas Engine in Blast Furnace Practice." There were 70 lantern slides showing several types of gas engines in section, both vertical and horizontal, in all stages of assembly in the shop and power plant. The lecture was of a popular rather than scientific nature.

As applied to blast-furnace practice, several views were shown of the two-stroke-cycle gas engines used at the Lackawanna Steel Company's works in Buffalo and the four-stroke-cycle engines at Gary, Ind.

Discussion lasted for nearly an hour after the close of the lecture and was of an interesting character.

In 1887 an engine built to the design of [illegible] by the [illegible] Manufacturing Company, of Scranton, Penn., was put into the Washington Mill at Lawrence, Mass. George H. [illegible], who has been in charge of the engine ever since, [illegible] that it is still running without a [illegible] of the cranks and [illegible], and in the same position that it was put in when it was erected.

Philanthropists in Disguise

One of the most amusing collections of statements intended as serious which we have ever read is contained in an address recently delivered at Adelphi College, Brooklyn, by Glenn Marston, who is old enough and intelligent enough to know better. Two extracts will suffice to indicate the general tenor of the address. Speaking of public-utility corporations, Mr. Marston said: "The good they do reaches far beyond the donations to charity and other worthy movements which constitute the outward and visible sign of public beneficence." Also: "The public-service corporation has solved the problem of combining business and philanthropy."

We were not aware that any such problem as the combination of business and philanthropy existed, but conceding that there is such a recognized problem, the claim that it has been solved by any of the lighting and power companies strikes us as distinctly humorous. In order to be philanthropic a person or organization must do good intentionally and unselfishly. If there is a single central-station manager in the country who is operating his plant on that basis we should like very much to learn his name and address. Most of the central-station men we know are honorable and fair-minded in their business dealings as well as in private life, but we do not know any who would be foolish enough to pose as philanthropists merely because they light unsavory localities—for due consideration—and furnish power—also for a consideration—to run sewing machines formerly "treadled" by overworked men and women.

A Fuel Extravagance no Longer Necessary

In Great Britain there are probably a dozen or more centers of blast-furnace activity, and no large center of population is very far from some one of them. Consequently, it would seem to be merely a matter of ordinary engineering to utilize all of the surplus blast-furnace gas for driving electric generators and to transmit the energy from these to profitable markets. Yet the furnaces continue to waste their surplus gases while coal-burning power stations, operating within short distances from them, deliver electrical energy to transmission lines.

The chief reason for this extravagant procedure appears to be a lack of confidence in the reliability of the gas engine, notwithstanding the numerous examples of continuous and satisfactory operation in Germany. Probably the real secret is the proverbial conservatism of the British.

A somewhat similar, though not strictly analogous, condition has existed in this country until very recently, and it has not entirely disappeared yet and probably will not until the Gary plant has fully justified the confidence of its projectors. On this side of the Atlantic, however, the whole gas-power industry received a serious check by the failure of the few bituminous producers based on foreign designs which were built here before the difference between American and European coals was understood, and of a relatively small number of engines built chiefly from imported or pirated designs.

Now that the Steel Corporation has gone ahead so boldly in the utilization of furnace gases and a few courageous pioneer manufacturers are beginning to reap the reward of their persistent attempts to produce clean gas continuously from bitumionus coal, it is to be expected that great strides will be made in the application of gas power in this country. Never mind the facts that the Steel Corporation exacted heroic guarantees and that many of the persistent attempts alluded to were foolishly unscientific; it is sufficient that we are really about to "get there."

A Trust in Water Power

For some time rumors more or less indefinite and not at all specific in their charges have hinted of the existence of a water-power trust. These reports have gained credence from their very persistence and are apparently justified by some positive assertions by Judson C. Welliver in the May number of *McClure's Magazine.* A trust of modest means is not predicted, but rather a combination of interests of unlimited resources already actively engaged in the pursuance of systematic plans to secure control of all available water power in this country and Canada. A successful culmination of these plans would mean a corporation with more wealth than that represented by all the railroads of the nation, with Standard Oil, United States Steel and a dozen or so of the minor trusts thrown in for good measure. Be this as it may, it is of interest to note that some of the companies mentioned are of particular prominence in the power field, but whether they actually form a part of the trust combination or are merely endeavoring to secure a legitimate market for their product is a question which would require careful investigation to determine.

Manufactures and transportation, it is reported, use about 31,500,000 horsepower, of which 26,000,000 is supplied by steam and the rest water power. Carefully compiled data of the Hydrographic Bureau of the Geological Survey show that a minimum development, based on the natural condition of streams without the construction of reservoirs, would produce 37,000,000 horsepower. This is the low-flow figure, and the same streams will develop a minimum of 56,000,000 horsepower for the six high-water months of the year, so that for half the year a total of 37,000,000 to 56,000,000 horsepower would be developed, and for the remainder of the year over 56,000,000 horsepower. Without storage and at minimum flow it is thus possible to develop considerably more power than is utilized at present, and it is estimated that if reservoirs were erected of capacity large enough to equalize the annual flow, a total of 230,000,000 horsepower could be produced, or over seven times as much power as the whole country is now using.

With the available supply of natural fuels rapidly disappearing, conservation and before long necessity, will demand recourse to the waterfalls of the country for a much larger proportion of the total industrial power than they now contribute. Long before this condition actually developed, a trust controlling practically all of the power produced by water would be in an enviable position and to a great extent would undoubtedly be able to dictate the price of power. New fuels may perhaps come into use which would obviate such a disaster, but it would surely be wise to guard our water resources.

More Boiler Inspection Legislation Needed

Both in the editorial and correspondence columns of Power and The Engineer the necessity for the enactment of suitable boiler-inspection laws has been urged until it has at times seemed as though the readers would become surfeited with matter on this subject. But as scarcely a day of the year is marked off the calendar without the transpiring of news of a boiler failure that in all probability would have been prevented by intelligent inspection, it becomes nearly if not quite impossible for the man in close touch with steam-boiler operation to keep silent.

Last summer a boiler belonging to the town of Dartmouth, Mass., was examined by one of the State inspectors and the pressure allowed reduced to a point which rendered it useless to the municipality as a source of power. It was sold for junk for fifty dollars to a man who represented to the New Bedford Ice Company that the boiler was safe for a much higher pressure than was allowed by the inspector. Possession was transferred to the ice company and the boiler was sent to a place in New Hampshire and erected for the purpose of furnishing steam to operate ice-harvesting machinery.

What might reasonably have been expected happened. The boiler exploded, fatally injuring the man who purchased it from the town of Dartmouth and installed it for the New Bedford Ice Company. One of the State inspectors from Massachusetts visited the scene of the disaster and succeeded in obtaining possession of the spring-loaded safety valve which had been attached to the boiler. This valve, when tested at the Massachusetts Institute of Technology, was found to blow at one hundred and thirty-one pounds pressure. As the valve had been set by the State inspector to blow at eighty pounds a few weeks before, it would appear that the erecting engineer had attempted to set the release at one hundred and thirty pounds, or fifty pounds above the limit allowed by the State inspector.

Now, while no State inspection law can be perfect in conception or operation, the existence of a law in New Hampshire similar to the one operating in Massachusetts would have prevented the importation into the State of a piece of apparatus known to be dangerous as a menace to the life and property of its citizens. That there should be an organized movement on the part of all citizens looking to the enactment of suitable boiler-inspection laws in all States, or toward national legislation in this direction, is so plain that to mention it is a platitude.

"What is everybody's business is nobody's business" is palpably true in regard to boiler-inspection legislation, and recognizing this apathy on the part of the public, due, of course, to ignorance of the possible and probable danger arising from the operation of uninspected boilers, the engineer should make every effort in his power toward exciting public interest in a matter that is of vital interest to the public.

Coal Specifications

John Hall Rider, in a paper upon the "Electrical System of the London County Council Tramways," presented to the Institution of Electrical Engineers at a recent meeting, gives briefly the conditions under which the coal is purchased. The specified standards are:

Calorific value, 12,500 B.t.u. per pound.

Small coal allowance, 20 per cent. by volume (measured by the quantity which will pass through a wire mesh of ¼-inch square mesh).

Moisture, 10 per cent. by weight.

The calorific value and moisture are measured by the council's chemist on samples taken from every [illegible] brought into the pier front. The calorific value is determined by a Mahler bomb calorimeter on a sample previously dried at 100 degrees Centigrade, and the percent of moisture is determined on a weighed portion of the sample as taken from an airtight sample tin. The proportion of small coal is ascertained on the pier and a sample of about 20 pounds in weight taken at the option of the council either from the hold or from the quantity unloaded by the grabs.

If the quality of the coal in any cargo as ascertained by the samples tested is found different as regards calorific value, moisture or small coal, from the foregoing standards, the price paid to the contractor is varied as follows:

(a) If the calorific value exceeds 12,500 B.t.u. per pound, the price per ton is increased in the same percentage ratio as the increase in the calorific value.

(b) If the calorific value is less than 12,500 B.t.u. per pound, the price per ton is decreased in the same percentage ratio as the decrease in the calorific value.

(The council, however, has the right to reject the whole cargo if the calorific value is less than 11,000 B.t.u. per pound.)

(c) If the moisture is less than 10 per cent. by weight, the weight of coal to be paid for is increased beyond the quantity actually weighed out by a percentage equal to the percentage decrease of moisture.

(d) If the moisture exceeds 10 per cent. by weight, the weight of coal to be paid for is decreased below the quantity actually weighed out by a percentage equal to the percentage increase of moisture.

(The council, however, has the right to reject the whole cargo if the moisture exceeds 15 per cent. by weight.)

(e) If the proportion of small coal is less than 20 per cent. by weight, the weight of coal to be paid for is increased beyond the quantity actually weighed out by a percentage equal to one-quarter of the percentage decrease of small coal.

(f) If the proportion of small coal exceeds 20 per cent. by weight, the weight of coal to be paid for is decreased below the quantity actually weighed out by a percentage equal to one-quarter of the percentage increase of small coal.

(The council, however, has the right to reject the whole cargo if the proportion of small coal exceeds 25 per cent. by weight.)

The number of boiler explosions in the United States in 1908 was [illegible]. This compares with [illegible] in 1907, [illegible] in 1906, [illegible] in 1905 and [illegible] in 1904. The number of persons killed by boiler explosions in 1908 was [illegible], against [illegible] in 1907, [illegible] in 1906, [illegible] in 1905 and [illegible] in 1904. The number of persons injured [illegible] in 1908 was [illegible], against [illegible] in 1907, [illegible] in 1906, [illegible] in 1905 and [illegible] in 1904. The record of boiler explosions in the United States for [illegible] years and three months, to October 1, 1908, shows a total of [illegible], in which [illegible] persons were killed and [illegible] injured.

The annual meeting of the National Electric Light Association will be held at Atlantic City, N. J., June 1, 2, 3 and 4. On the first two days there will be two sessions each day; on the last two days there will be parallel sessions devoted to commercial, technical and accounting subjects. The [illegible] department [illegible] will be on Young's "Million Dollar Pier." The association's headquarters will be [illegible].

Improved Dexter Valve Reseating Machine

Thousands of good valves have been thrown away merely because there was no suitable reseating machine at hand and engineers, rather than bother, have ordered new and discarded the leaky valves. The accompanying illustrations

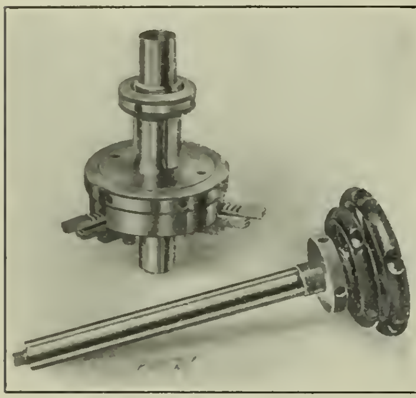

FIG. 1. DEXTER VALVE RESEATING MACHINE

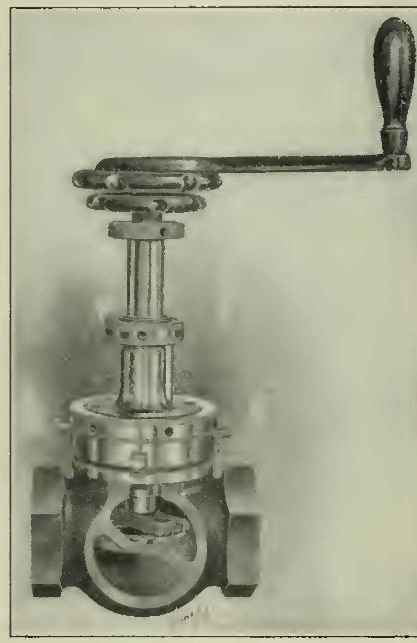

FIG. 2. APPLICATION OF DEXTER VALVE MACHINE TO GLOBE VALVES

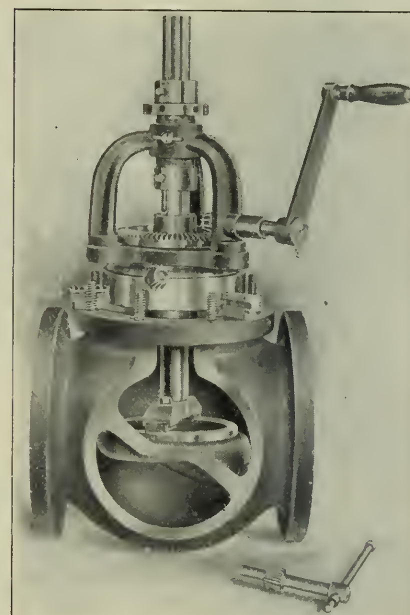

FIG. 4. DEXTER MACHINE FOR RESEATING VALVES UP TO 12 INCHES IN SIZE

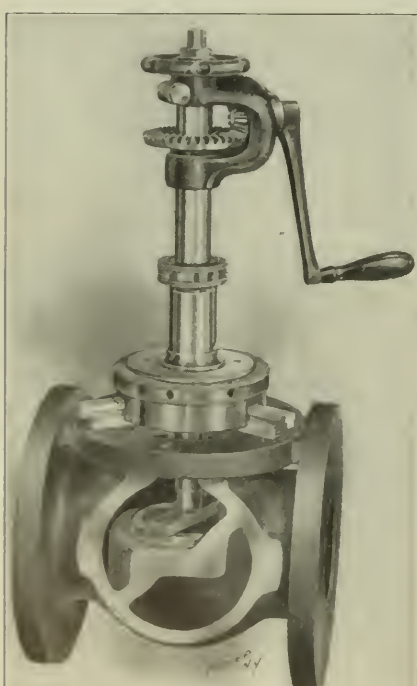

FIG. 3. APPLIED TO LARGER GLOBE VALVES

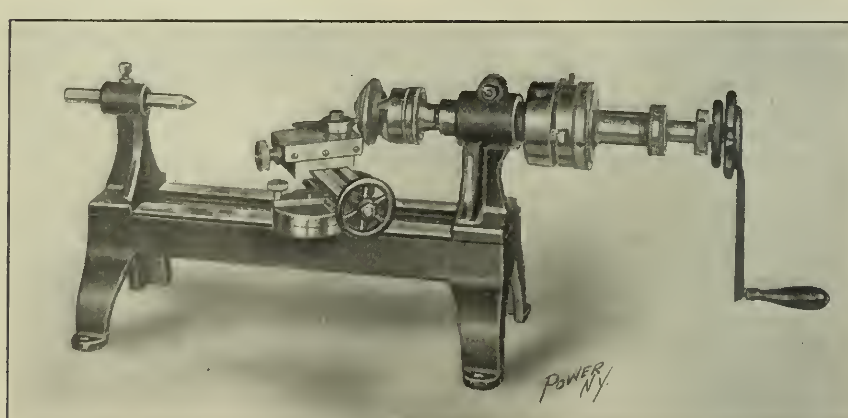

FIG. 5. TURRET-LATHE DISK CUTTER

show the application of the Dexter valve machine, manufactured by the Leavitt Machine Company, Orange, Mass.

Fig. 1 illustrates an improved valve-reseating machine with the tool spindle removed from its bearing sleeve in the body of the machine. This bearing sleeve extends through the chuck and is threaded on the inside of its upper end. These threads engage with the threads of the feed screw shown under the speed wheel of the tool spindle. The bearing sleeve and the tool spindle are slidable through the chuck, and instantly lowered to or raised from the valve seat and held in position by rotating the large nut shown on the body of the machine. This bearing sleeve supports the tool spindle for practically its entire length, which greatly strengthens the tool shaft and aids in keeping it in line.

Fig. 2 shows the application of this device for reseating globe valves from ¼ to 4 inches in size. The illustration shows a machine at work on a valve seat. The jaws of the machine are quickly and simultaneously adjusted to the valve casing by merely rotating the scroll of the chuck. This centers the machine, when the tool shaft is in alinement. Then a few turns of the handle and the seat is cut to a too flat surface.

Fig. 3 shows the machine as applied to valves from 3 to 6 inches in size. This machine carries a 6-inch cutter and is said to meet all requirements for this size of valve.

Fig. 4 illustrates the Dexter machine for reseating the larger size of valve up to 12 inches. The machine is geared 5 to 1, making a very powerful machine that carries the largest cutter easily, cutting the hardest metal smoothly without chattering, it is said. The jaws of the machine are quickly and simultaneously adjusted as in the case of the machines already described. The machine, being portable, is taken to the valve on the pipe line, the valve seat being trued without disconnecting the valve. This model is carried in three sizes for reseating all flat and taper-seated valves from 3 to 8 inches, 3 to 10 inches and 4 to 12 inches.

Fig. 5 shows a new turret-lathe disk cutter. Owing to the number of positions to which the turret head that holds the cutting tool can be adjusted, all kinds and shapes of valve disk can be easily and quickly recut. With one setting of the head, a crowning face can be cut on a valve disk; by feeding forward on the nurled nut, a 45-degree angle can be cut; or by feeding on the feed nut of the machine a true surface can be turned parallel with the machine; all without resetting the head. The turret head carrying the cutting tool can be quickly adjusted for turning up all kinds of work usually done in small lathes. This machine is portable, but can be attached to a bench.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer

Horsepower to Turn Drum

Give a formula by which to obtain the horsepower necessary to drive a drum 8 feet in diameter by 16 feet long, resting on six 12-inch sheaves, with 12-inch faces, three of the sheaves being drivers and the other three mounted on an idler shaft. The drum when loaded will weigh about 27 tons and make 10 turns per minute. A

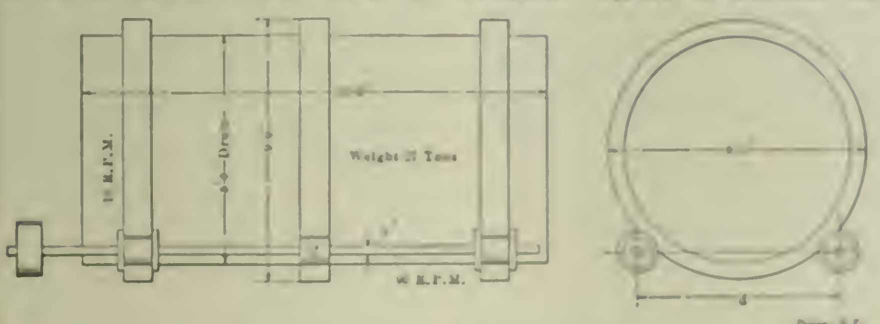

FIG. 1. ARRANGEMENT OF DRUM AND ROLLERS

FIG. 2. GRAPHICAL SOLUTION OF PROBLEM

sketch of the arrangement is shown in Fig. 1.

S. C. G.

Assuming the load to be distributed equally in the drum, the formula for horsepower at the periphery of the drum may be deduced graphically. In the accompanying sketch, Fig. 2, the large circle represents the drum, and the two smaller circles the rollers.

$$Sin\ \theta = \frac{c\,b}{a\,c} = \frac{\frac{d}{2}}{5} = \frac{d}{10}.$$

Make $f\,e$ parallel to $a\,g$ and $e\,g$ parallel to $a\,f$. Then the resultant $a\,e$ will represent the weight W of the drum.

$$a\,o = \frac{a\,e}{2} = \frac{W}{2}$$

and

$$a\,f = \frac{a\,o}{\cos\theta} = \frac{\frac{W}{2}}{\cos\theta}.$$

Therefore,

$$a\,f = P_1 = \frac{W}{2\cos\theta} = \frac{W}{2\cos\sin^{-1}\frac{d}{10}} =$$

$$\frac{W}{2\,\frac{\sqrt{10^2 - d^2}}{10}}.$$

Now as

$$P_1 = P_2 \text{ or } P_1 + P_2 = 2\,P_1,$$

the formula for friction would be

$$Friction = 2\,P_1\,f = F$$

and the formula for work would be

$$Work = F \times 9\,\pi \times 10 = 2\,P_1\,f\,90\,\pi =$$

$$\frac{180\,W\,f\,\pi}{2\,\frac{\sqrt{10^2 - d^2}}{10}}.$$

The horsepower at the periphery of the roller would be

$$H.P. = \frac{90\,\pi\,f\,W}{33{,}000 \times \frac{\sqrt{10^2 - d^2}}{10}}.$$

For cast iron rolling on cast iron the coefficient of friction is 0.004 and substituting in the previous formula for the horsepower required to overcome the rolling friction, the following result would be obtained:

$$H.P. = \frac{90 \times \pi \times 0.004 \times 54{,}000}{33{,}000 \times \frac{\sqrt{10^2 - d^2}}{10}} =$$

$$\frac{18.5}{\sqrt{10^2 - d^2}}.$$

To overcome the bearing friction on the roller shafts the horsepower would be calculated as follows: On the idler shaft the horsepower to overcome the bearing friction will be

$$H.P. = \frac{90 \times \pi \times \frac{1}{4} \times \frac{54{,}000}{2}}{33{,}000 \times \sqrt{10^2 - d^2}} \times 0.05$$

$$= \frac{90 \times \pi \times 54{,}000 \times 5}{33{,}000 \times 4 \times \sqrt{10^2 - d^2}} \times 0.05 =$$

$$\frac{28.9}{\sqrt{10^2 - d^2}}.$$

On the driving shaft let R equal the resultant of the belt pull and the pressure P_1. Then the following formula will give the horsepower required to overcome the bearing friction on this shaft:

$$H.P. = \frac{90 \times \pi \times R \times 0.05}{4 \times 33{,}000} = \frac{3.53\,R}{33{,}000}.$$

The total horsepower would simply be a summation of the values obtained for rolling friction, friction on the idler shaft, and friction on the driving shaft, and would read as follows:

$$Total\ H.P. = \frac{3.53\,R}{33{,}000} + \frac{47.4}{\sqrt{10^2 - d^2}}.$$

Then by inserting the value of R which can be ascertained in the plant, and the value of d, which is the distance between the idler shaft and driving shaft, the total horsepower required may be obtained.

Does Expanding Tubes Cause Leaks?

Do leaks usually occur when new tubes are expanded beside others which are badly incrusted with scale?

C. D.

It depends entirely on how much the old tubes are disturbed by the process of removing the tubes that are to be replaced. There is nothing in the tube itself or of expanding it properly that would cause a leak in another tube, no matter how badly scaled.

Location of Drip Pipe

The drip pipe from a header over a horizontal boiler extends through the shell into the water near the bottom of the boiler. Why was it not put in so that it would discharge into the steam space?

D. E.

Engineers and some others have prejudices against allowing water which, however hot it may be, is colder than the water from which it is condensed, to pass into the steam space of a boiler, as a water hammer of a more or less serious nature is liable to result.

Modern Science Club Program

In the program of lectures and discussions at the rooms of the Modern Science Club, of Brooklyn, the following features are announced for the balance of May: Saturday, May 8, general discussion on "The Rating and Reliability of House Heating Boilers;" Tuesday, May 11, a paper by Prof. John E. Sweet, illustrated by the stereopticon, on "The Growth of the High Speed Engine, or the Straight Line Engine in Particular," will be read by the secretary; Tuesday, May 18, H. J. Atticks will continue his discussion of "Steam Engine Governors;" Saturday, May 22, general discussion on "Turbine Governors," opened by Frank Martin; Tuesday, May 25, F. E. Town will read a paper on "Elevator Accidents and their Prevention." All lectures will start promptly at 8:15 p.m.

Business Items

Ira J. Owen, consulting engineer, of Chicago, has removed from the Marquette building to 855 First National Bank building and will continue to make a specialty of factory engineering.

The Pittsburg office of the Du Bois Iron Works, of Du Bois, Penn., manufacturer of gas engines, etc., has been removed from 1206 Park building to more commodious quarters at 1429 Park building.

The Parker Boiler Company has received an order for a 300-horsepower boiler from the Astoria Veneer Mills, Long Island City, N. Y. This company installed a 500-horsepower Parker boiler about a year ago.

The Carnegie Steel Company has added to the 1550 horsepower in Crocker-Wheeler form W motors in its Duquesne plant by the purchase of three more Crocker-Wheeler motors of the same type, especially designed for rolling-mill work, aggregating 225 horsepower.

The Union Electric Power Company, Union, Iowa, has ordered from the Minneapolis Steel and Machinery Company a 55-horsepower Muenzel producer gas engine and gas producer which will be installed in its new electric-light plant. The engine will be belted to two generators.

The Larson Lumber Company, Bellingham, Wash., has purchased a 20x36-inch Twin City Corliss engine with special Twin City frame from the Minneapolis Steel and Machinery Company. This is the second Twin City engine that they have purchased within the past three months.

The Buckeye Engine Company, of Salem, Ohio, announces the appointment of: Louis Bendit, associate, American Society of Mechanical Engineers, Kansas City sales manager, with offices at 501 New York Life building; also, J. R. Detweiler, district manager, at Wichita, Kan., with offices at 505 Barnes building.

In the March 23 issue, on page 543, in the article descriptive of the new power plant of the L. S. Starrett Company, Athol, Mass., it was stated that the chimney is of the Custodis type. We wish to correct this statement, as the chimney is constructed of radial bricks by the M. W. Kellogg Company 18 Church street, New York.

The Du Bois Iron Works advises us that it recently appointed James L. Kimball New England representative, with offices at 53 State street, Boston, Mass., also the James F. Marshall Company, 608 Chestnut street, Philadelphia, general sales manager for eastern Pennsylvania, Delaware and the southern half of New Jersey.

The Trill Indicator Company, Corry, Penn., is sending out a neat circular, recently issued, containing a list of a few of the concerns using the Trill "Triumph" indicator, among which are the William Todd Company, Cambria Steel Company, Jones & Laughlin Steel Company and a number of prominent universities.

C. A. Dunham & Co., of Marshalltown, Iowa, will shortly start operations on a new $50,000 office and factory building, as their present quarters are inadequate. The building will be used entirely for their heating and trap departments. They report a big improvement in business and recently opened branch offices in Fort Worth, Tex., Pittsburg and Denver.

The Ideal Automatic Pump Governor Company has been reincorporated under the laws of the State of New York, and has changed its corporate title to the Ideal Automatic Manufacturing Company, as its line of steam specialties now embraces pump governors, pressure-regulating and controlling valves and "Ideal" packing. The offices and works of the company are at 125 to 129 Watts street, New York.

"Belt Talks" is the title of a little cloth-bound book of about 100 pages which gives a lot of information about belting and will make good reading for any engineer who has anything to do with the belting about his establishment. There are a number of illustrations to help out the text. Of course the object of the book is also to tell about Bird's "Bulls-Eye" belting. It is sent free upon application to J. A. & W. Bird & Co., 34 India street, Boston, Mass.

We have been advised by the Keystone Lubricating Company, of Philadelphia, that the case which has been pending in the Denver courts for infringement upon its trademark by the Keystone Oil and Supply Company has been decided in its favor. There are several infringements upon the company's trademark throughout the United States by petty concerns, and action has not been taken against them on account of the pending decision.

The city of Bellevue, Ia., has placed an order for a Foos three-cylinder vertical gas engine, with gas producer complete, with the Foos Gas Engine Company, of Springfield, O., to replace a steam engine in the city electric-light plant. This will run in parallel with a steam engine, it being anticipated that the remaining steam engine will be displaced by another gas engine. The Foos company is doing a large business in gas-producer plants, both for electric work and pumping installations.

The Homestead Valve Manufacturing Company, of Pittsburg, Penn., reports several sales of Homestead valves for use on pressures of 5000 pounds hydraulic. These valves, they say, are meeting with great success and they have had several repeat orders from customers using them for this purpose. Many users of valves know the Homestead valve as a blowoff valve only, but they desire to call attention to the fact that it is successfully used on the highest known pressures.

The Willcox Engineering Company, of Saginaw, Mich., manufacturer of the Willcox automatic water weigher, has issued in pamphlet form, illustrated, "A Consulting Engineer's Report on the Willcox Automatic Water Weigher," it being a reproduction of part of an article, on "Recent Refinements in Boiler Testing," which was published in Power and The Engineer, February 23, 1909. The Willcox water weigher is highly endorsed in a letter accompanying the pamphlet, from the Michigan Sulphite Fibre Company, of Port Huron, Mich., which gives the weigher large credit for a saving of from 10 to 20 per cent. in the coal bill.

The Hewes & Phillips Iron Works, Newark, N. J., has under construction for the Windham Manufacturing Company, Willimantic, Conn., a cross-compound Corliss engine, 18x36x48, 100 revolutions, to develop 1000 horsepower. With this engine they are also installing a complete motive-power outfit consisting of a 750-kilowatt Crocker-Wheeler belt-driven generator, Stirling water-tube boilers, pumps, heaters, etc. The Oakville Company, Oakville, Conn., is installing a new Hewes & Phillip cross-compound condensing Corliss engine, equipped with the improved "Franklin" silent valve gear. This engine is 14x28x33 and will run at 300 revolutions, direct-connected to a 300-kilowatt generator. The engine is arranged to connect to a 12-inch barometric condenser; it will also have a primary heater and all the latest heat-saving apparatus.

The Hewes & Phillips Iron Works, Newark, N. J., is rebuilding one of the large Corliss engines operating the Wamsutta mills, New Bedford, Mass., furnishing two high-pressure 20-inch diameter by 72-inch stroke cylinders and new pistons and new valve gear for all four cylinders. The valve gear will be of the "Franklin" type. They are also building for this engine a wood-rim flywheel 26 feet in diameter by 102 inches face, with double arms. The engine will be speeded from 58 to about 70 revolutions per minute. The Downs-Plum Company, boxboard paper manufacturer, Blanchard and Ferry streets, Newark, N. J., is also having a 22x42, 400-horsepower Hewes & Phillips Corliss engine installed for the operation of its paper mill. The engine will work noncondensing, using steam in the dryers.

One of the oldest and largest printing establishments in Texas, that of Clarke & Courts, Galveston, has just completed the electrification of its drives. The order for 21 motors recently placed with the Birmingham office of the Crocker-Wheeler Company makes a total of 61 Crocker-Wheeler motors in this plant. The motors just ordered are for the following purposes: A 10-horsepower motor for driving the elevator; two 3-horsepower and a 2-horsepower for driving cutters; a 1-horsepower driving a group of numbering machines and a 1-horsepower driving a group of wire stitchers; a ½-horsepower driving a box machine and a similar motor driving a punch; eight ½-horsepower motors driving ruling machines and a ¼-horsepower driving a sewing machine. In the electrotype shop there are two 5-horsepower motors driving groups of machinery, a 1-horsepower motor driving a black-leading machine and a 3-horsepower driving a plating dynamo. This plant covers a whole block and is four stories high. It is considered the highest-class printing establishment west of the Mississippi river.

Reversing Valve Gears in General Use

A Bird's Eye View of Link and Other Reversing Motions, Including Double- and Single-eccentric Motions; Direct, Bevel and Spur-wheel Drive

BY SIMPSON RICE

While volumes have been written on the subject of reversing valve gears, there does not seem to be any place in which all of the principal types now in use are illustrated and described, particularly with reference to noting the differences between them. That such a comparison has elements of value goes without saying, for, while the steam engine may, to quote the view expressed by many, be becoming a "back number" in the field of power generation, for any service which requires reversing, it is still the only dependable machine, and there is much which may yet be done to perfect the various types of gears by which reversing is accomplished. Therefore, a review of those which have thus far stood the test of continuous or intermittent operation, and the study of their essential characteristics, will be found helpful in a consideration of means for improving, or adapting to new service, the working parts of any individual type.

For the article following, which treats principally of the several methods employed for imparting the desired motion to the valves by means of eccentrics, cranks, bevel and spur wheels, rods, etc.—usually in combination with blocks and links—there has been prepared a group of diagrammatic sketches, uniformly conceived, which give what might be termed a bird's-eye view of all link and other reversing motions now in general use, and shows very clearly the differences between them. Supplementing these sketches are a number of other figures taken from drawings of engines now in operation, which show how the details of the leading types are applied in actual engineering practice. Such information of value as the article imparts will come chiefly from a close, analytical scrutiny of the several figures by which it is illustrated. Beyond what is said of the first motion described, no attempt will be made to follow out the movements of the various gears in detail further than is necessary to show radical differences in type; and for more complete information the reader is referred to standard works on the subject.

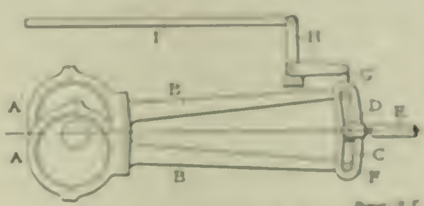

FIG. 1. STEPHENSON'S GEAR

In the lettering of the several figures similar parts have been uniformly indicated, as follows:

A = Eccentrics.
B = Eccentric rods.
C = Link.
D = Block working in connection with link.
E = Connection to valve.
F = Point of suspension of link.
G = Rods which support link and radius rod.
H I = Levers and connections by which reversing is effected.
J = Connecting rod.

In grouping the various gears for purposes of comparison, it seems desirable to separate them into three sections, viz., those having double-eccentric link motions, single eccentrics, and direct, bevel and spur-wheel drive. Were the mechanisms to be considered in their entirety as "reversing motions," it would of course be necessary to use an entirely different classification, as determined by the number, character and arrangement of the valves. [illegible] for our present purpose the following valve details affecting [illegible] of [illegible] lead, [illegible], etc., will be [illegible] only in passing [illegible] the particular [illegible].

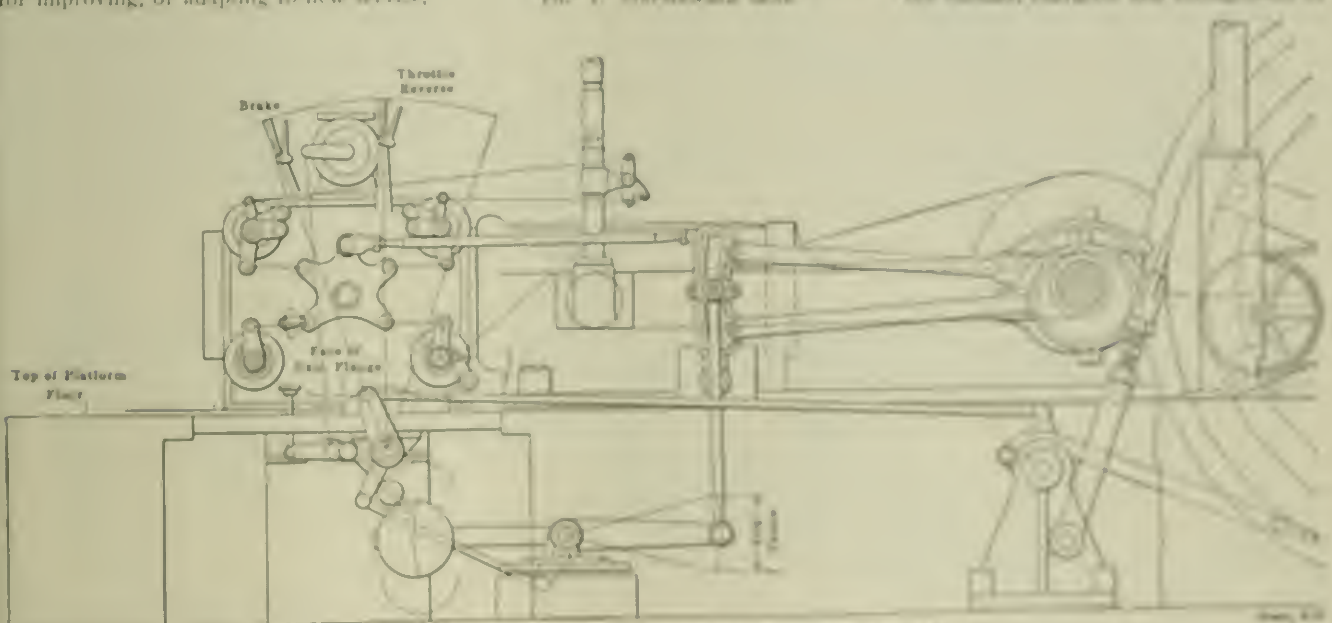

FIG. 2. STEPHENSON LINK ON [illegible] HOISTING ENGINE

Double-eccentric Link Motions

The Stephenson Link Motion—Link motions, [illegible] unquestionably belong to the most important [illegible] movements that occur in machinery." Among the earliest of arrangements for reversing engines and changing the ratio of expansion, and the one still most commonly used, is the Stephenson gear, illustrated in Fig. 1. The details and operation of this gear are as follows: The two eccentrics *A* and *A'* are keyed to the crank shaft, and to the link *C* are connected the two eccentric rods *B* and *B'*. The radius of the curvature of the link, suspended from the point *F* by the system of levers, is equal to the eccentric rod length. The block *D*, which fits the link, slides in it when the latter is raised or lowered, and is connected directly to the spindle *E* operating the valve. By moving a lever which actuates the rod *I*, the link is raised or lowered through the operation of the bell-crank lever *H* and the rod *C*.

When the eccentric rod *B'* is nearly in line with the valve spindle *E*, the action of the valve is the same as if there were but one eccentric, viz., *A'*. But, if the link is raised so that the block is near its lower end, the admission of steam is under the control of the eccentric *A*, since the eccentric rod *B* is nearly in line with the valve spindle; the eccentric *A'* will then cease to affect materially the action of the valve and the direction of the engine will be reversed. When the valve occupies a position at any point between the extremes of the link, it is under the influence of both eccentrics, but mainly controlled by the nearest one. If in the exact center of the link, it is subject to both eccentrics and the engine will not run in either direction, as each eccentric is working in direct and equal opposition to the other.

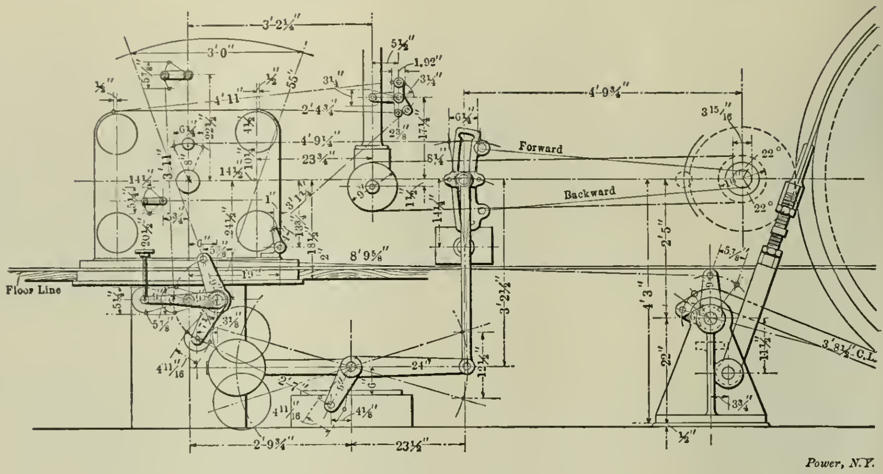

FIG. 3. DETAIL DESIGN OF STEPHENSON GEAR ON ENGINE OF FIG. 2

At such times as the block is not at the extreme of the link, the valve will not travel its full distance, or the eccentric throw, but only a distance which lessens as the block approaches the central point; but if the block is at either extreme of the link, the valve will travel a distance equal to the throw of the eccentric; at any other point the travel is less, being the same as if determined by another eccentric of smaller radius than either of those used.

The effect of decreasing the valve travel is customarily shown graphically by valve diagrams. Decreasing the valve travel results in cutoff at a point earlier in the stroke; the ratio of expansion is, therefore, increased; compression and release both occur earlier; the lead also is increased slightly. Hence it will be apparent that the combination of a pair of eccentrics with a link and sliding block allows both change in the direction of the engine and in the ratio of expansion. For those reasons, this gear has been extensively employed for locomotive, marine, rolling-mill and hoisting-engine service. The length of the link, which is curved

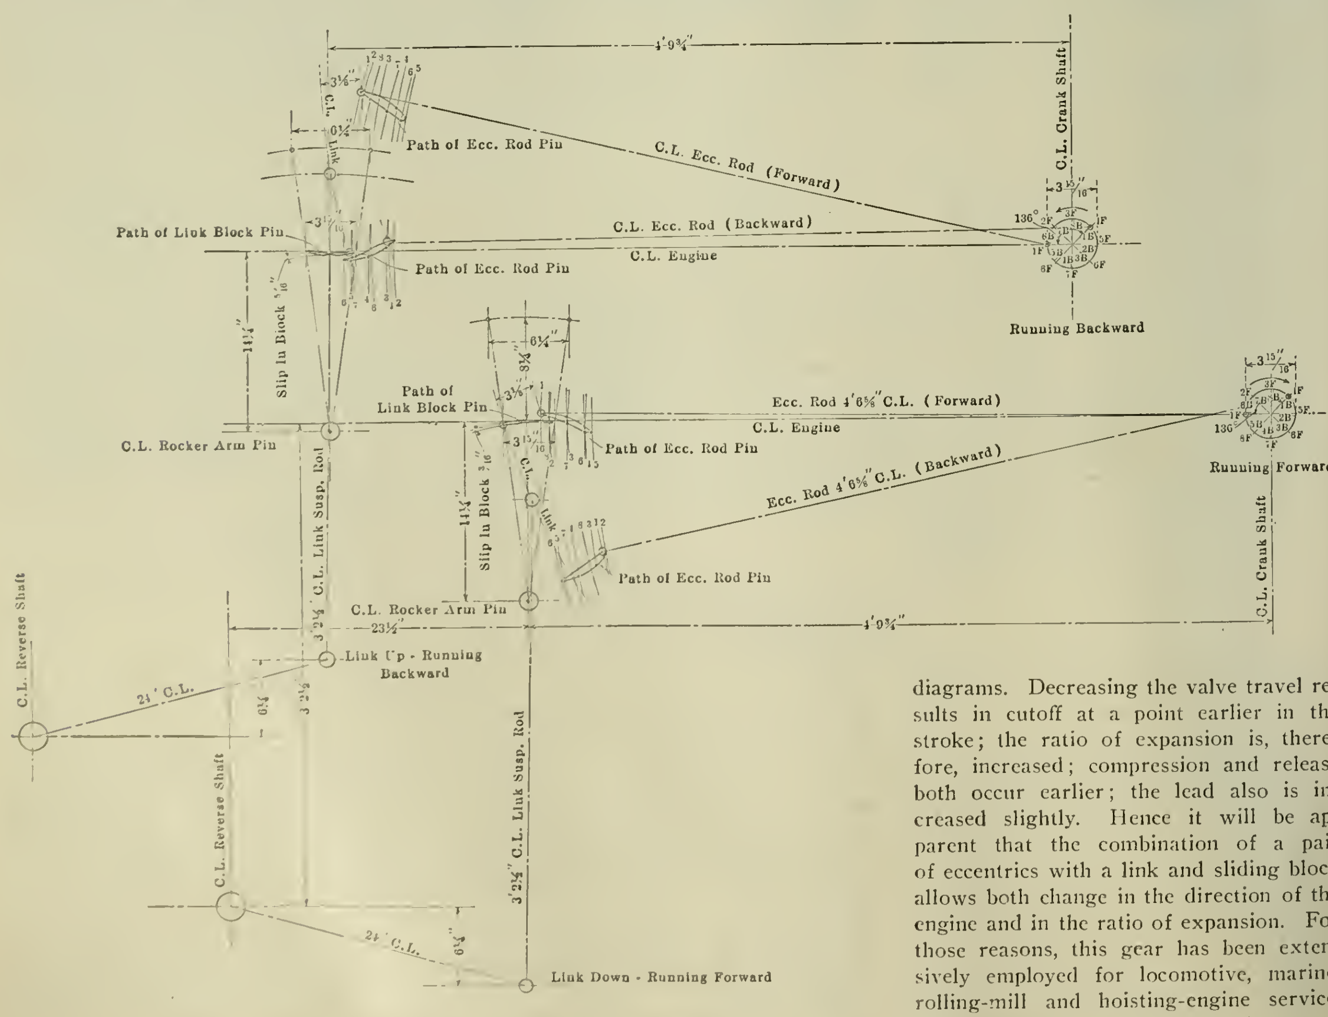

FIG. 4. GRAPHICAL METHOD OF LAYING OUT LINK MOTION

so that the lead will be equalized for all travels, should not be less than three times the full travel of the valve. It may be suspended from above or supported from beneath.

Figs. 2 and 3 show the Stephenson link gear applied to a geared hoisting engine, the details of which are plain. An arrangement such as this adapts itself readily to a gear where a variable cutoff

the pins, etc., each calculation being indicated by name. These are particulars which there is hardly space to dwell upon in a general comparison of this kind, but they are shown here for the reason that the same principle of laying out each part in exact mathematical relation to the whole and upon the lines of a single construction diagram, applies to the work of designing all types of reversing valve

[illegible] pins, so that the swinging of the upper [illegible] (backward eccentric) has very little effect on the valve travel. This link is supported on each side, so that the strains due to swinging, as the ordinary Stephenson link, are obviated.

Open and Crossed Rods.—According as to whether the angular advance of the two eccentrics is to be equal or unequal, the eccentric rods are either open or crossed.

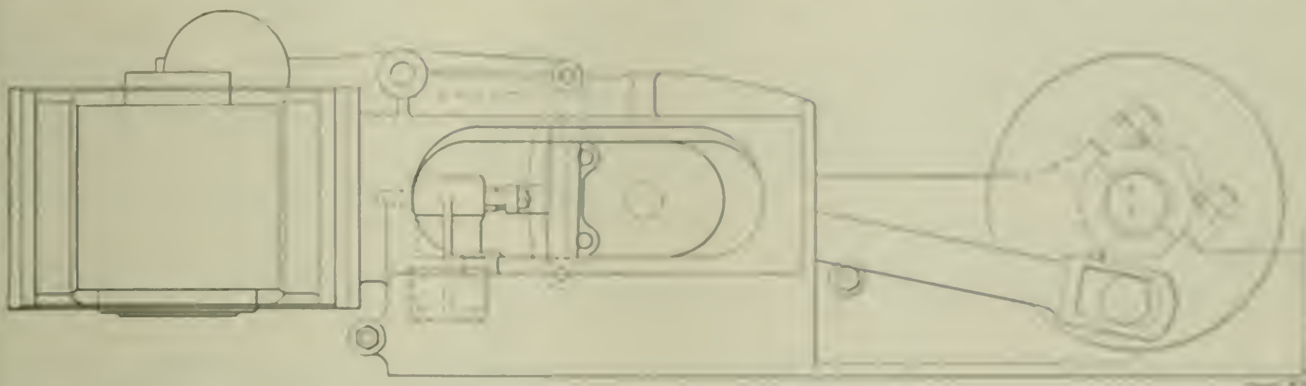

FIG. 5. MODIFICATION OF STEPHENSON LINK GEAR

is desired. This is accomplished, as above indicated, by moving the link block up or down, nearer to or away from the working eccentric-rod center. In the particular case illustrated, two engines were coupled on one crank shaft; consequently, a link was required for each, but they were both connected, through the medium of necessary levers and cross shaft, with the lever keyed in the center, so that each could be operated simultaneously with the other. The essential features of Figs. 2 and 3 are, of course, identical. The reason for giving both of them here is to illustrate, first, an outline of the side

FIG. 6. GOOCH LINK

The meaning of this term and what it implies, if not already understood by the reader, can be readily gathered from any reference book on link motions.

The Gooch Link.—Having considered the link motion principally in use, various other arrangements will be briefly described by which it has been sought, with

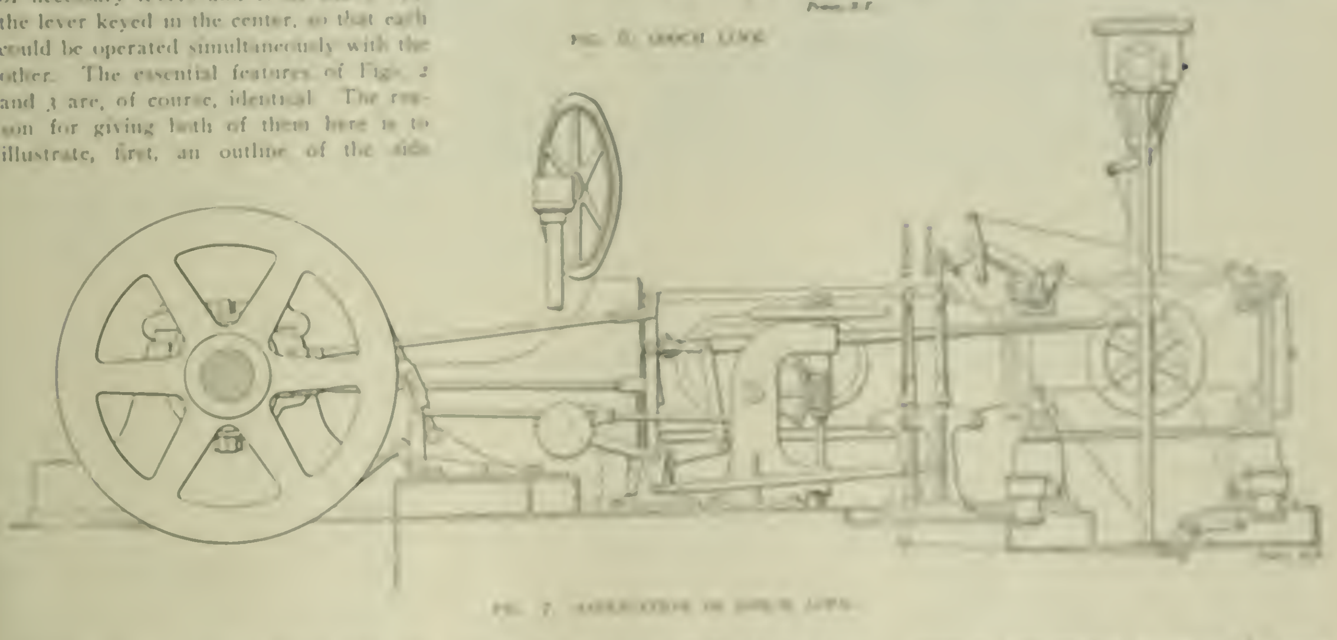

FIG. 7. APPLICATION OF GOOCH LINK

elevation of an engine fitted with the Stephenson gear, as it appears on the sketch of a proposed machine submitted by the builder to a prospective user, and, second, to show the design more in detail as worked out in the drafting room.

Proceeding still farther, Fig. 4 shows a graphical representation of the method of laying out the different points in the link motion, the slip of the link block, paths of

gear. The theory will be found in detail in Zeuner's treatise on the subject.

Fig. 5 shows an interesting modification of the Stephenson link gear for use on dredge engines or any engine which runs mostly in one direction [illegible] and the valve motion for backing and running on the [illegible] is not so important. As will be seen, the [illegible] connections to [illegible]

[illegible] so as to obtain the same [illegible] is the Gooch gear, the action of which is [illegible] to that of the Stephenson link. With this gear the link is not [illegible] The radius of the arc [illegible] that of the Stephenson link, is equal to the length of the radius rod [illegible] that the block may occupy different positions in the link, from one extremity to the other, without moving the valve. Therefore the lead is constant for all points of cutoff. The block, instead of being on the inside of the link, has its wearing surfaces on the outside of the link and is adjustable by means of wearing plates. The arrangement is shown in Figs. 6 and 7.

The Gooch link gives constant lead, but it has more joints to wear and cause lost motion and it requires more space than the Stephenson. In choosing the type of link motion the importance of a given feature must be well considered. Both gears may be designed to give an equalized cutoff. To illustrate by specific examples:

A hoist is a very slow-speed machine when starting and runs at higher speed when under way. A slow-speed engine requires but little lead, while for higher speeds considerable lead, early admission, exhaust and a larger amount of compression are necessary in order that the drum may run smoothly.

In starting, the link motion is thrown into full forward gear, which causes a late cutoff and slight lead. After the hoist is well started, the engine, like a high-speed power engine, requires more lead and considerable compression. An early admission and release are desirable in order that the steam may be admitted and exhausted freely. By raising the Stephenson link, these conditions are attained, as well as the advantage of using the steam expansively.

In marine engines the link motions are used more for reversing than for varying the expansion. Usually a marine engine runs at full speed and under full load. When the speed decreases, if the link is shifted toward mid-gear, there is excessive compression and early release. Engines of this type often use independent cutoff valves.

Allan Gear—Fig. 8 shows the Allan, or straight-link gear, and Fig. 9 a recent application of it. At the time the Stephenson gear was invented the means of slotting out had not been brought to the present-day perfection, and the construction of a curved link with large radius involved considerable difficulty; hence

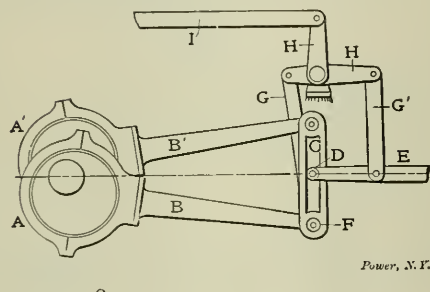

FIG. 8. ALLAN STRAIGHT-LINK GEAR

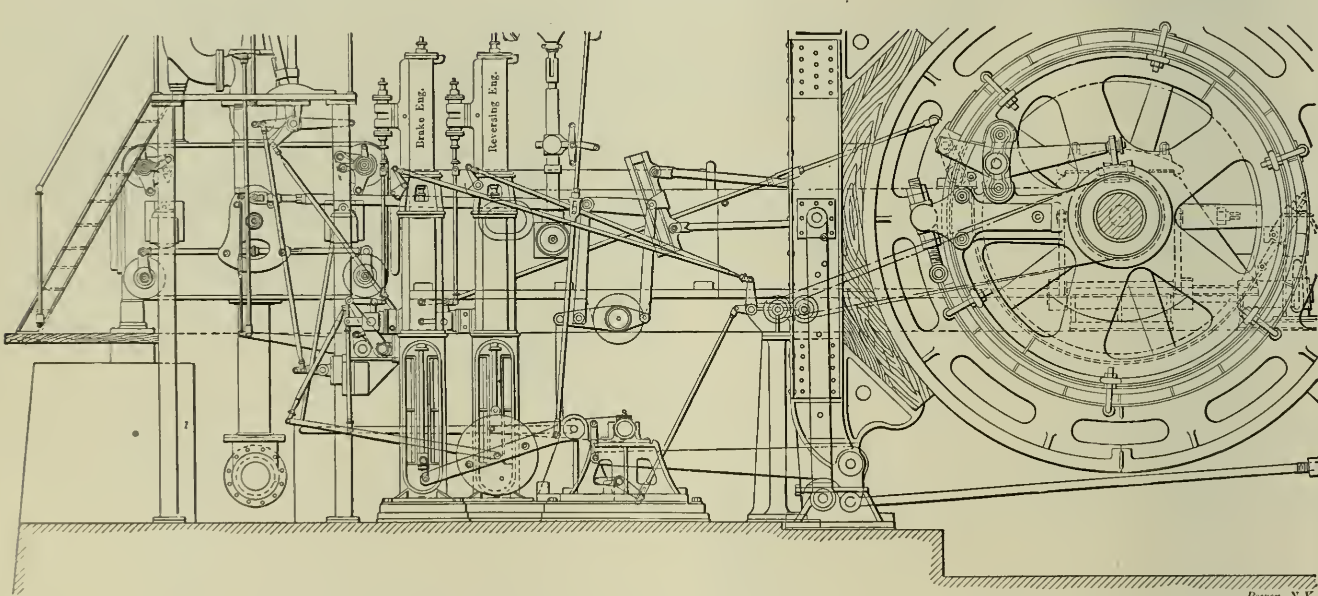

FIG. 9. RECENT APPLICATION OF ALLAN GEAR

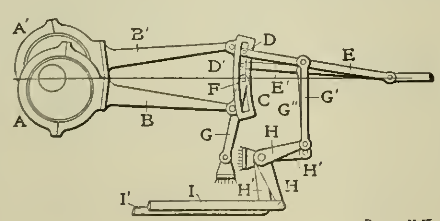

FIG. 10. POLENCEAU REVERSING AND CUT-OFF GEAR

Allan's straight link was designed as a substitute. In this gear the radius rod is moved upward as the link is moved downward and *vice versa*, causing the valve to travel evenly on each side of a fixed point; and, theoretically, the end sought can be completely attained, but in practice it has not worked as well. This motion is not now very extensively employed. It combines, however, the principal features of the Stephenson and Gooch links and is intermediate in relation to them. Fig. 9 is a modified form of the gear shown by Fig. 8 and has the link hanging down instead of being supported from below. In either case the motion is the same.

Trick Gear—A gear practically identical with the Allan link motion was independently brought out in Germany by the inventor whose name it bears, and mention is made of it here for the reason that the straight-link gear is sometimes referred to under that title.

Polenceau Gear—Very similar in its initial arrangement to the Gooch gear, and constituting practically a modification of it, is the Polenceau reversing and cut-off gear shown by Fig. 10; but, with this arrangement, a separate expansion valve is operated in connection with the main valve, necessitating two valve spindles E and E', as illustrated. It is plain to be seen from the sketch how this gear works. If the engineer wishes to throw the expansion valve out of action, so as to use the gear as a simple Gooch motion, he merely brings the levers in line and locks them together. The Polenceau gear is ingenious and has been extensively utilized, but it possesses a number of serious disadvantages, which will not be gone into here, that have made it unpopular in this country.

Meyer Gear—A modification of the Polenceau gear, which permits of all possible degrees of expansion from zero on, is the Meyer gear, largely used in rolling-mill engine service. This, however, affects principally the valve construction, which is not of interest here, and on the eccentrically operated link end a number of combinations, on the order of the foregoing, have been worked out, which have given the Meyer gear a wide range of adaptability. Among its good points is a minimum of valve friction.

Borsig, Breval, Gonzenbach, Napier and

Rankine, Farcot, and Georges gears, each of which embodies a separate expansion valve, are closely related to that of Polenceau's and have been used to a considerable extent in Europe, the last named being similar to the Meyer gear in that it fulfils most of the conditions of a perfect expansion gear. The arrangement of eccentrics, link and rods offers in each case, however, no essential difference from what has already been illustrated, and they are mentioned here only for the sake of completeness.

Guinotte Gear—A gear which can be actuated by Stephenson's, Gooch's, Allan's or a single-eccentric link motion, such as Waldegg's hereinafter described, is that of Guinotte. It differs, however, from Polenceau's and the other separate expansion-valve motions in the fact that, with this gear, the direction of an engine can be reversed without altering anything in the mechanism that controls the cutoff.

"It is an interesting fact," says a well known authority with reference to Stephenson's, Gooch's and Allan's gears, "that among the infinite number of possible cases, practice has picked out by trial just those three which have been found to be theoretically the simplest and most feasible." This remark applies with nearly equal force to the other link and valve motions referred to in the foregoing, but it seems hardly probable that inventive ability in this line has been so far exhausted as to preclude any material improvements in future. Of late, however, the efforts of engineers designing reversing engines appear to have been concentrated more upon motions of the several types described in the following sections, which have for convenience been classified under the headings of single-eccentric, direct-, bevel- and spur-driven gears.

SINGLE-ECCENTRIC MOTIONS

From the fact that a single-eccentric gear is much less expensive to construct than the double-eccentric link motion, a great deal of effort has been expended upon designing methods for reversing engines by the use of only one eccentric and a simple arrangement of rods with which to transmit the motion to the valve.

Hackworth Gear—Hackworth's reversing gear, which was the prototype of the Marshall gear shown in Fig. 11, works according to the principle that the motion of a point on a rod, one end of which moves in a circle and the other on a straight line passing through the center of that circle, is on an ellipse whose major axis coincides with the straight line; but that if the end of the rod slides on a line inclined to this center line, the major axis of the ellipse will be inclined. In Hackworth's gear, therefore, a single eccentric is keyed to the shaft exactly opposite to the crank; the eccentric rod has its end attached to a block which slides on a guide bar inclined to the line through the center of the shaft, and a rod from about the middle of the eccentric rod is connected to the valve rod, which works in a line at right angles to the line through the eccentric rod when in mid position. Now, if the guide bar on which the eccentric-rod block slides is moved so as to reverse its inclination, the inclination of the axis of the ellipse and, consequently, the motion of the engine are reversed.

Marshall Gear—The Marshall reversing gear is a modification of Hackworth's and differs from it only in the method of [illegible] at the ultimate motion of the rod end. In Fig. 11 it will be seen that the eccentric rod B is hung by means of a rod W from a point near the upper end of the lever V in such a way that the point W moves on the arc of a circle inclined to the center line. The motion is not quite as perfect as with the inclined sliding bar used for Hackworth's gear, and necessitates special designing of the lower end of the slide valve in order to get as much opening to steam there as at the top end, but there is less friction and, on the whole, it works most satisfactorily. The pins need to be of good size and require adjustable brasses to provide for the large amount of wear which necessarily comes upon them.

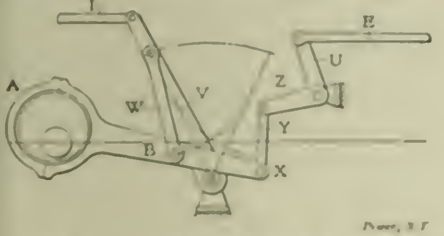

FIG. 11. MARSHALL REVERSING GEAR

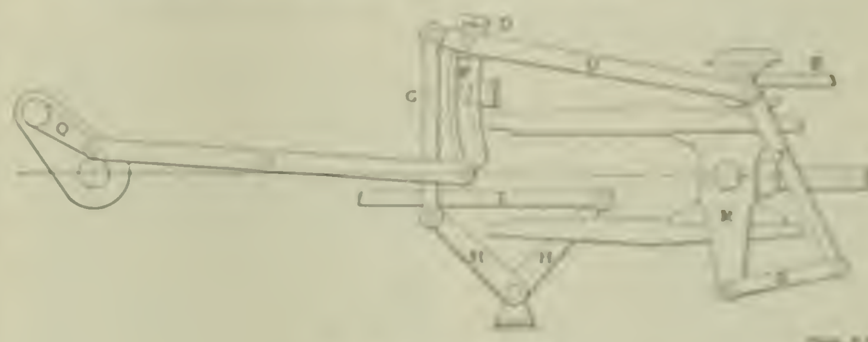

FIG. 13. WALSCHAERT GEAR

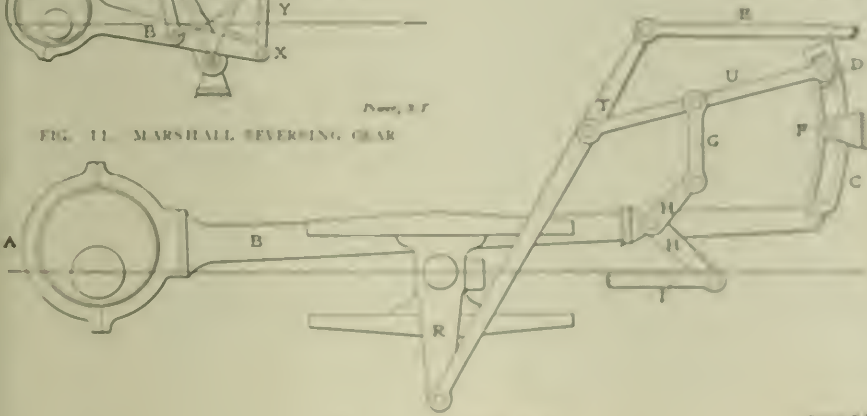

FIG. 12. WALSCHAERT GEAR

Among the great advantages of this gear, which were very clearly brought out in an article appearing on pages 660-661 of the April 21, 1908, number of POWER AND THE ENGINEER, is the excellent motion imparted to the valve, inasmuch as there are two quick and two slow motions in a revolution, the quick ones occurring at cutoff and the slow ones during exhaust and previous to opening. Constant lead and a large variation in the amount of cutoff are also possible with this arrangement without wiredrawing from small opening and slow closing of the port, as is the case with the ordinary link motion. The chief objections urged against the Hackworth gear were the excessive friction and consequent wear on the sliding blocks and the liability of so many pins to derangement. In Marshall's gear, however, these difficulties are largely overcome, making it particularly adaptable to marine and rolling-mill engine service.

Walschaert Gear—This valve gear, shown in Fig. 12, has fixed upon the crank of the driving axle an eccentric R whose center line forms a right angle with the center line of the crank. The eccentric rod B gives to the link C, which turns on the fixed pin F, an oscillating motion. The link has a curved slot in which the sliding block D can be moved up and down, so as to produce a variable expansion. The radius rod U is connected with a lever whose upper end is attached to the valve spindle E, while its lower end moves in a bracket H on the crosshead. The lever has a [illegible] pin attached to it [illegible] end moves back and forth with the piston rod, the point of connection with the radius rod *U* gets from the link another oscillating motion, and the upper end of the lever connecting with the valve spindle *E* is given a movement which, as experience has shown, is most suitable for producing the desired effect on the valve. In the gear for which this link motion is be called the link, to rise and fall, and the eccentric-rod motion is principally backward and forward. These two separate motions are combined at the point *X*, which moves in either a circular or an elliptical path, according to the relative proportions of the bell-crank lever arms *T* and *T′*.

The motion of the point *X* actuates the zontal travel of the valve rod similar to that produced by an ordinary link motion. The point *L* on the eccentric arm, however, has a somewhat complicated motion, being practically a distorted ellipse, the form of which is dependent on the motions of *X* and *Y*. The motion of *Y* is modified by the position of the supporting point *Z*, which is controlled from the cab

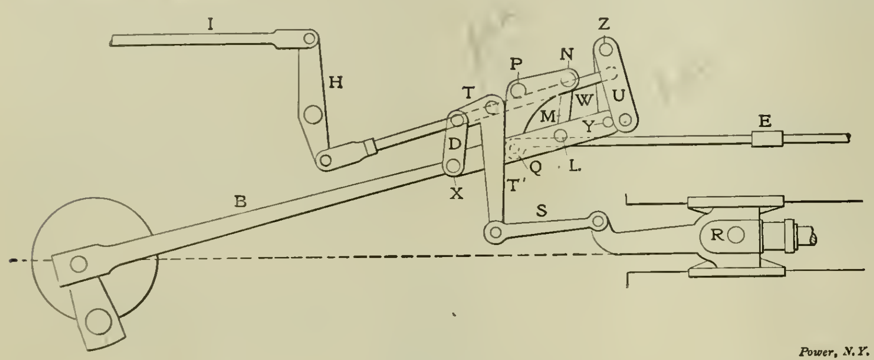

FIG. 14. BAKER-PILLIOD GEAR

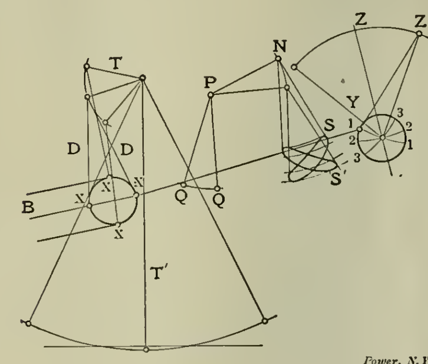

FIG. 15. DIAGRAM OF BAKER-PILLIOD GEAR

designed, the principal end sought is to secure a constant lead, and this object is completely attained; but the arrangement is generally considered too complicated, and constant lead is obtained at the expense of other qualities.

Walschaert Gear—The Walschaert gear, which has long been used on locomotives, is represented by Fig. 13, in which its essential features are clearly shown. As in the case of Waldegg's gear, the lower end of the lever *T* is connected to a bearing carried by the traveling crosshead, but it sustains a different relation to the radius rod *U*, the oscillating motion of which combines with the reciprocating movement of *T* to give a motion to the valve spindle *E* analagous to that obtained from a stationary link, as in the Gooch system. The eccentric is in the form of a return crank from the main crank pin. This arrangement is practically as complicated as that of the Waldegg gear, but constant lead is secured without many of the disadvantages attendant upon the latter.

Baker-Pilliod Gear—This gear, which has only recently been tried out on locomotives of the Chicago & Alton and Toledo, St. Louis & Western railways, is arousing a great deal of interest among operating men, and there is every indication that it will be largely adopted in this country. For that reason a somewhat extended description of it is given here. The mechanical construction of this gear, which has a constant lead, is similar to that of the Walschaert gear, but having considerably less throw. Referring to Fig. 14, the point *X* at the end of the eccentric rod is supported by an arm *D*, which takes the place of the link in the Walschaert gear and hangs from the short arm of a bell crank *T T′*. The lower end of *T′* receives its motion from the crosshead *R*. The pivot point of this bell crank is fixed. The crosshead motion causes *D*, which for convenience will eccentric arm *X Y*, and at the point *Y* this arm is supported by an arm *W* swinging about the point *Z*, which is held up by the reverse yoke *U* supported at a fixed point. The point *Z* is shifted by the movement of the reverse yoke *U*, controlled by the connection to the rod *I*, as shown in the figure. From this it will be seen that the operator can alter the position of the supporting point *Z* from which hangs the radius arm *W*, and so vary the curve made by the point *Y*. Now it will be seen that, as the eccentric arm *X Y* has a circular or elliptical motion at the end *X* and a radial motion at the end *Y*, all intermediate points along *X Y* will have motions compounded, so to speak, of the motion of *X* and the motion of *Y*.

Now for the method of actuating the valve rod. At a suitable point *L* on the eccentric arm *X Y* an upright arm *M* is placed. The upper end of this link is attached at *N* to one end of a bell crank which is pivoted at *P*. This point *P* is another fixed point on the motion. The

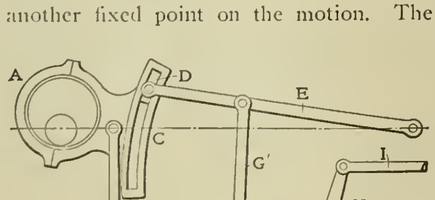

FIG. 16. FINK GEAR

point *Q* at the lower end of a vertical arm of this bell crank is where the valve rod is attached. The motion of the point *L* on the eccentric arm actuates the bell crank and the point *Q* swings on a curved path in obedience to the movement of the bell crank. The point *Q* has a radial motion about the pivot point *P*, and the movement is one of approximately hori- for forward or backward running and for all intermediate cutoff points.

The diagram, Fig. 15, shows the shape of the distorted elliptical path of the point *L*, and the portions of the ellipse passed over by the point *L* for the port openings and for lap and lead. The same letters that are used in Fig. 14 are used in Fig. 15. The ellipse marked *S* is the path followed by point *L* when in forward gear, and the ellipse *S′* is that followed in backward gear. The curve marked *1, 1* is that followed by the point *Y* in full forward gear, the curve *2, 2* is that followed when the reverse lever is in the center, and curve *3, 3* is that for full backward gear.

Among other things it is claimed for this gear that "It maintains uniform lead at all points of cutoff; a larger port opening at all points of cutoff; 5 per cent. travel of the piston required for full port openings; uniform cutoff; any cutoff from 75 to 85 per cent. can be had at full gear by lengthening the quadrant so that the reverse lever can be moved down, thus dropping the reverse yoke lower, which increases the travel of the valve and increases the cutoff at full stroke; late release, at quarter stroke releases at 85 per cent., that is, on 24-inch stroke with a 6-inch cut-off exhaust port opens when piston has traveled 20½ inches or 85 per cent. of stroke; late and balanced compression; excessive compression in the short cutoff is entirely eliminated; reduced back pressure because of quick complete release; lower terminal pressure which permits of larger exhaust nozzle; total absence of pre-admission and it produces 25 per cent. higher range of temperatures."

Young Gear—In relation to the Young valve motion there is considerable difference of opinion, and, as it is the valve alone that presents any new features, the gear will not be described here. In outward appearance it resembles the Walschaert.

Fink Gear—The Fink gear, shown in Fig. 16, although not strictly of the reversing type, is the least complicated of all link motions, and, while inferior to other gears for most conditions of service where reversing is required, has often

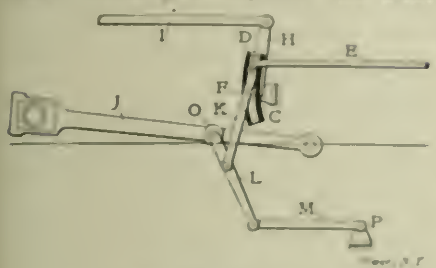

FIG. 18 JOY GEAR

been applied, either simply or with modifications. An ingenious application of it is exemplified by Fig. 17, which illustrates the gear used on a small reversible barring engine. It will be seen that in this arrangement the eccentric takes the form

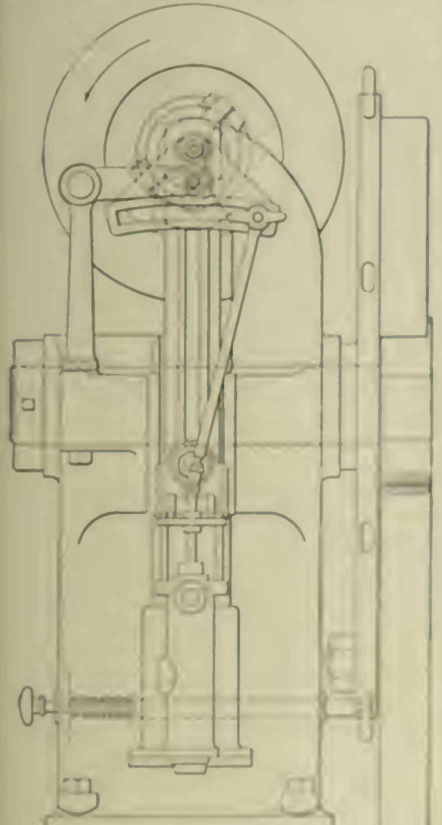

FIG. 17 FINK GEAR ON REVERSIBLE BARRING ENGINE

of a short crank on the end of the main crank shaft. There is no slip in the link block, because it is clamped in position for working anywhere in the curved slot. The link, it will be observed, is curved in the same direction as the Gooch link. This gear belongs to what is termed the radial type and has practically a constant lead. Other modifications of it have been made

but are in general more complicated than the one here shown.

RADIAL-, BEVEL- AND SPUR-GEAR DRIVE

Joy Gear—One of the most common methods of driving valves without using eccentrics is that embodied in Joy's valve gear, Fig. 18, which can be used on all types of engine and is especially adapted

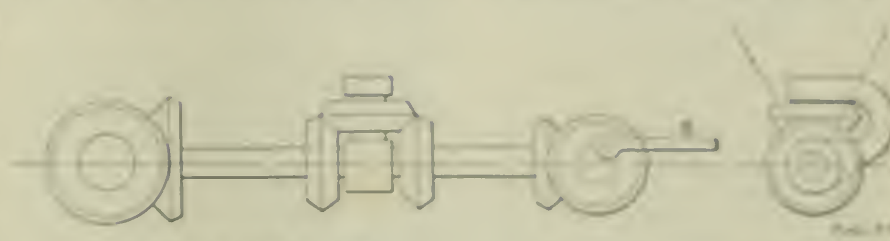

FIG. 20 BEVEL GEAR REVERSE

for marine and locomotive service. Fig. 19 illustrates the gear as applied to a marine engine. This gear gives a rapid motion to the valve when opening and closing and less compression at short cutoff than the link motion. The cutoff can be made nearly equal for all grades of the gear. With it constant lead is also to be secured.

Bevel Gear Reverse—In this gear, illustrated by Fig. 20, the reverse cross shaft indicated at the right has a motion coincident with the drum shaft on the other side and is driven by a series of seven bevel wheels. The reversing mechanism is actuated by the fourth gear and is movable up and down by hand or power, often by a small auxiliary engine. On each end of the reverse shaft is keyed a disk in which is formed a pin corresponding to an eccentric on other gears. It drives the valve mechanism by means of reach rods and gives them the same motion at all times. This is used mostly for hoisting engines, where the hoisting is done in balance, and the cutoff is under control of a regulator.

Sell's Spur Gear Reverse—This gear is a modification of the bevel-gear reverse, which it has largely superseded. Two eccentrics, set at [illegible] degrees apart, drive the shaft [illegible], Fig. 21, [illegible] second [illegible] gear wheels [illegible]. Reversing is accomplished by [illegible] the [illegible] through [illegible] to change the valve position.

These and similar gears are not, of course, to be taken as in any sense standard; they merely represent applications of perhaps well known mechanical principles which have been used in reversing engines designed for work of a special character, usually under conditions commonly found and with a view to some gain of definite advantages.

It is, however, a noteworthy fact that

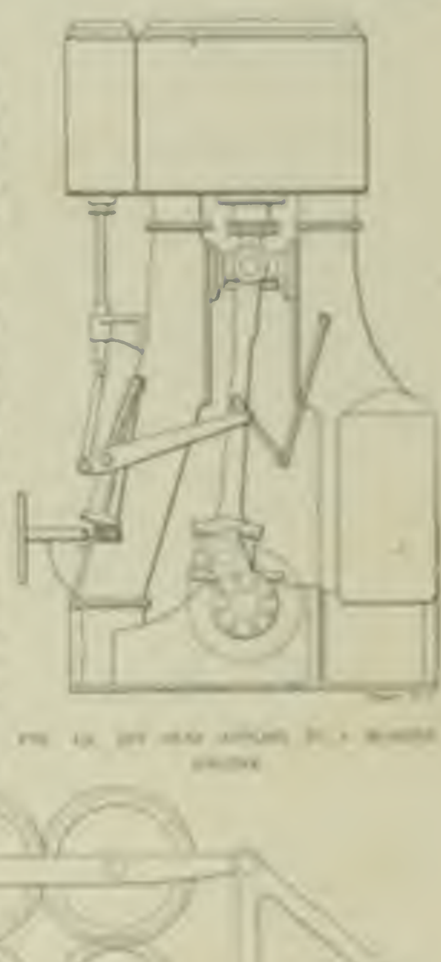

FIG. 19 JOY GEAR APPLIED TO A MARINE ENGINE

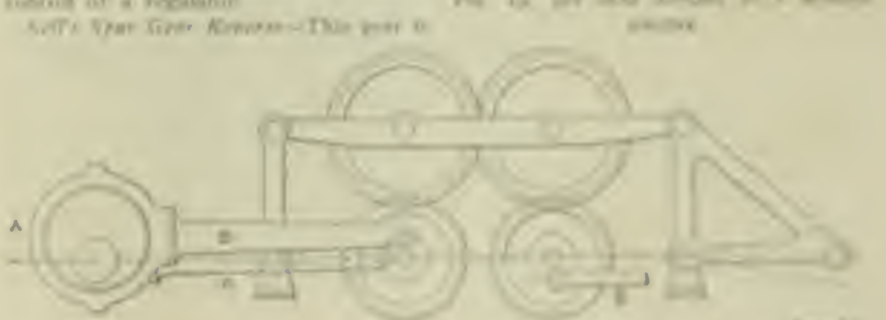

FIG. 21 SELL'S SPUR GEAR REVERSE

with the [illegible] Stephenson and Walschaert gears, these "freak" gears, as they may be termed, [illegible] ence book devoted entirely to them, with uniform diagrammatic sketches showing the various features of similarity and also the essential differences between them, would have in it much of value to the student of steam engineering.

Location and Repair of Troubles in Direct Current Motors

By R. H. Fenkhausen

When trouble develops in a motor, whether it is a failure to start or some other abnormal condition, a systematic course of action should be laid out and followed in each case until the trouble is located. The following tests, if carefully

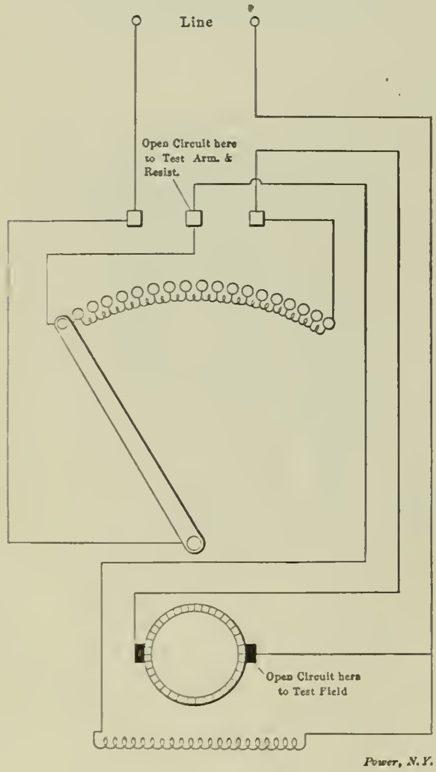

FIG. 1

made in the order given, will result in a speedy location of the fault:

In case the motor fails to start, first be sure that current is on the line, and see that the fuses are not blown, then inspect the brushes and make sure that they are not worn down enough to allow the brush holders to rest on the stops and prevent contact between the brushes and the commutator. If no trouble is found at any of these points, the load should be removed by taking off the belt, and the armature revolved several turns by hand to see if the bearings are free, after which another attempt to start the motor should be made. If it still refuses to start, the trouble is due to an open circuit, or in case of a newly installed machine either an open circuit or an incorrect connection.

Inspect all wiring and connections, to both the motor and the starting device, for loose or open connections and make sure that none of the wires is broken inside the insulation; this frequently occurs and is a very difficult trouble to locate blindly. If no fault is discovered the field-winding lead should be disconnected at the rheostat, the switch closed and the starting lever placed on the first contact for a moment and released. If an arc is drawn the continuity of the circuit through the armature and resistance is proved, and the field-winding circuit may be tested in the same way by replacing the connecting wire and opening the armature circuit by means of a match or piece of paper inserted between each brush and the commutator, and then testing as before. (See Fig. 1.)

If a motor sparks badly it may be due to overload, incorrect brush setting, flats on the commutator or trouble in the field or armature winding. The remedies for the first three troubles are obvious, but in case the windings are at fault the motor should be taken to the shop and repaired, as will be explained later.

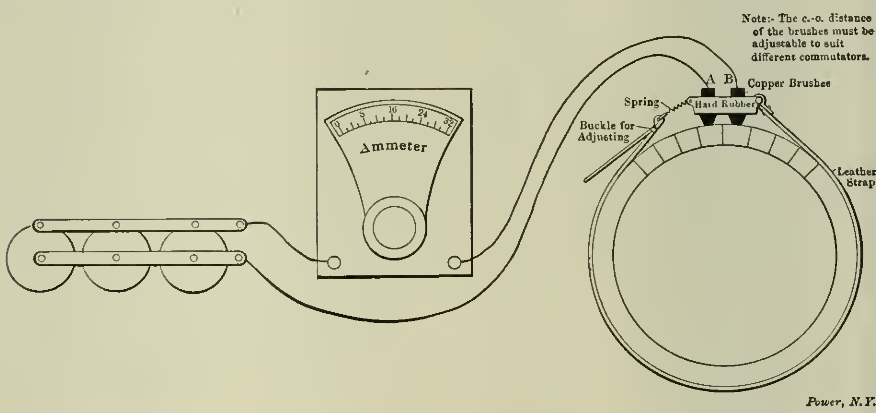

FIG. 2

Sparking due to overloads, improper brush setting or unbalanced field due to burned-out field coils is likely to be continuous, whereas sparking due to open coils, short-circuits or flats on the commutator will be intermittent in character and will occur once or twice per revolution. The sparking due to an open armature coil is readily distinguished by the deep pitting of the mica and rounding of the edges of the bars connected to the faulty coil.

Excessive heating of the windings of a motor may be due either to overload or to a partial short-circuit of the field or armature winding. If a motor becomes dangerously warm the load should be removed and the armature kept in motion, as the heat will be dissipated better than if the armature is stationary. The temperature should fall as soon as the load is removed; if it does not, the trouble will be due to a short-circuit and the motor should be stopped and the windings felt by hand.

A short-circuited field coil may be detected by its low temperature, as it will always be much cooler than the good coils. If two or three armature coils are hotter than the rest of the winding they are short-circuited either within themselves or by the commutator bars to which they are connected, but if the entire armature is hot, the cause will probably be found in a commutator partly short-circuited by oil-soaked mica insulation between the bars.

When the speed of a shunt-wound motor increases, after the field-magnet coils have been overheated, it may be taken as an indication that the field winding is partly burned out and some of the current is passing from layer to layer instead of traversing the entire winding.

In case trouble is located in the rheostat, it should be taken down and the resistance examined for an open coil, which if found may be bridged over until such time as it can be replaced. If the field circuit of the motor tests open, trouble should be looked for in the retaining magnet on the starting box, and if that is burned out or open-circuited in such a way as to make repairs very difficult, and the motor is urgently needed, the magnet terminals may be short-circuited and the rheostat lever tied in the running position. As this leaves the motor unprotected in case the power should be shut off and turned on again before the rheostat lever is released, the motor should be closely watched until such time as the proper repair can be made.

Should trouble be located in a field-magnet coil, the faulty coil should be removed from the motor and untaped. The cause of trouble will usually be found either in broken or short-circuited end connections which are easily repaired; but if the defect is in the inner layers of the coil, the wire must be unwound until the faulty place is located. If the insulation of the wire is so badly charred that it can be scraped off with the finger nail, a new coil is the only remedy. The burning out of a field-magnet coil is usually the result of a short-circuit of one of the other coils, which overloads the remaining coils and burns them out.

Open circuits in armature coils usually occur in the end connections leading to the commutator, where they are easily repaired without removing the armature, but in case the open circuit is inaccessible or the coil is short-circuited, and temporary repairs must be made, the faulty coil should be entirely disconnected and the commutator bars to which it was connected short-circuited until such time as proper repairs can be made. If a coil is short-circuited it will also be necessary to cut each turn of the coil or else sufficient heat may be developed to destroy the adjacent coils.

Most of the repairs previously mentioned can be made in a short time and without removing the motor from service, but in case the trouble is serious the motor must be taken to a shop, where proper facilities exist, for the accurate location of trouble and its speedy repair.

Owing to the low resistance of an armature winding the location of open, grounded, or short-circuited coils with a magneto or test bell is impossible and use must, therefore, be made of some instrument sufficiently sensitive to detect small differences in resistance, such as a Wheatstone bridge. These instruments are not often available and some substitute must be devised. Fig. 2 shows a testing outfit, the materials for which may be found in almost any plant, and which is sufficiently sensitive to locate an unsoldered or partly broken connection.

A few cells of dry battery having low internal resistance and high amperage should be connected in parallel, 1/16x[illegible] inch copper ribbon being used for connections, as shown. These batteries should be in series with a low-resistance ammeter having a 20- or 30-ampere range and flexible testing leads connected. All wiring should be at least No. 8 Brown & Sharpe gage, with all connections as short as possible, the idea being to make the resistance of the testing outfit small as compared with that of the armature. If terminals *A B* are brought in contact, the armature indication should be very nearly full scale. The brushes and ring shown in Fig. 2 should be applied to the commutator, with the brushes separated a distance equal to the thickness of one bar of the commutator. The brushes should then be advanced bar by bar and a reading taken each time, being sure the surface of the commutator is perfectly clean. If the armature winding and connections are sound, practically uniform readings will be obtained, which in the case of a 5-horsepower 220-volt motor will be in the vicinity of 10 amperes.

If a short-circuited coil or pair of bars is found, the reading will be higher, depending, of course, on the amount of the coil that is affected. If an open-circuited coil is found the reading will be very low, as the current must traverse the entire armature instead of one coil (see Fig. 3), and if two or more open circuits exist the ammeter will indicate zero (see Fig. 4). If the ammeter gives a reading much lower than the standard, but too large for an open circuit and the motor acted as if open-circuited, it will probably be found that a coil is open, but that the broken ends are in light contact inside the insulation. When the motor is started centrifugal force separates the ends and causes an open circuit, which closes again when the motor stops.

When testing for a ground one of the test terminals is clamped to the shaft and the other touched to each commutator bar until the one that gives the highest reading is found. The ground will either be in this bar or one of the coils connected to it.

Trouble with burned-out coils and open circuits is often caused by mica between commutator bars, and if there is reason to suspect this trouble all the bar leads should be taken out of the commutator. This will leave each bar without connection to any other. A pair of test terminals (Fig. 5) should be connected in series with a few 110-volt lamps and the mica between any two segments that will not stand the application of the test terminals without smoking or getting hot.

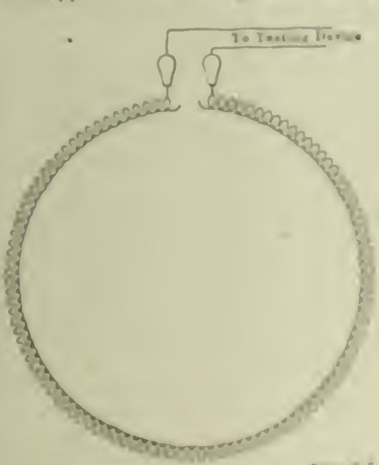

FIG. 3

FIG. 4

FIG. 5

When a commutator wears into one or two large flats it is often due to the segments having been cut at different times and not being of the same degree of hardness. There is no remedy for this, but conditions may be improved by taking the commutator apart and spacing the soft segments evenly around it. When new mica is to be placed in a commutator it must be carefully selected, for if it is too hard it will not wear as rapidly as the copper, and will project above it and cause sparking; and if it is not of the proper thickness trouble will be experienced in assembling the commutator.

A V-shaped tool, slightly rounded on the point and without lip should be used for turning commutators and only very light cuts should be taken; otherwise, small wedges of copper will be drawn over and imbedded in the mica, causing short circuits.

When polishing a commutator after turning only sandpaper should be used; if emery cloth is used small particles of emery will be imbedded in the copper and cause subsequent cutting.

An electric-power plant for Bogotá, Colombia, is projected, according to Consul-General Jay White. At present the streets of Bogotá are not lighted because the electric company, which has its power station [illegible] miles from the city, has not sufficient power to supply the necessary current for both house and street lighting. The site of the new plant is three miles from Bogotá, and [illegible] about the [illegible] of the city. The city could be well lighted with [illegible] arc lamps or with [illegible] lamps and [illegible] incandescent lamps. The cost for the [illegible] is estimated as follows: The [illegible] [illegible] [illegible] and incandescent [illegible] [illegible]

Some Live Steam Separator Tests

Showing Efficiency of Separation Decreases with the Velocity and Increases with the Percentage of Moisture in the Entering Steam

BY PROF. G. F. GEBHARDT*

A number of tests made at the Armour Institute of Technology on steam separators of various types and sizes tend to show that in practically all separators:

(1) The efficiency of separation decreases as the velocity of the steam increases.

(2) The efficiency increases as the percentage of moisture in the entering steam increases.

(3) The drop in pressure increases rapidly with the increase in velocity.

The few published tests of separators conducted by different investigators appear to confirm these results although comparisons are difficult on account of the meagerness of available data.

Fig. 1 gives a diagrammatic arrangement of the apparatus as used in the Armour tests. Steam is led from the boiler through the 8-inch pipe *A* and valve V_1 to the service separator *M*. The steam leaves this separator practically dry and saturated, the exact quality being determined by throttling separator T_1. From this point the steam passes through pipe *P* (the size of which conforms to that of the separator to be tested) to separator *S*, which is to be tested. The quality of the steam entering *S* is varied by a water spray *W*, the temperature of which is maintained at practically that of the steam leaving the separator *S* is checked by separator *B* (two sizes larger than separator *S*) and throttling calorimeter T_2. The pressure in the system is regulated by valves V_1 and V_2 and the pressure drop through separator *S* is determined by gages G_3 and G_4. The weight of steam entering separator *S* was determined by collecting the entrainment in chambers *D* and D_1 and the condensation from the surface condenser. The velocity was calculated, on the dry-steam basis, from

Q_1 = Quality of mixture entering separator,

Q_2 = Quality of mixture leaving separator,

E = Efficiency of separation.

Then

$$Q_1 = \frac{S}{S + W}. \quad (1)$$

$$Q_2 = \frac{S}{S + W - D}. \quad (2)$$

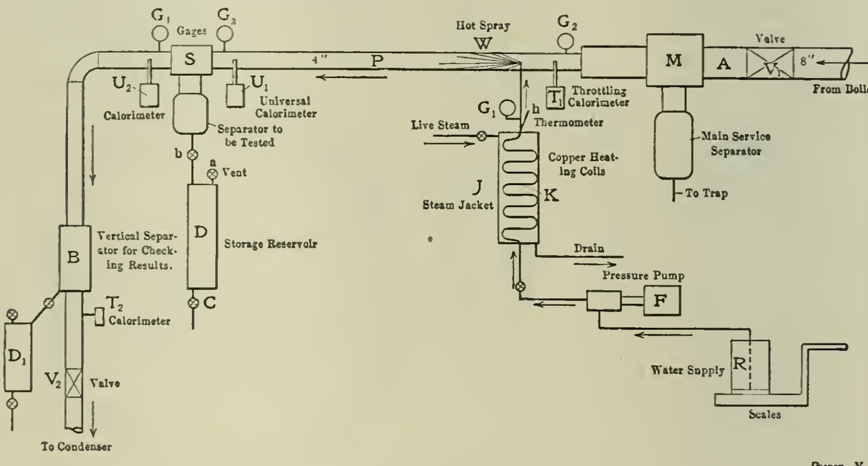

FIG. 1. ARRANGEMENT OF SEPARATOR AND APPURTENANCES

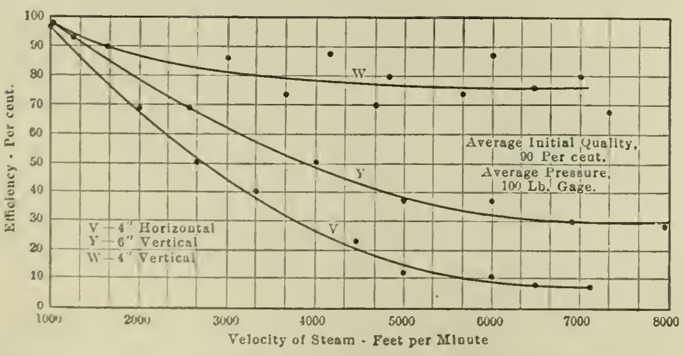

FIG. 2. EFFICIENCY DECREASES WITH VELOCITY

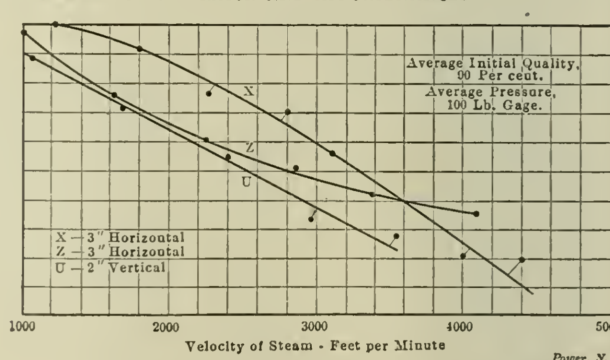

FIG. 3. EFFICIENCY DECREASES WITH VELOCITY

in pipe *P* by means of heating coils *K* and steam jacket *J*. Heating the spray in this manner minimizes the condensation in pipe *P* and insures a more intimate mixture of moisture and steam. The quality of steam entering and leaving separator *S* is determined by universal calorimeters U_1 and U_2. The moisture entrained by separator *S* is trapped in storage reservoir *D* and the weight determined. The quality of the steam the known area of pipe *P*. In draining reservoirs *D* and D_1, valve *b* is closed, vent *a* opened and the contents drained through valve *C*. All pipes and fittings were carefully lagged and all instruments calibrated before and during the test. Let

S = Weight of dry steam entering separator *S*,

W = Weight of water injected by spray *W*,

D = Weight of water removed from reservoir *D*,

This is on the assumption that steam leaving service separator *M* is dry and saturated. If the quality is less than 100 per cent., suitable corrections must be made.

$$E = \frac{D}{W}. \quad (3)$$

From equation (2)

$$D = S + W - \frac{S}{Q_2}. \quad (4)$$

This equation was used in determining

*Professor, mechanical engineering, Armour Institute of Technology, Chicago, Ill.

D from the tests not made at Armour, and in which only S_1, Q_1 and Q_2 were given.

Five different types of separator were tested, and, since the parties for whom the tests were made were unwilling to have the name of the separator published, they will be designated as *U*, *V*, *W*, *X*, *Y* and *Z*.

Separator *U*: 3-inch vertical; no baffles; current reversed once.

Separator *V*: 4-inch horizontal with single baffle plate of the fluted type; steam current reversed once.

Separator *W*: 4-inch vertical with two baffle plates of the smooth type; steam current reversed once.

Separator *X*: 3-inch horizontal; several fluted baffle plates; no reversal of current.

Separator *Y*: 6-inch vertical, centrifugal type; current reversed once.

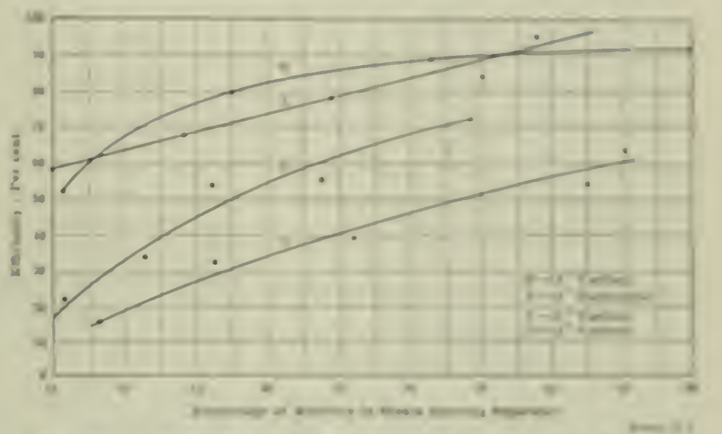

FIG. 4. EFFICIENCY OF SEPARATION INCREASES WITH PERCENTAGE OF MOISTURE

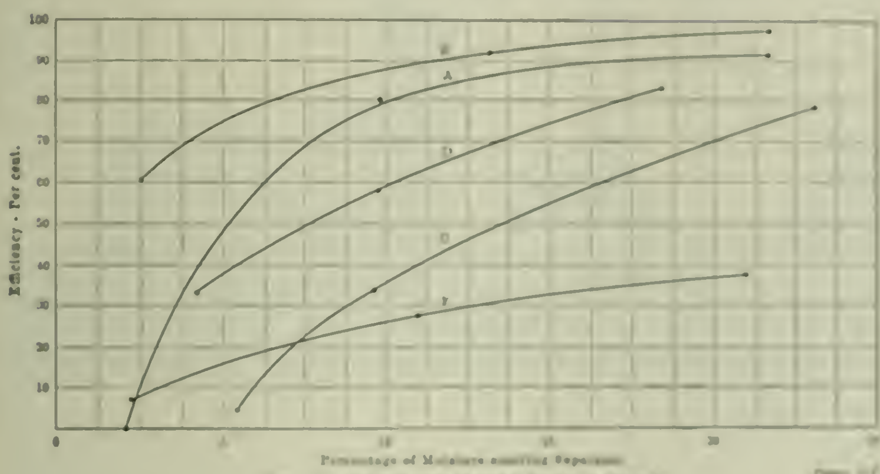

FIG. 6. EFFICIENCY CURVES FROM TABLE 1

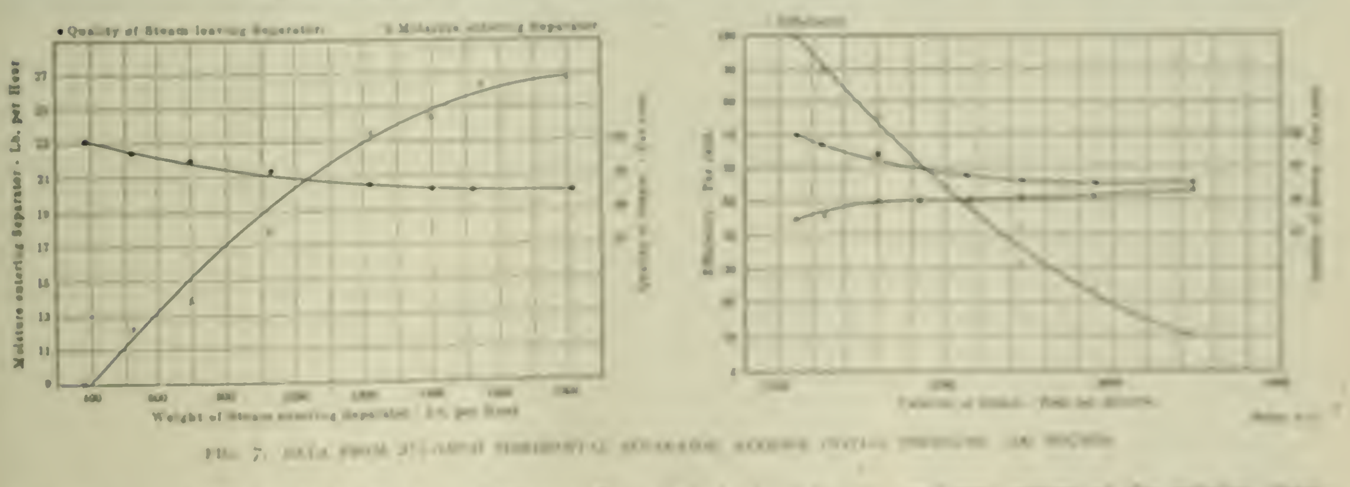

FIG. 7. DATA FROM 3½-INCH HORIZONTAL SEPARATOR [illegible]

Separator *Z*: 4-inch horizontal; current reversed twice; steam impinges on horizontal fluted baffle during reversal.

The influence of the velocity of the steam on the efficiency of separation is shown in Figs. 2 and 3. It will be noted that, the quality of the entering steam remaining constant, the efficiency of separation decreases as the velocity increases and reaches a point where the separator is practically useless.

From Fig. 4 it will be seen that the efficiency of separation increases as the percentage of moisture entering the separator increases. The velocities in Fig. 4 were not the same for all separators and hence the curves are not truly comparable, but a few scattering tests with constant velocities (not included here) show that the efficiencies vary substantially as illustrated.

Fig. 5 shows the increase in pressure drop for different velocities. It will be noted that the pressure curve has a characteristic similar to that for the flow of steam in pipes. The curves in Fig. 6 are plotted from the results of separator tests made by Prof. R. C. Carpenter, Cornell University, on several types of separators.* These curves are similar to those in the Armour tests, Fig. 4. In all these tests the efficiency increases with the moisture content of the entering steam, but there is a considerable variation between the various separators.

The curves in Fig. 7 are plotted from the results of tests at the University of Michigan on a 3½-inch Cochrane separator.

143.0	14.0	2.11	85.0

rator.** The quality of the steam leaving the separator remains practically constant for a wide range in capacity. Plotted on the velocity and efficiency basis, however, the efficiency drops off rapidly with the increase in velocity. An inspection of the "quality" curves shows that although the moisture leaving the separator is very small, the weight of moisture entering is also small. In other words, only a small portion of the water is eliminated.

Tables 1, 2, 3, 4 and 5, taken from the tests of separators of various types and by different investigators, show a decreasing efficiency with increase of velocity. The efficiencies in these tables are high, but it will be noted that the velocities are comparatively low; by plotting these results and continuing the curves to velocities of 4000 feet per minute or more, the efficiencies will fall very low, as in Figs. 2 and 3. The practice of using separators larger than those designed for a given pipe size is apparently a wise one.

TABLE 5. EFFICIENCY TEST OF SIX STEAM SEPARATORS.

("Engineering News," September, 1891, p. 233).

Make of Separator.	Quality of Steam Before.	Quality of Steam After.	Efficiency Per Cent.
B	97.5	99.0	60.0

E	98.1	98.5	21.1
F	97.7	97.9	8.7
C	95.6	95.8	4.5
A	98.0	98.0	0.0
Steam with about 10% of moisture.			
B	87.0	98.8	90.8
A	90.1	98.0	80.0
D	89.6	95.8	59.6
C	90.6	93.7	33.0
F	88.9	92.1	28.8
E	88.4	90.2	15.5
Steam with about 20% of moisture.			
B	78.1	98.8	94.5
A	79.5	98.2	91.2
D	81.7	97.9	83.5
C	78.2	95.6	79.8
E	82.4	90.4	45.5
F	79.3	87.2	38.1

The conclusions drawn from the tests are based upon the performance of only a few small separators of different designs and under 6 inches in size and do not necessarily refer to all types and sizes.

A remarkable undertaking for the development of electric power is reported from Halifax, N. S. An application has been made to parliament for a charter authorizing the damming of the head of the Cumberland basin, the basin of Minas and several other streams emptying into the Bay of Fundy, with the object of utilizing the tidal flow to develop electric power for sale in New Brunswick and Nova Scotia. There is a tidal flow of about 40 feet in the Bay of Fundy, from which it is believed that an immense amount of power can be developed.—*Mechanical World.*

****The Engineer*, March 15, 1906.

How the Government Saves Money on Coal

The technologic branch of the United States Geological Survey reports that the plan inaugurated two years ago by the Government for the purchase of coal on its heating value has resulted in the delivery of a better grade of fuel without a corresponding increase in cost and with, therefore, a saving to the Government. At the present time, 40 departmental buildings in Washington, the Panama Railroad, more than 300 public buildings throughout the United States, navy yards and arsenals are buying their fuel supplies on specifications the prime element in which fixes the amount of ash and moisture.

Premiums are paid for any decrease of ash below 2 per cent. from the standard at a rate of $0.01 per ton for each per cent. Deductions are made at an increasing rate for each per cent. of ash when it exceeds the standard established by 2 per cent.

It has been demonstrated by the technologic branch, which has charge of the analyses of the coal, that under these specifications the Government has been getting more nearly what it pays for, and paying for what it gets.

The purchase of coal on specifications is but one of the activities of the Government looking toward a more efficient use of the fuel resources of the country. Engineers of the Survey are studying the problem in all its phases at the experiment plant, in Pittsburg, Penn. The investigations, by suggesting changes in furnace equipment and in methods of firing the coal, are indicating the practicability of the Government purchasing cheaper fuels, such as bituminous coal and the smaller sizes of pea, buckwheat, etc., instead of the more expensive sizes of anthracite, with a corresponding saving in price. The fuel bill of the Government now aggregates about $10,000,000 yearly, the saving on which, through securing coal containing less ash, alone amounts to $200,000.

Since the Government has been purchasing coal on the basis of its heating value a growing interest has been manifest on the part of manufacturers and the general public in this important subject and a demand has been created for authentic information concerning the results accomplished. In response to this demand the results of the Government's purchases of coal under the heat-value specifications for the fiscal year 1907-8 have been assembled in a bulletin just issued by the Survey in the hope of promoting a better understanding of this method of buying fuel. John Shober Burrows, the engineer in charge of this part of the fuel problem, has included in the bulletin a list of the contracts with abstracts of the specifications for the current fiscal year.

In explaining the nature of the specifications, Mr. Burrows says:

"Government specifications are drawn with a view to the consideration of price and quality. For manufactured articles and materials of constant and uniform quality they generally can be reduced to a clear statement of what is desired. For coal, however, the variation in character makes this impracticable.

"This lack of uniformity is the feature recognized and provided for in the coal specifications prepared by the Geological Survey. Under these specifications, bidders are requested to quote prices on the various sizes of anthracite, a definite standard of quality being specified for each size, and to furnish the standard of quality with price for bituminous coal offered. Awards are then made to the lowest responsible bidder for anthracite and to the bidder offering the best bituminous coal for the lowest price. The specifications become part of the contract, and the standards of quality form the basis of payment for coal delivered during the life of the contract. For coal delivered which is of better quality than the standard, the contractor is paid a bonus proportional to the increased value of the coal. For deliveries of coal of poorer quality than the standard, deductions are made from the contract price proportional to the decreased value of the coal. The actual quality and value of coal delivered is determined by analysis and test of representative samples taken in a specified manner by agents of the Government and analyzed in the Government fuel-testing laboratory at Washington. The necessity of paying for coal on a sliding scale was fully discussed by D. T. Randall in a recent paper."

The advantages of buying coal on specifications are explained by Mr. Burrows as follows:

"The advantages of this system of purchasing coal may be briefly summarized as follows:

"Bidders are placed on a strictly competitive basis as regards quality as well as price. This simplifies the selection of the most desirable bid and eliminates controversy and criticism in making awards.

"The field for both the Government and dealers is broadened, as trade names are ignored and comparatively unknown coals offered by responsible bidders may be accepted without detriment to the Government.

"The Government is insured against the delivery of poor and dirty coal, and is saved from disputes arising from condemnation based on the usual visual inspection.

"Experience with the old form of Government contract shows that it is not always expedient to reject poor coal, because of the difficulty, delay, and cost of removal. Under the present system rejectable coal may be accepted at a greatly reduced price.

"A definite basis for the cancellation of contract is provided.

"The constant inspection and analysis of the coal delivered furnishes a check on the practical results obtained in burning the coal."

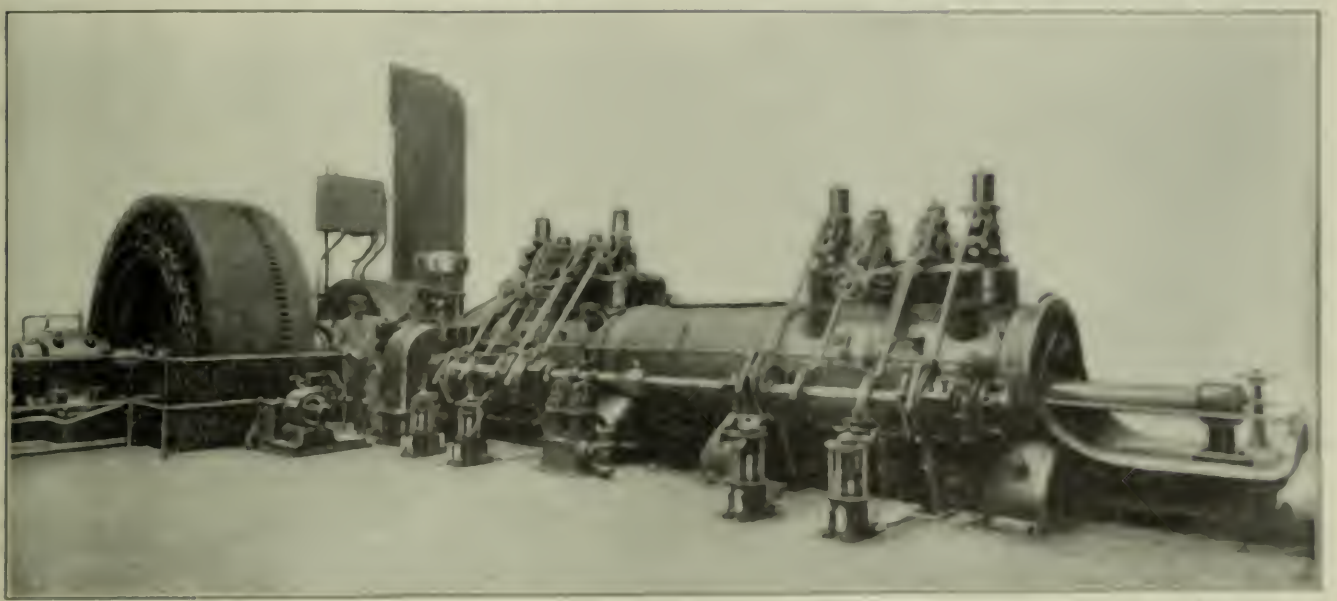
A few years prior to the adoption of the present system the necessity for a uniform standard in the purchase of coal became apparent to a few of the Government departments, and the idea of purchasing on the heat-value basis was introduced. It proved successful, especially in the treasury department, under which purchases are made for the postoffices and other public buildings throughout the United States. The treasury department had at that time a well-equipped laboratory and was thus enabled to do all of the necessary testing. Other departments were unable to follow the example of the treasury department because of lack of laboratory and proper facilities. In 1904, at the Louisiana Purchase Exposition in St. Louis, the Geological Survey began a comprehensive study on a practical scale of the utilization of coal, J. A. Holmes being placed in charge of the work. These investigations are still in progress at Pittsburg, Penn., and they have resulted in making authentic information of great practical value available to the public as well as to the Government departments.

This work led up to the development of a general and uniform specification plan for purchasing the Government coal supply.

A Nuernberg Gas Engine Running on Mixed Gases

By J. B. Van Brussel

There was recently installed in the power plant of an English steel works, a gas engine of the Nürnberg type, which is giving continuous service on a fuel composed of coke-oven and blast-furnace gases, mixed with air, of course. The engine is directly coupled to a three-phase alternator generating current at 550 volts and 50 cycles; this current is supplied directly to various motors at the colliery, coke ovens, steel works, etc., while for use at the works [illegible] power for pumping, [illegible], grinding mill, etc., the [illegible] is transformed to [illegible] volts. The engine is of the standard double-acting tandem type with cylinders 39 inches in diameter and a stroke of 51.2 inches. It gives a continuous output of 900 brake horsepower. At each end of each cylinder there are a single inlet valve and an exhaust valve, operated by means of eccentrics; there is also a gas-inlet valve regulated by a cut-off, under the influence of the governor, which regulates the quantity of gas in the mixture to suit the load.



A 900-BRAKE-HORSEPOWER NUERNBERG GAS ENGINE

The engine fuel consists of 10 per cent. coke-oven gas and 90 per cent. blast-furnace gas, the latter being obtained from a furnace delivering 120 tons of pig iron per twenty-four hours. The furnace is provided with only a single bell, and after leaving the furnace the gas enters a very large dust catcher from which the dust is drawn every other day. From the dust catcher the gas passes through a main 164 feet long into the scrubbers, which consist of eighteen vertical wrought-iron pipes, 15 inches in diameter and 46 feet high. The coke-oven gas pipe joins the blast-furnace gas pipe before the gas enters the scrubbers. Water is injected into the condensers twice a week for three hours. This serves to remove any dust which may have collected there. The boxes on which the scrubbers stand are cleaned once daily, being flushed out by a stream of water supplied through a rubber hose. After leaving the scrubbers the gas is finally cleansed in a Theisen washer before passing to the engine. Because of the scarcity of water in the neighborhood of the works, the water is used several times over in the washer, for a period of a fortnight. The dirty water flows from the Theisen washer to settling pools, and the clean water is pumped to an elevator tank, whence it flows once more to the Theisen washer. By this practice the actual consumption of water for cleansing the gas is said to be only 0.25 liter per cubic meter of gas, and the quantity circulated is from 1.75 to 2 liters per cubic meter of gas. The cleansing is very effective; the content of dust per cubic meter of gas amounts to only 0.013 to 1.007 grams, consequently it has been possible to run the engine continuously for seven months, Sundays excepted. One cubic meter of the coke-oven gas has been estimated to contain about 2.5 to 3 grams of sulphur. To reduce this sulphur, which has an injurious effect on the exhaust pipes, etc., a special purifying plant has been installed which reduces the sulphur to less than 0.25 gram per cubic meter.

Each time the blast-furnace bell is lowered the pressure of the gas falls from 4.5 inches of water to zero, rising again as soon as the bell is closed; but notwithstanding this, the gas engine has run very regularly, and the governor has been able to deal with all the variations of gas pressure and composition. The calorific value of the mixture is from 125 to 135 B.t.u. per cubic foot. If a tuyere at the blast furnace has to be changed and the blast taken off, air is admitted to the furnace through the tuyere peepholes, and, the furnace bell being closed, the furnace acts by virtue of its natural draft as an ordinary gas producer. The quantity of gas then delivered is sufficient to supply the engine.

With the exception of a steam engine for the blowing plant and one for the rolling mill, there is no steam equipment now in operation at the steel works where this gas-engine plant is installed, which indicates the degree of reliability that is confidently expected of the engine.

Heat Value of Coal from Dulong's Formula, Based on Ultimate Analysis

By N. A. Carle

Coal is organic matter that has undergone chemical changes and to which mineral impurities have been added. The chemical changes of carbon, hydrogen and oxygen from cellulose through the various stages to anthracite is indicated by the following table showing the average ultimate analyses:

Material.	Carbon.	Hydrogen.	Oxygen.
	Per Cent.	Per Cent.	Per Cent.
Cellulose	44.4	6.2	49.4
Wood	50.0	6.0	44.0
Peat	59.0	6.0	35.0
Lignite	69.0	5.5	25.5
Bituminous coal	82.0	5.0	13.0
Anthracite	95.0	2.5	2.5

These figures show that the transformation is accompanied by an increase in the percentage of carbon and a decrease in the percentages of hydrogen and oxygen. Sulphur and nitrogen are usually present, especially in bituminous coal and anthracite, but in showing the transformation of the elements carbon, hydrogen and oxygen, the percentages of sulphur and nitrogen are not included. The table is given merely to show that the elements of any fuel will vary in the percentages of carbon, hydrogen and oxygen.

Ordinary fuels contain foreign matter usually classed as impurities, consisting of moisture, nitrogen, sulphur, ash, dirt, etc. Of these, the sulphur has capacity to produce heat, but the nitrogen is inert and is usually classed with the moisture, ash, dirt, etc., as impurities.

The heat value of a fuel may be determined with more or less accuracy by any one of three methods, namely, chemical analysis, combustion in a calorimeter, or actual trial under a steam boiler. The first two methods give what may be called theoretical values and the third the practical value. The accuracy of the first two methods depends on the precision of the method of analysis or calorimetry adopted and upon the care and skill of the operator. They give with considerable accuracy the heat value which may be obtained under the conditions of perfect combustion and complete absorption of the heat produced.

The results of the third method are subject to numerous sources of variation and error, and may be taken as approximately true only for the particular conditions under which the test is made. There may be more or less imperfect combustion and numerous and variable losses. It may give the highest practical heat value if the conditions of grate area, draft, heating surface, method of firing, etc., are the best possible for the particular fuel tested, and it may give results far beneath what can be accomplished if the conditions are adverse or unsuitable to the fuel.

This article is intended to cover only the determination of the probable total heat of combustion from the chemical analysis. The calculation of the heat value of any fuel from the chemical analysis assumes that the heat value of the fuel will vary in accordance with some definite law based on the relative amounts of carbon, hydrogen, oxygen and impurities.

The total heat of combustion of any fuel is approximately equal to the sum of the heat values which could be produced separately by the combustion of its constituent parts. When oxygen and hydrogen are present in the proportion of one part of hydrogen to eight parts of oxygen, by weight, water is formed and these constituents have no effect in making up the value of the total heat of combustion. If a large quantity of water is thus formed, the latent heat of its vaporization must be deducted from the probable total heat of combustion. However, for the commercial fuels ordinarily encountered in the regular market, the heat necessary to vaporize the amount of water formed during combustion can be neglected.

The formula in general use is that known as Dulong's formula and is as follows:

$$Q = 14{,}500\ C + 62{,}000\ \left(H - \frac{O}{8}\right) + 4000\ S,$$

where

Q = B.t.u. per pound of fuel,

C = Percentage of carbon by weight per pound of fuel,

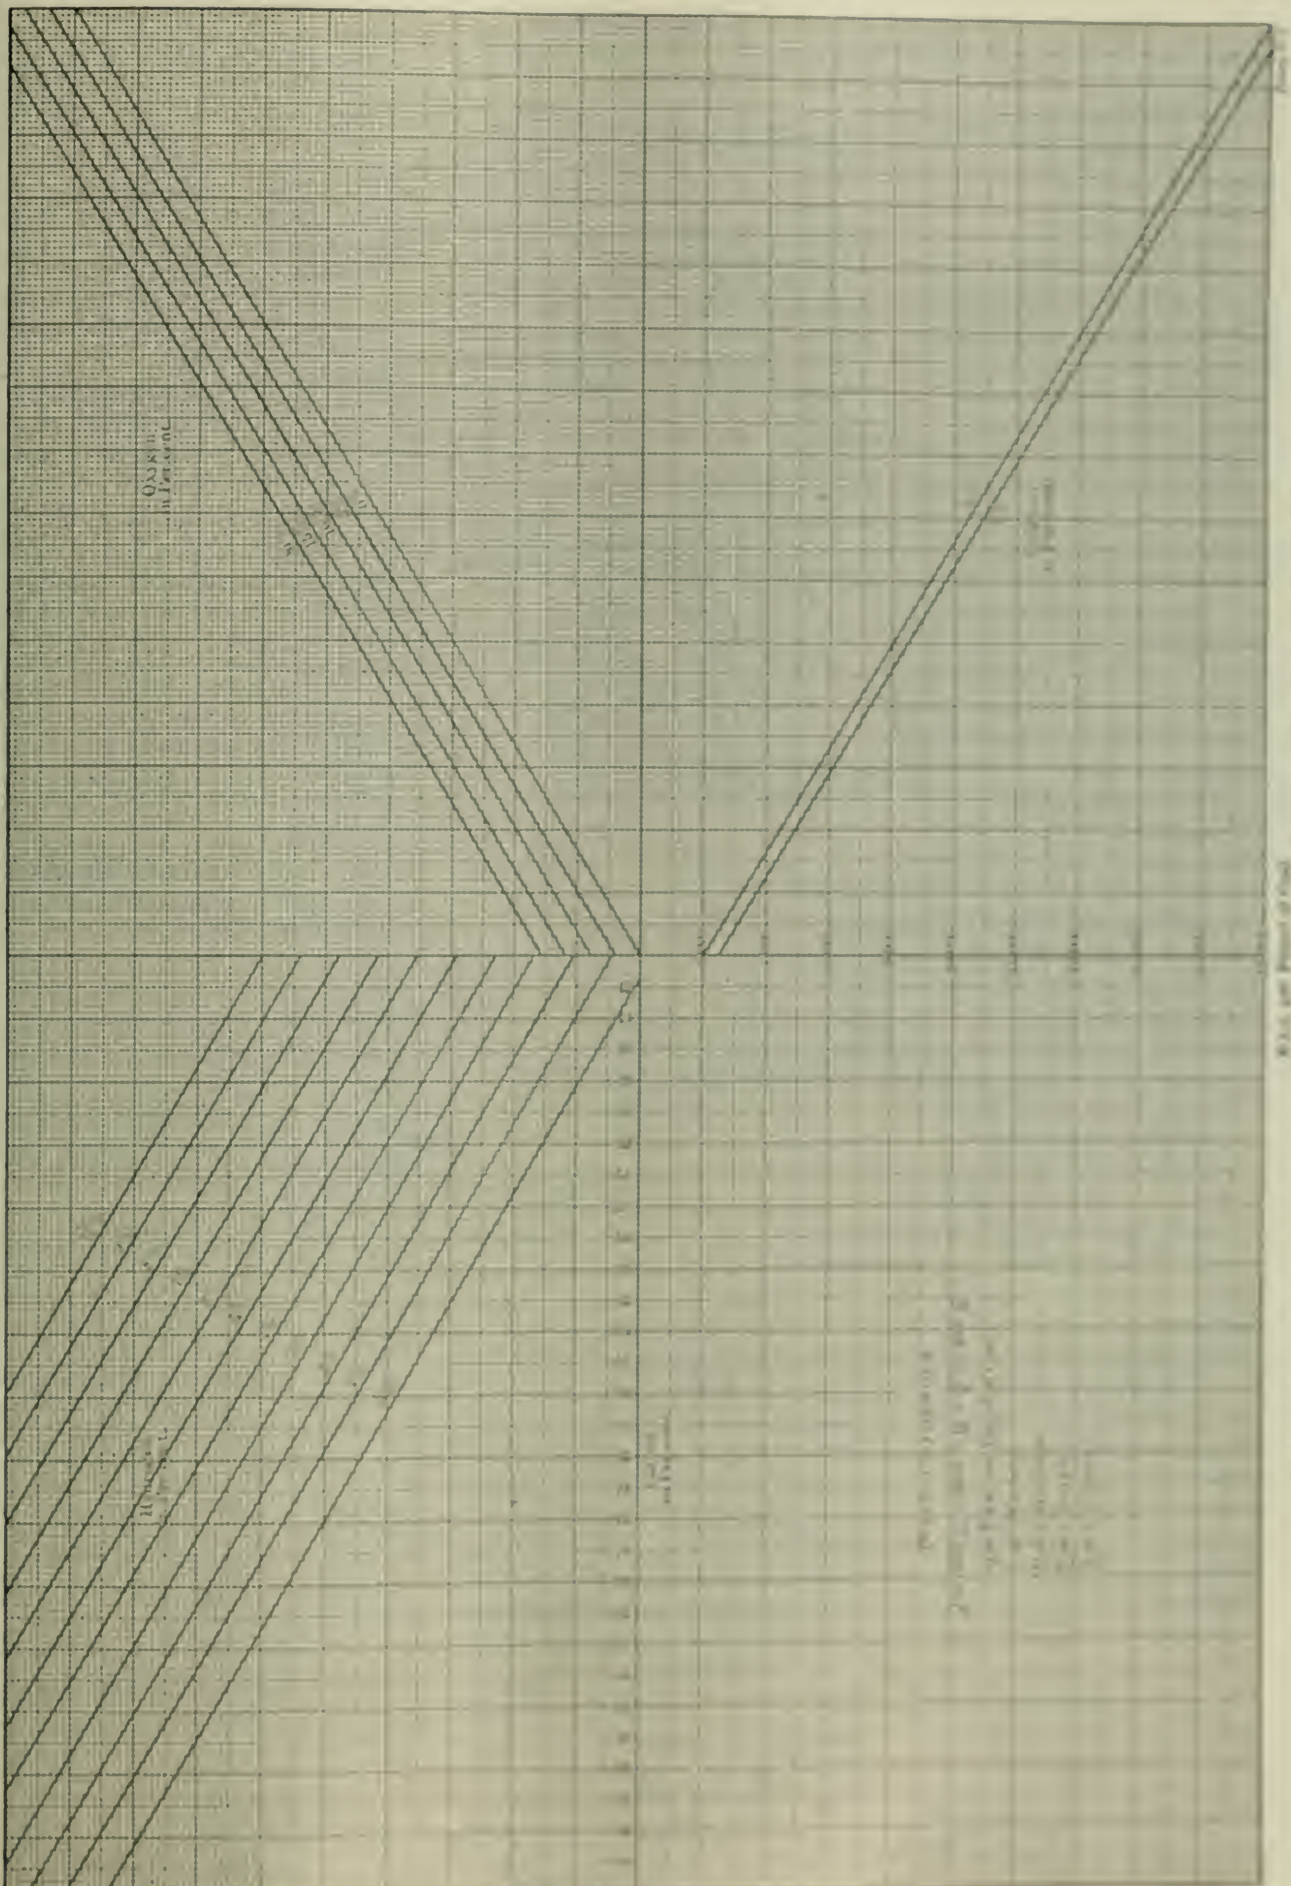
H = Percentage of hydrogen by weight per pound of fuel,

O = Percentage of oxygen by weight per pound of fuel,

S = Percentage of sulphur by weight per pound of fuel.

The impurities consisting of moisture, nitrogen, ash, dirt, etc., are not taken into account directly in the formula, but the percentages of the constituent parts in the formula are those per pound of fuel and their sum will be less than 100 per cent. by the amount of the impurities which are considered inert.

The chart, on page 839 is intended to show graphically the heat value of fuel as calculated by Dulong's formula. It is to be noted that the oxygen values subtract from the sum of the carbon and hydrogen values. This allows for the formation of water by the combination of hydrogen and oxygen, if they exist in the proper proportion. The added heat value due to the



sulphur is small because the percentage of sulphur is usually small and its heat value is low. In fact the sulphur can usually be neglected. The chart indicates very clearly that the elements carbon and hydrogen are the governing factors in the heating value of any fuel.

Examples

(1) If the ultimate analysis of a bituminous coal showed the following proportions, by weight, what would be the heat value per pound of this coal according to Dulong's formula?

	Per Cent.
Carbon	70
Hydrogen	5
Oxygen	10
Sulphur	2½
Impurities	12½
	100

Starting with 70 per cent. carbon, on the horizontal scale, read up to 5 per cent. hydrogen, then across to 10 per cent. oxygen, then down to 2½ per cent. sulphur and across to approximately 12,600 B.t.u. per pound of coal.

(2) Suppose the ultimate analysis of a semibituminous coal showed the following values by weight:

	Per Cent.
Carbon	80
Hydrogen	5
Oxygen	8
Sulphur	0
Impurities	7
	100

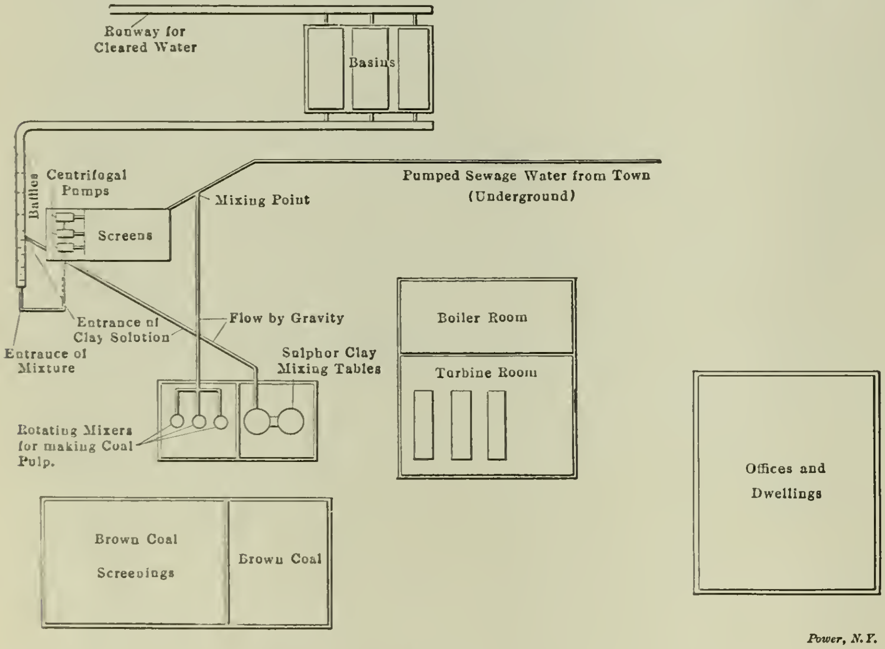
What would be the heat value per pound of this fuel according to Dulong's formula?

Starting with 80 per cent. carbon, read up to 5 per cent. hydrogen, then across to 8 per cent. oxygen, then down to 0 per cent. sulphur and across to approximately 14,100 B.t.u. per pound of coal.

Sewage and Brown Coal as Fuel

By R. W. Rogers

An interesting departure in the use of lignite, known as *jünger braun kohle*, is exhibited in the city electric-light station of Copenick, a town near Berlin with a population of some 30,000 and containing a number of factories, such as nitric-acid works, die works, washeries, etc. About three years ago it was decided to install an electric-light plant, and after careful consideration conclusions were reached to make some use of the city sewage waters as a possible fuel medium, and at the same time eliminate the contamination of the neighboring river water. In the process finely ground coal is used as a deodorizer in connection with a clay containing sulphur, aluminum sulphate, as a cleansing agent. Thus the object of the plant was to clean the waste water and give a practical use for the brown-coal dust, which otherwise is of very little value. The coal dust used is simply mine screenings with a chemical analysis of 61.5 per cent. carbon, 5.5 per cent. hydrogen, 33 per cent. oxygen and a heating value of 9000 B.t.u. per pound.



GENERAL OUTLINE OF COPENICK PLANT

A summary of the process is as follows: The brown-coal screenings are ground up fine and mixed with clear water to form coal pulp. This pulp is led by gravity to the intake of the sewage water, and mixed in the general ratio of one pound of coal to 8 cubic feet of sewage water. This solution is pumped by centrifugal pumps to an open conduit provided with numerous baffle walls and with a sufficient incline to reduce the initial velocity of about 9 feet per second to less than 1 foot per second at the outlet. Near the entrance to the conduit the sulphur clay is added, which is in the form of a liquid mixed in the proportion of one pound of clay to 16 U. S. standard gallons of water. This solution flows by gravity from elevated mixing tanks, and 1 cubic foot of the solution to 75 cubic feet of sewage is admitted to the conduit. The final mixture continues a zigzag path around the baffle walls, which gradually reduce its velocity of flow before it enters the clearing basins.

These basins are three in number and are approximately 700 feet long by 150 feet wide, with a slope of about 1 foot in 200 feet. In these basins a rapid settling takes place, leaving the water practically clear. It is then conducted to the neighboring river free from all contaminating ingredients. The three basins are used as follows: One is being filled while the second is allowed to evaporate and the third is being cleared of its *schlammkohle*, as the product is called. In summer a basin is cleared every three weeks, while in winter it generally takes from five to six weeks to obtain the product.

The product obtained from the basins looks like brown coal and is handled very easily, being dug out and carted to the storage bins. Owing to the moisture content, which varies from 25 to 35 per cent. in summer to 60 or 70 per cent. in winter, a correspondingly greater or less amount of brown coal is burned with it. On the average one pound of brown coal to four of the *schlammkohle* is used in summer, while in winter it is necessary to burn half as much brown coal as *schlammkohle*. The grate is composed of narrow slanting bars, and the resulting ash is hard, but easily removed. The product naturally varies in heating value from time to time, depending on what factor is most active during the period of settling, and as a consequence no definite figures can be given.

Commercially, the plant is reported as being highly satisfactory, the cost of operation per kilowatt-hour being 1.25 cents, while the fuel cost is 0.25 cent. The electrical plant consists of three 1000-kilowatt turbo-generators. As to the waste-water end, the plant has a capacity of from 1,000,000 to 1,760,000 cubic feet of waste water per day of 24 hours, and its initial cost in round figures was about $36,000. The plant has been in operation since April 18, 1907, and in its operation requires six firemen, six engineers and one man to tend the water-clearing end, the entire force working in eight-hour shifts.

A few other items in connection with the waste-water plant will undoubtedly be of interest. The time of properly mixing 200 pounds of the sulphur clay is one hour; 5.35 cubic feet of coal pulp gives one pound of *schlammkohle*; 350,000 cubic feet of waste water gives from 65 to 90 pounds of *schlammkohle*. The average percentage of sulphur in the resulting product is 16 per cent.

Catechism of Electricity

1041. *Show a diagram which illustrates this last method applied to two induction motors.*

Fig. 289 illustrates this case. The stator winding of the motor *b* is connected in series with the rotor of the motor *a*, which consequently starts with a strong torque. The motor *b* receives its current at a reduced frequency and therefore starts also with good torque.

1042. *How is one to know the kind of work that can economically be performed by an induction motor?*

An induction motor works well where it can run at full speed with a load that requires to be started only occasionally. It will usually be economical and satisfactory when applied to the same kind of work that could be done well by a direct-current shunt-wound motor. When working at or near full load and at constant speed the efficiency and power factor of an induction motor are at the best.

1043. *In what respect is an induction motor preferable to a synchronous motor?*

It requires less attention.

1044. *What effect does an induction motor have upon the current in the circuit on which it is running?*

It causes the current in the supply circuit to lag behind the voltage and therefore impairs the power factor of the circuit.

1045. *What effect does a synchronous motor have upon the current in its supply circuit?*

It produces a leading current if working under a steady load and with strong field excitation. If, therefore, synchronous motors are connected to the same line with induction motors the leading currents produced by the former tend to neutralize the lagging currents produced by the latter.

1046. *In starting an induction motor by the resistance method, what precaution should be observed regarding the starting resistance?*

Care must be taken before closing the main switch to see that the starting resistance is not short-circuited. If the starting resistance is short-circuited the motor will take excessive current from the line and it may not start at all.

1047. *How long should the starting resistance be left in the motor circuit?*

Only during the starting period. As the motor comes up to speed the resistance should be gradually cut out, and each step of the cutting-out process should be only of such duration as will permit the motor to come up to the maximum speed for that step. At the final step, the rotor winding is practically short-circuited through the brushes. The total time for starting should not exceed thirty seconds.

1048. *When resistance is used for controlling the speed of an induction motor, cannot this resistance be left in the armature circuit as long as desired?*

Yes, because this resistance is specially designed to carry the full current continuously.

1049. *What effect upon the normal output of an induction motor has the resistance generally used for speed control?*

A motor designed for 50 per cent. speed control usually has a resistance of ample capacity to reduce the speed to 50 per cent. of normal without affecting the normal full-load torque. The horsepower output of the motor at the lower speed is therefore 50 per cent. of the normal output and varies in about the same proportion for other speeds less than normal.

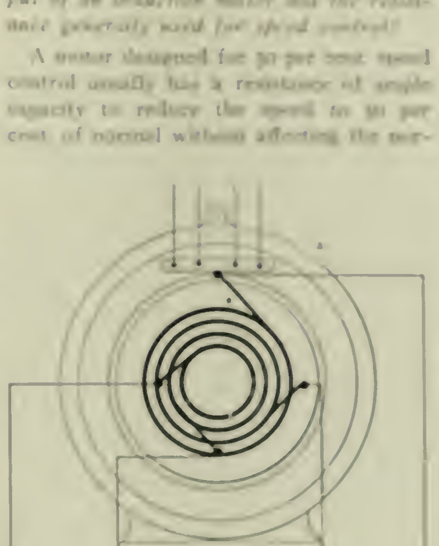


FIG. 289. ARRANGEMENT FOR STARTING AN INDUCTION MOTOR AT LOW FREQUENCY

1050. *If an induction motor fails to start, what may be the cause of the trouble?*

A broken wire or faulty connections. The current fails or is shut off at the station. Excessive friction in the bearings. A blown fuse. The motor switch open. A heavy overload.

1051. *In case the motor stops during operation, where may the trouble be found?*

The same defects given in answer to 1050 will cause a motor to slow down or stop during operation.

1052. *What important points must be considered in the operation of induction motors in which the starting resistance is introduced in the armature circuit through contact rings and brushes?*

The contact rings should be kept clean. The brushes should make proper contact with the rings when the armature is at rest and should be clear of them when the armature has reached its normal speed. New brushes should be installed as soon as there is any danger of the brush-holders striking the rings, and they should be sandpapered to the shape of the ring so that contact will exist over the entire face of the brush. Failure to do this will cause poor contact and sparking, which soon pits the rings and necessitates turning them down to a smooth surface. A little sparking at the brushes and some noise when starting, however, should not occasion alarm, as this lasts but a short time and ceases when the armature has come up to speed and the contact between the rings and brushes has been broken.

1053. *If it becomes necessary to take out the armature, what precautions should be taken in handling it?*

Do not pick up the rotor with a sling, unless it has a spreader to keep the rope or chain from injuring the winding. Do not take out the rotor and set it on the floor without placing a thick, heavy mat under it, or else supporting it by blocks under the shaft so that the rotor core is clear of the floor.

1054. *What mechanical defects may cause trouble?*

The bearings may become worn and need renewing, in which case the rotor may strike the stator core. The bearings may become scratched and roughened by grit or dirt in the oil. If any such foreign matter is seen, the bearings should be cleaned and the oil renewed. In no case should old oil be used without cleaning it.

1055. *What special attention should be given the starting switch or handle?*

It must not be left in the "starting" position while the motor is connected to the circuit. It must be moved to the "off" position when the motor is shut down.

1056. *Is grease or oil preferred for the bearings?*

[illegible]

1057. *What is frequently the cause of oil coming in contact with the windings?*

Loose bearings caused by the oil being too thin on the bearings, the armature shaft not being level, or the end [illegible] on the bearings not being properly [illegible].

Decrease in Weight of Lignite in Transit

Results of Experiments with Texas Lignite to Determine Changes in Weight and Heat Value Due to Temperature and Humidity Conditions

BY ARTHUR C. SCOTT

There has been more or less contention between shippers and consumers of lignite concerning shortage in weights of carloads delivered, and I believe that such contention is in many instances due to misunderstandings, first, as to the necessary decrease in weight that must occur in transit due to the properties of the lignite and, second, as to the fact that a smaller weight of lignite at the consumer's plant as compared with the weight at the mine does not necessarily mean that the consumer has lost money in proportion to the shortage; on the contrary, the fact seems to be established by data and results that follow that the consumer is actually the gainer in the transaction, provided the loss in weight is not abnormal.

My attention was first directed to the matter because of a shortage in weights of carloads of lignite furnished to the University of Texas by various lignite dealers, and in order to obtain satisfactory information on the matter an attempt was made to calculate the approximate decrease in weight that should occur in transit and, by testing the lignite under different conditions, to determine the loss in heat units due thereto. Through the courtesy of F. E. Merrill, of the Bastrop Coal Company, I was allowed to inspect the mine at Glenham, Tex., and on April 11, 1908, personally obtained from three different localities in the mine samples of lignite as it was being picked out by the workmen. The writer himself placed the samples of lignite, selecting some lumps and some fine material, in glass jars which were sealed in the mine and taken in that condition to the University of Texas. I also went with the superintendent of the mine and the pit boss over the principal portion of the mine, and in no case found water in any considerable quantity. Probably not more than a bucketful of water was seen anywhere in the mine, although there was, of course, some moisture in the air.

The lift from which the samples of lignite were taken was about 87 feet below the surface, and the mine was satisfactorily ventilated. The lignite was picked out with no evidence of any blasting having been done, and the layer of lignite, which varied from about 3 feet to 5½ feet in thickness, everywhere showed good, clean coal. No seams of dirt or rock were observed anywhere interlain with the lignite, and the latter, as brought to the surface in small cars by the elevator, is clean lump, requiring no screening, and is loaded directly into cars, weighed on railway scales and shipped.

Moisture

The three samples of lignite which were taken from the mine to the university were tested for moisture content immediately after the jars were opened, with the following results:

No. 1. Moisture evaporated in one hour by heating at 104 to 107 degrees Centigrade	28.2%
No. 2. Moisture evaporated in one hour by heating at 104 to 107 degrees Centigrade	28.0%
No. 3. Moisture evaporated in one hour by heating at 104 to 107 degrees Centigrade	32.2%

A lump of the lignite was soaked for twenty-four hours in water, and subsequently a test for moisture, made as for the other samples, showed 39.1 per cent. moisture. This indicates that, taking the average of moisture content of the three samples from the given data, amounting to 29.4 per cent., it is possible for the lignite to contain 9.7 per cent. more moisture than it does contain after it is taken directly from the mine, under the general conditions of this particular mine.

Calorific Value

Two attempts were made to obtain the calorific value of samples containing 28.2 per cent. moisture as it came from the mine, but each of the charges exploded in the open calorimeter before a determination could be made, because of the amount of moisture present. Sample No. 2, containing 28 per cent. moisture, was then tried; and a determination was made which showed 7574 B.t.u. per pound. It was evident that the amount of moisture with which a determination could be made was at the limit for the 28 per cent. value, and the other samples were therefore not investigated farther in that respect. The average B.t.u. of the three samples, when a portion was dried at 104 to 107 degrees Centigrade for one hour, was 11,003 per pound of lignite.

Loss by Air Drying

A portion of each of the three samples previously referred to was placed in a tin box, open at the top, and the boxes placed in the thermometer and hygrometer house of the meteorological station at the university. Each sample was weighed twice a day for several days, and once a day thereafter for nearly two weeks, an accurate record of temperature and humidity conditions of the air being kept by means of a recording thermometer and a recording hygrometer placed close to the samples. At the end of the test period for the evaporation of moisture from the samples, the average values of temperature and humidity were ascertained; the charts upon which were recorded the values of humidity were checked with a polar planimeter in order to obtain an accurate average of the humidity during the time that the lignite was exposed, and the results agreed very closely with the average of the records of humidity made each time that the samples were weighed.

The lignite which was exposed in the three samples consisted of lump and moderately fine material which was intended to be as nearly as possible an average of the quality of the coal as loaded upon the cars. The weights taken in the beginning for each of the three samples were as follows:

No. 1	268.80 grams
No. 2	315.65 grams
No. 3	308.70 grams

The percentage of loss of each of the samples was found to be very nearly the same as on the remaining lignite, so that an average is given in the following table of the loss for the three samples. The table also gives the average humidity and the temperature corresponding for the day when readings were taken and the percentage of loss calculated:

1	83	75	2.47
2	84	77	4.73
3	93	68	6.94
4	95	66	6.72
5	83	70	8.15
6	77	74	9.51
7	82	75	11.11
8	67	71	12.58
9	59	67	15.76
10	69	69	18.52
11	69	67	19.48
12	59	63	20.61

Average temperature for first week	72 degrees Fahrenheit
Average temperature for twelve days of test	70 degrees Fahrenheit
Average temperature for one year previous to date of making test	66 degrees Fahrenheit
Average humidity for twelve days of the test	75 degrees Fahrenheit
Average humidity for month of April, 1907	73 degrees Fahrenheit
Average humidity according to "Monthly Weather Review," for one year previous to date of making test	73 degrees Fahrenheit

It will be obvious that the temperature and humidity conditions under which the test was made were about the same as the average over a year's time, and therefore they are fortunately of value in calculating the average loss due to evaporation.

throughout the year. The table shows that on the fourth day of the test there was a slight gain in moisture over that of the day previous, but this is due, without doubt, to the high humidity, the average being 95 for that day.

After exposure to the air, as described for twelve days, during which time the average loss of the samples was 20.6 per cent., determinations were made of heat values, and an average of 9764 B.t.u. per pound obtained. The heat values obtained for the dry lignite (dried for one hour at 104 to 107 degrees Centigrade) averaged 11,003 per pound, as already stated. The data given as to the calorific value of the lignite as a whole show that it is very desirable to determine the precise moisture content of the fuel when comparing determinations of B.t.u. per pound, since the greater the amount of moisture contained in the lignite when the calorific test is made, the lower will be the number of heat units per pound.

Weight Lost in Transit

The specific gravity of average lignite appears to be about 1.25, which would make the weight of a cubic foot about 78 pounds. The size of a car marked "For Lignite Only," with a rated capacity of 80,000 pounds, was found to be 34 feet 4 inches long, 4 feet 2 inches deep and 8 feet 6 inches wide. Assuming that the lump fuel, as loaded upon the car, allows more or less air to circulate to a depth of 6 inches, the number of cubic feet so affected would be 146, and 146 cubic feet of lignite weighing 78 pounds per cubic foot would amount to 11,388 pounds. According to the table, 2.47 per cent. of moisture is lost on the first day, or 281 pounds. After the second day the loss would be nearly twice the amount, and so on up to the twelfth day, when there would be a total loss of something more than one ton on a 40-ton car.

It must be remembered in this connection that the samples which I exposed were standing still, while the lignite on a car is moving for a considerable portion of the time consumed in transit, and whenever the car is in motion there will be a greater rate of evaporation from the surface of the coal than if the lignite were stationary for the same length of time. How much greater the evaporation would be could only be determined accurately by experiment, of course.

Another noticeable and very important result shown by the tests is the effect of alternate wetting and drying; this causes the coal to slack and fall to fine material very readily. It is, therefore, probable that after a carload of lignite in passing from the mine to its destination, is allowed to stand out in the rain, and afterward the sun and movement of air over the surface of the car and the fuel dry it considerably and then another rain strikes the car, considerable of the lignite which started from the mine as lump would be reduced to fine material. When lumps of lignite are exposed to the air-drying process, but water other than the moisture of the air does not reach them, they do not fall to powder but retain their original shape, with the exception that fine cracks run in all directions through the lumps. Of course the lumps can be broken then much more readily than before, and as soon as lumps in that condition come into contact with water they are readily reduced to powdery condition.

Change in Heat Value in Transit

Considering, now, the question of relative number of heat units which would be obtained by the consumer when the coal in transit has been subjected only to evaporative conditions, and presuming that rain has not fallen upon the coal between the mines and its destination, the tests show, for one pound of lignite in the condition at the mine referred to, an average of 7574 B.t.u. per pound. After exposure for twelve days 20.61 per cent. by weight has evaporated, according to the test. If the lignite remained on the car for the full length of that time, the comparative results would be shown as follows: In a carload (80,000 pounds) of lignite having 7574 B.t.u. per pound, there would be 605,920,000 available B.t.u. in the fuel at the mine. It has been shown that for an assumed depth of circulation of air of 6 inches for this carload 11,388 pounds would be affected by evaporation. Since 20.61 per cent. by weight would evaporate in twelve days, the amount lost would be 2347 pounds. This amount subtracted from the 11,388 pounds leaves 9041 pounds, which tests 9764 B.t.u. per pound. The number of available heat units, then, in the top 6 inches of the carload would be

$$9041 \times 9764 = 88,276,324.$$

The remaining weight in the car is 68,612 pounds, and the available heat units for this part of the carload would be

$$68,612 \times 7574 = 519,667,288$$

B.t.u. Then the total heat units available in the carload, therefore, would be

$$88,276,324 + 519,667,288$$

or 607,943,612. Now, the car started out with 605,920,000 available heat units, and there would be, therefore, a gain in available heat units amounting to 2,023,612 B.t.u. on the whole carload, which amounts to one-third of 1 per cent.

It might appear at first thought that there is a mistake here, that the car would not possess more heat units after it has been out twelve days than it had when it started from the mine; but as to the actual heat units contained that is true; the gain is in the available heat units; when the lignite contains a higher percentage of moisture a larger part of the contained heat units are used in the evaporation of the moisture and are, therefore, not available to the consumer for useful purposes. It is evident, therefore, that if a carload of lignite be not rained upon in transit, even though it be on the road for several days, there will probably be no loss in available heat units to the consumer and, moreover, the cost of handling the lignite in the boiler room is slightly reduced, because there is less weight to handle for the same number of available heat units obtained.

It is of material advantage to the consumer to unload the cars into bins and allow the lignite to dry out somewhat before it is used. If the lignite is rained upon, and slacks as a result, of course the loss would occur largely because of the fine material falling through the grates, and would amount to whatever part of the carload is thus wasted. It appears that the large shippers and consumers of lignite might profit materially by building rain sheds to protect cars of lignite that are likely to remain for some days at the terminal of the shipping lines.

The results of the tests above should indicate clearly that a decrease in weight in transit is to be expected, and is certain to occur, and the tests were carried out with such care that I consider that a reasonable approximation may be made as to the probable amount of such decrease for any given case. Of course, the amount lost due to the movement of air over the surface of the cars due to their motion is indeterminate from the present data and I intend to pursue the investigation further to clear up that point if possible. The assumption of 6 inches as the depth to which the air actively penetrated in producing evaporation was made after consulting several consumers of lignite on the point and averaging all opinions concerning the matter.

I propose to visit other mines where probably the moisture content and calorific value of the lignite differ somewhat from those at [illegible], repeat the experiments already made and make supplementary ones, with a view to obtaining results that will further benefit producers and consumers and tend to conciliate unpleasant controversy between them.

Consul Ralph J. Totten writes from Puerto Plata that there are very few windmills used in Santo Domingo, while tanks are much in demand. If Spanish-speaking salesmen could be sent to interest [illegible] the utility of the windmill in connection with agriculture, and much [illegible], a demand could be created. Many portions of this country, especially [illegible], suffer from lack of moisture in the dry season. This difficulty could be overcome by windmill and tank irrigation. [The consul forwards a list of hotel and [illegible] who might be interested in [illegible] which is on file in the Bureau of Manufactures (Department of Commerce and Labor).]

Practical Letters from Practical Men

Don't Bother About the Style, but Write Just What You Think, Know or Want to Know About Your Work, and Help Each Other

WE PAY FOR USEFUL IDEAS

Packing for Steam Engine Piston

One of the first metallic piston packings consisted of a bull ring and two packing rings, the packing being adjusted by means of springs and packing bolts.

This packing answered its purpose very well when the adjusting was done by men who thoroughly understood doing so, but it was not at all unusual for an engineer to put too much pressure on the packing springs, resulting in a badly cut cylinder and rings. Finally the Z-spring shown in the piston, Fig. 1, was introduced. It was fast becoming the favorite packing, when the "snap-ring" packing was introduced. There being no danger of getting too much pressure on the packing rings by their use, this design of spring soon replaced all other springs for use in large cylinders, but for some reason never came into general use in small cylinders.

As compared to the spring packing the "snap-ring" type could not be considered an improvement.

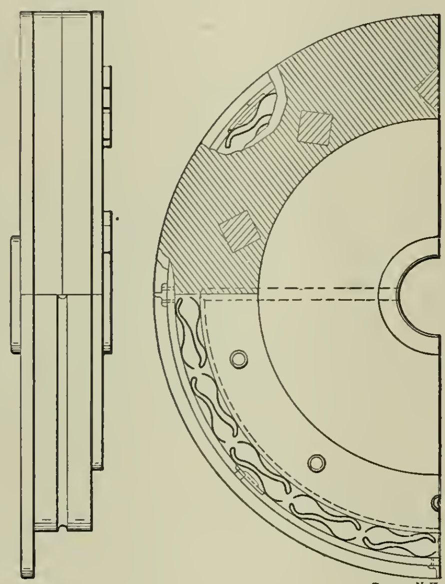

FIG. 1

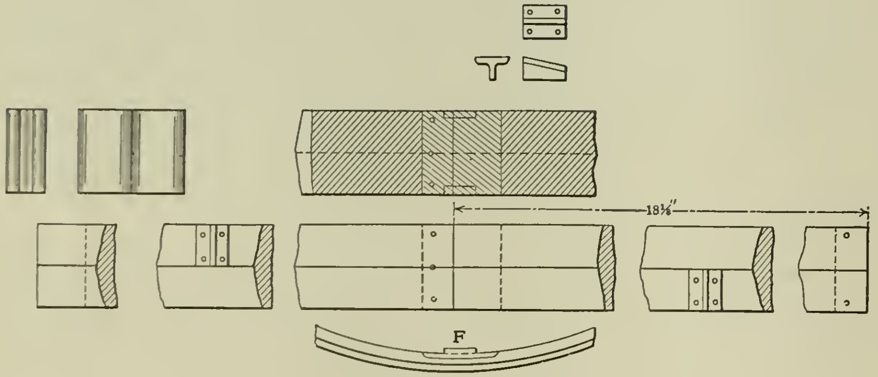

FIG. 3

As a rule, packing rings of all kinds are made from a hard, close-grain metal, usually iron, but I have seen them made from composition metal in a 30-inch piston. Regardless of what hard metal they are made of, the packing rings will wear to a very sharp knife-edge that acts very much like a scraper on the walls of the cylinder. While the hard metal will give lasting qualities to the rings, it will also greatly increase the cutting power of the sharp edges.

It is claimed that a ring must be made of hard metal or it will not be "resilient." This quality can be given a ring made of soft iron by simple round-wire springs, in the shape of rings of the same diameter as the inside diameter of the rings.

One of the first "snap-ring" packings brought out had small "ports" for the live steam to get back of the rings. It was soon discovered that the ports were not required, as the live steam got back of the rings, anyway.

Another very objectionable feature in snap-ring packing is the shoulder worn at each end of the cylinder.

Fig. 2 shows a design of piston packing free from the defects inherent in piston packings as now made. In the cylinder is shown a side elevation of a piston head in half-section. Leading from the packing-spring space into the passage in the piston rod is shown an opening that allows any steam back of the packing rings, due to leakage at the joints of the rings, to escape readily, so that at no time is there more than the pressure due to the springs on the packing rings. The steam can be led to the condenser or exhausted

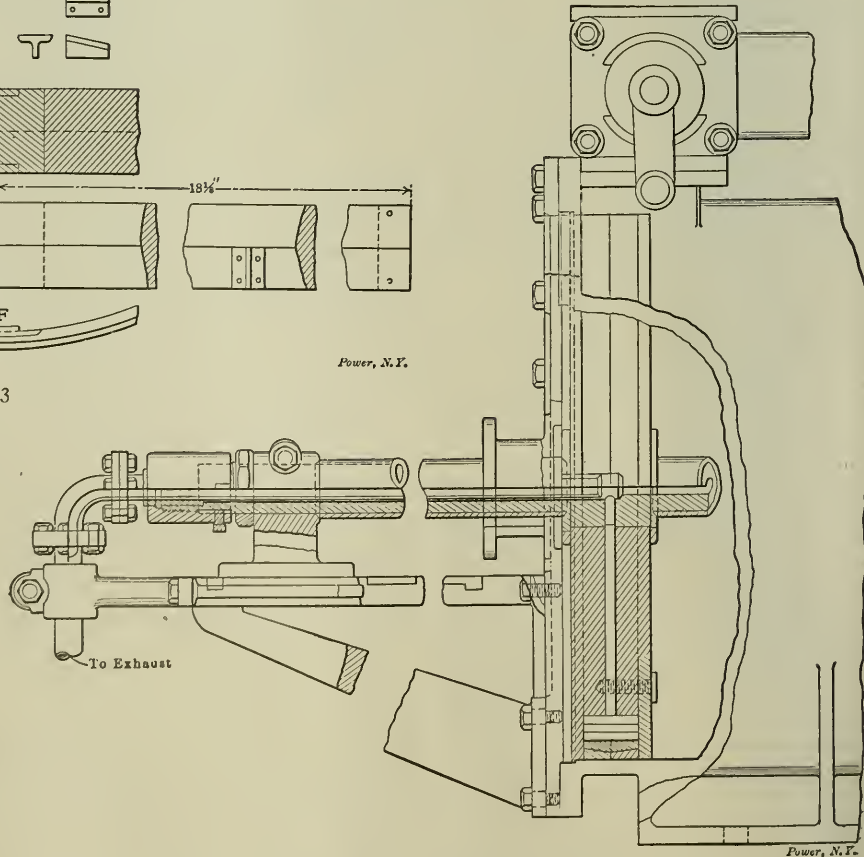

FIG. 2

into the air. If the steam is led to the condenser, the effect of the vacuum on the packing must be given some little consideration when adjusting the springs. Any weakness the springs may develop can be remedied by shims or liners between the springs and the spider.

The bull ring and packing rings are made to form parallel wedges. This allows the packing rings to become self-adjusting for wear at the follower and spider. I believe the angles of the wedges should be more acute than I have shown them in the drawing. The packing will be much more resilient if the members are made in sections.

In connection with the half-plan view of the piston head is shown a side elevation of it, Fig. 1, exposing in half section the shoulder on the spider against which the packing springs bear. The groove shown in the face of the shoulder is a channel for the ready escape of steam due to leakage. Fig. 3 shows a distorted plan view of two sections of the bull ring.

Denver, Colo.

Water Column Connections

The accompanying sketch shows the way the water columns were connected in a small plant in Ohio. The old boiler was properly connected. When boiler *B* was installed it was passed by the inspector before being fired up. As will be seen, there is a 1½-inch nipple on boiler *B*, in which is a cross with a 1¼-inch line to the water column, a ¾-inch line to a whistle and a 1½-inch line across to boiler *A*, which is extended to feed a deep-well pump, a boiler-feed pump and an injector. It will not be hard to imagine how the water acts in the glass on boiler *B* when the boiler-feed and deep-well pumps are running.

With the boiler-feed pump on, the water in the glass would show 2 or 3 inches higher than in the boiler, and when the deep-well pump was started the water would rise about 5 or 6 inches.

It is not necessary to say that after the boiler was put in service it was not long before the water column on boiler *B* was connected independently of the cross line.

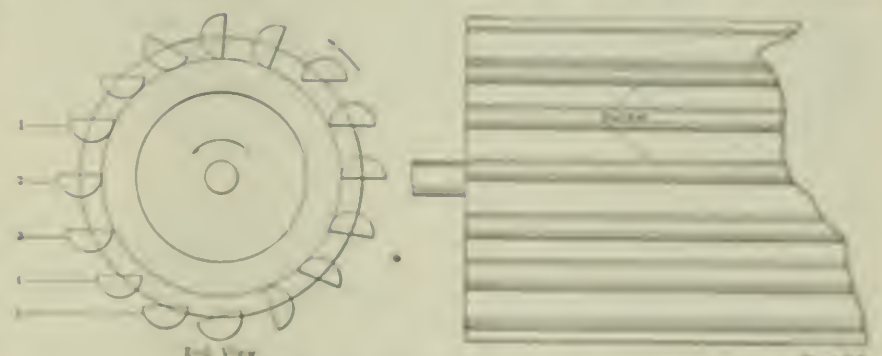
B. L. Monroe.

Fremont, Ohio.

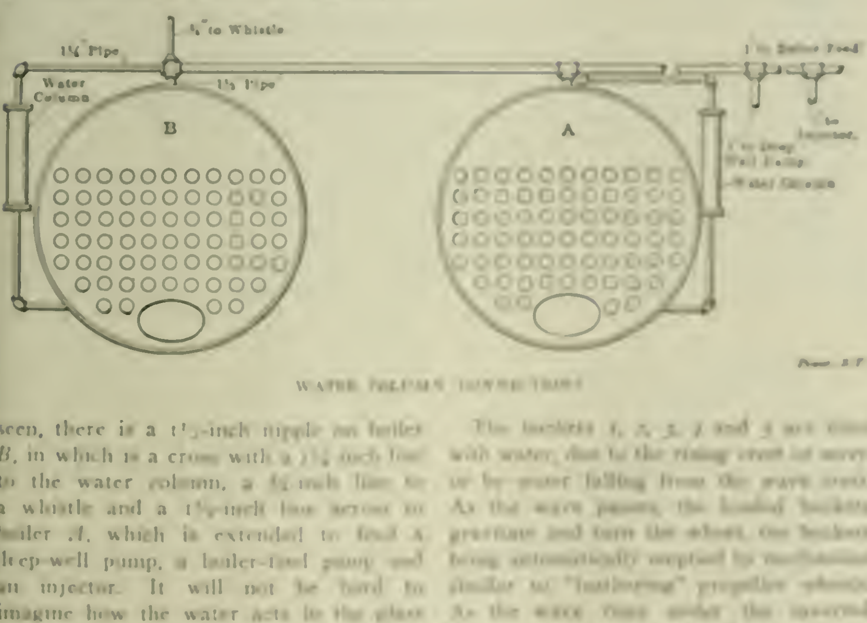
The "Snee" Wave Motor

The description of the "Snee" wave motor in the March 2 number was very interesting. I have read numerous articles relating to this device and had concluded it was in the class in which you put it.

The accompanying sketch is a mere idea, with possibly some features that might prove practical. The bottom of the wheel would be just above the level of the water when undisturbed. I am inclined to think it would at least be as successful as the "Snee" motor.



MR. KOELZ'S WAVE-MOTOR IDEA



WATER-COLUMN CONNECTIONS

The buckets 1, 2, 3, 4 and 5 are filled with water, due to the rising crest of wave, or by water falling from the wave crest. As the wave passes, the loaded buckets gravitate and turn the wheel, the buckets being automatically emptied by mechanism similar to "feathering" propeller wheels. As the wave rises under the inverted buckets it will tend to lift and exert power in the direction of rotation of the wheel as indicated by the arrow.

The direction of the wave motion should have no effect upon the operation and the wheel could be made to operate in either direction by a reversal of the buckets.

Frank G. Koelz.

Milwaukee, Wis.

Graft

I have read with a good deal of interest the letters appearing [illegible] in regard to the subject of graft. Graft permeates the whole business fabric regardless of the position occupied or the amount of salary received by its victims. Engineers are by no means the only class who stoop to this sort of thing, so that when any subject is discussed as applied to engineers, purchasing agents, master mechanics, millwrights, superintendents or whoever, it should not cause others who might belong to any of these classes to get "sore."

That the recipient of graft is dishonest and on the same level with the thief, I am sure every honest man will admit. It seems to me that the blame for this condition of things, which is so prevalent, should not rest so heavily on the victim as on the employer who offers it. The desire to obtain something for nothing is a trait in human nature which lies pretty near the surface and it isn't to be wondered at that many an otherwise honest man falls a victim when temptation comes to him.

When I first came to New York I was told by an employer that I could never do business here without graft, and that in every deal he figured on a certain sum was included as a graft to the engineer or mechanic who "had the say" in the transaction. After more than nine years I am still able to pay my bills and have no prospect of going out of business. [illegible] is the foundation upon which all supplies should stand or fall. So long as I handle a material having merit above that of my competitors I know that I can do business without graft. As a matter of fact, in the eleven years that I have been in the supply business I and my agents have had very little trouble on this score.

Some of my friends are among engineers and I am sure they are as "straight as a string." I have no reason to believe that the graft evil is any [illegible] engineers than with those who occupy positions where the [illegible] can get the work.

Charles F. Chase.

New York City.

Finding Capacity of Tank in Gallons

Recently there appeared a short rule for finding the capacity of a tank in gallons, as follows: "Multiply the square of the diameter in feet by half the length in inches." This was followed by the remark that the result is about 3 per cent. *too low*. This rule-of-thumb, while concise and simple, gives the result about 2 per cent. *too high*.

The rule is evidently found as follows: Let D equal the diameter of the tank in feet and L its length in inches; then its volume in cubic inches is

$$\frac{\pi}{4} 144\, D^2 L.$$

Taking

$$\pi = \frac{22}{7}$$

and dividing by 231, the number of cubic inches in a gallon, we have: Capacity in gallons equals

$$\frac{22 \times 144\, D^2 L}{7 \times 4 \times 231} = D^2 \left(\tfrac{24}{49} L\right).$$

The enunciation of the rule is then apparent from the formula, since

$$\tfrac{24}{49} L$$

is almost one-half the length. But if we use one-half instead of $\frac{24}{49}$, we get a value larger than the true result by

$$\tfrac{1}{98} D^2 L, \text{ or } \tfrac{2}{98}\left(\frac{D^2 L}{2}\right).$$

That is, the result as calculated is 2 per cent. too large. Thus a tank 4 feet in diameter, length 18 inches, holds by actual calculation 141 gallons. The rule gives

$$4 \times 4 \times 9 = 144 \textit{ gallons},$$

and if 2 per cent. of this, or 2.88 gallons, is taken off we have 141.12 gallons, the correct result.

This may appear to be a small item, but its chief trouble is that the rule as given made the result appear to lean toward the safe side, when in fact it does not. It might be assumed in some case coming up that the 3 per cent. would be a safe margin of allowance and lead to error.

W. L. Benitz.

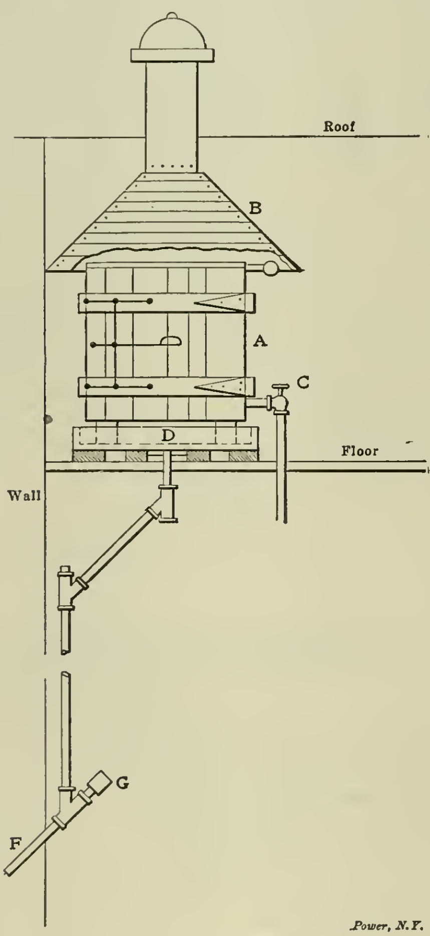
Notre Dame, Ind.

Piping a Steam Box

A steam box used for steaming yarn in a woolen mill was a continuous source of trouble, wherefore the following changes and improvements were made:

Whenever the door A of the box was opened, a cloud of steam would escape into the room, condensing on the machinery and rusting it. This was remedied by putting a hood B over the box, with an outlet through the roof. A slide in the top of the box allows the steam to escape through the hood before the door is opened.

Although the door was made of 2-inch cypress planks, two heavy iron hooks are required to keep it from warping. They are made in such a way that the attendant can open the box without being burned. A valve is required for the live-steam inlet at C. The heavy galvanized-iron pans D rusted through in a few weeks, so we made one of No. 28 gage copper with a brass floor flange sweated on the bottom for the waste-pipe connection. This pan was lined with 1 inch of concrete, with a piece of heavy-wire screen to keep



PIPING A STEAM BOX

the cement from cracking. Four bricks were used to support the box.

Originally the 1-inch waste pipe was connected by 45-degree ells. This pipe frequently choked with rust and dirt, and it was changed to 1½-inch galvanized pipe, connected by Y-branches. Now the pipe can be cleaned out by simply removing the plugs and using an iron rod. The pipe F was outside of the building, and frequently froze in winter. This was remedied by a bushed coupling at G, with a small pipe going through and projecting at F. A cup of hot water poured into the coupling G melts the ice, and the accumulated water comes down with a rush.

Charles Haeusser.

Albany, N. Y.

Air Pumps

One apparent assumption has been, and still obtains, that for a given vacuum a certain air-pump capacity is necessary, without considering in the least the probable variations due to the temperatures and quantities of circulating water. The capacity is usually taken as cubic feet per pound of steam condensed. The practice that a larger air-pump capacity is necessary as the vacuum is increased has some truth in it, provided the conditions are identical, but conditions are the ruling factors.

Consider the varying conditions possible under which an air pump may have to work: The condensed steam may be of low temperature or approaching the vacuum temperature, the circulating-water inlet may be abnormally cold or very little rise may take place, while the amount of air present may be excessive, or it may be practically air free, and after this all kinds of artificial conditions may be created. Another thing of very great importance is the degree of completion of condensation reached by the steam.

Treating first the influence of the temperature of the condensed steam, the most casual student appreciates the fact that the capacity of the pump is increased if the temperature of the mixture of vapor and water entering the pump is low. Another and probably greater influence of this cold water is that of producing on the top side of the bucket a vacuum differing from the condenser by a greater amount than if hotter water were there. This reduction in temperature can be overdone.

Another great advantage gained by the large differences of pressure at the top of the bucket and condenser is the resulting flow of the air and vapor which has a very marked effect upon the results obtained. With hot water approaching temperature due to vacuum, the vapors also have a higher temperature, thus weight for weight these have a greater volume than cold ones, comparatively reducing the volumetric capacity. It is possible to get water so hot as to cause any capacity of air pump per pound of steam to be too small; the vacuum difference between the top and bottom of the bucket being very small, little flow takes place.

In the case of incomplete condensation a different state of affairs exists, and is due entirely to an overloading of the condenser or a shortage of circulating water. The effects are soon evident as, assuming the water passing to the air pump to be cold compared with the temperature of saturated steam at the vacuum obtaining, it is discharged so much hotter that the temperature of the water leaving is as high as that of saturated steam at the condenser pressure, or even slightly higher. Under these conditions the vacuum will gradually fall off until the condenser predominates, or in other words creates a point of equilibrium.

Cause and effect here are not hard to trace and locate. In this case the falling off is due to a large percentage of water vapor, which retains its latent heat and, being present in the air-pump suction pipe, gains access to the pump. The condensed steam takes up the latent heat of this vapor on the discharge or compression stroke of the pump. Thus, a loss of possible vacuum takes place from several causes under conditions such as the temperature of the air-pump suction pipe, the capacity requisite to deal with the gases and the temperature of the vapor on the vacuum forming side of the bucket.

The cases dealing with the air which causes a breakdown in a condenser have already had considerable attention drawn to them by Professor Weighton, D. B. Morison and Professor Josse, but it must not be forgotten that the quantity of air going into a condenser is not nearly as detrimental as the quantity left in. The mixture of air and vapor can only be withdrawn when the temperatures obtaining correspond to the mixture at the various vacua and when the inducing action is such as to avoid all air-pocketing effects. But these temperatures are not necessarily the rules of the situation, as probably in many cases they are the sequence of the pump's rarefying capabilities.

Instances do occur when the pump's capacity and temperatures are such that with a very increased quantity of air the only apparent difference is the power required to work the pump; this indicates that under these conditions the pump has a percentage of its capacity to spare.

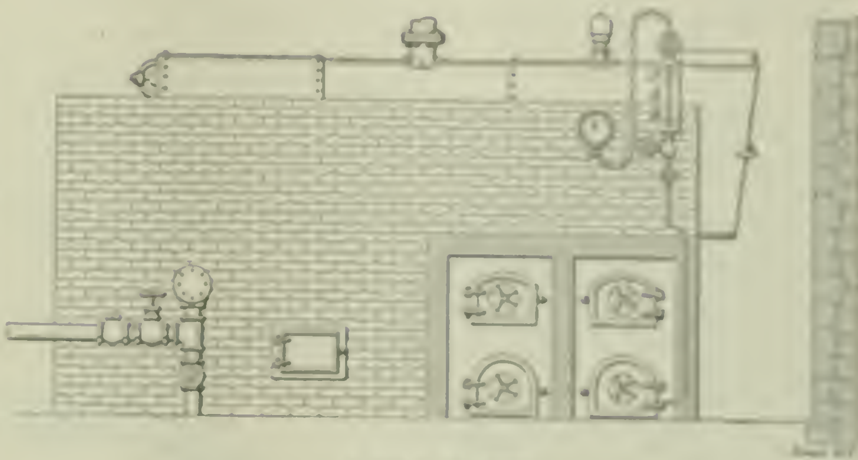
An Oddly Set Boiler

The peculiar expedients which must often be devised in the erection of power generators and machinery in places where the economical utilization of space is the thing most to be desired, or where the



AN ODDLY SET BOILER

work must be adapted to adverse conditions in the shape of narrow and restricted quarters, insufficient head room, etc., are exemplified in the accompanying sketch, which shows the method resorted to in setting the furnace for a horizontal return-tubular boiler, in order that it might be crowded into the space set apart for a boiler room in the basement of an apartment building.

In all essential details the setting conforms to the usual practice with boilers of the type in question, except that the exigencies of the job necessitated placing the furnace [illegible] of the boiler, as shown.

Another objectionable feature of the arrangement is the close proximity of the basement wall to the flue breeching, which makes the job of cleaning the tubes particularly annoying, inasmuch as it has to be performed with a scraper having a [illegible] made up of [illegible].

A. J. Dixon.

Kerosene in Boilers

While I do not say that kerosene will clean the scale from every boiler, I know it got the [illegible] of a bad lot at one time. I had only one Manning boiler to run an electric plant with. We had a spring that supplied pretty water enough, with the help of a few [illegible]. In a short time we had a pretty dirty boiler, and sent some of the water to be analyzed and some of the scale to be tested for a compound. We used two barrels of the compound and the boiler kept getting worse.

One night I took a piece of scale and stood it up in a pail with about 2 inches of kerosene in it. The next morning the scale was so soft it would [illegible] to be lifted out of the pail. I decided to try kerosene. I [illegible] oil feeder and kept it feeding drop by drop day and night, and in about a week the scale began to come down in [illegible] from [illegible] to 1 inch thick, and some of it was a foot long. For two weeks or more I had to blow the boiler down every morning and take a bucket of scale from the tube sheet. In a couple of months I had a practically clean boiler.

Now, [illegible] of the kerosene oil [illegible]. [illegible] I think it would do any good to pump 2 gallons a day, [illegible] I also think [illegible] something to do with it.

I have found that kerosene will [illegible] [illegible] will not attempt to say that it will not, but I will say that I never had any trouble from it. Even if it did do so, I should have said that the oil did a good job. While I do not belong to the oil trust, I am booming kerosene for boiler scale in some cases.

E. A. Young.

Isabella, Tenn.

Bridgewalls in Theory and Practice

Mr. Wakeman's Fig. 1 is unquestionably wrong, as the wall is too close to the shell of the boiler. Fig. 2 is worse, as it would undoubtedly, in addition to choking the draft, fill to a considerable extent the combustion space back of the bridgewall. But the engineer referred to was certainly right in his theory, his error in Fig. 1 being in too small a space between wall and shell which should be 8 inches instead of 3½ inches.

Mr. Wakeman says, in effect, that the bridgewall is only a barrier to prevent firing coal too far back. In his case and in many others he is certainly right, but he fails to recognize that it is also possible, if properly done, to make it a great aid to combustion, especially in burning the gas from "soft" coal. It is also true, but to a less extent, in burning "hard" coal.

I. J. Babcock.

Chicago, Ill.

Exhaust Steam for Heating

On the editorial page of the March 23 number is an article on the use of exhaust steam for heating. The trouble with this idea is that judgment is not always used. While it is well known that if all the steam that a simple and cheap engine will exhaust can be used for heating purposes, there are cases where it requires some foresight in order to use it economically.

One of these cases is the heating of buildings through about six months of the year. That may require all the steam, and during a large part of the remaining time exhaust will be going to waste. Should the engine be large enough to run noncondensing for the winter, it will be too large for summer, when running condensing.

Another point has come under my observation. A mill has water and steam power. They have the idea that as long as the steam is used for heating it costs nothing for power and so they do not run their wheel in winter, but do all their work with the engine, and on warm days a great deal of exhaust goes to waste.

Whether there is saving or loss by this proceeding is not known, as they keep no record of coal burned and only know that at the end of the year a certain amount of money has been paid for coal, but as they have been told that exhaust costs nothing for heating they carry out the practice stated.

Another case is of a concern that put in a condensing engine 18 and 36 by 42, running at 120 revolutions. For some reason the exhaust from this engine is 12 inches in diameter.

With a vacuum of 28 inches in the exhaust pipe, and that pipe being just perceptibly warm to the hand, at 450 horsepower there is but 10 pounds vacuum in the cylinder, and at 500 horsepower but 9 pounds. What it will be when the engine gets its load of 650 horsepower remains to be seen. The ports of the engine are about right for 75 revolutions.

In the vicinity is an engine 16 and 30 by 42, running at 100 revolutions, with a 12-inch exhaust. The exhaust is used for heating in winter and works well. This engine never has had a condenser.

The first-named concern has been advised to expend about $3000 to change its piping so as to use the exhaust in winter, with the single idea that it is cheaper to run noncondensing when it is possible to use the exhaust for heating, and reference is made to the second-named concern as using a compound engine for heating the shop.

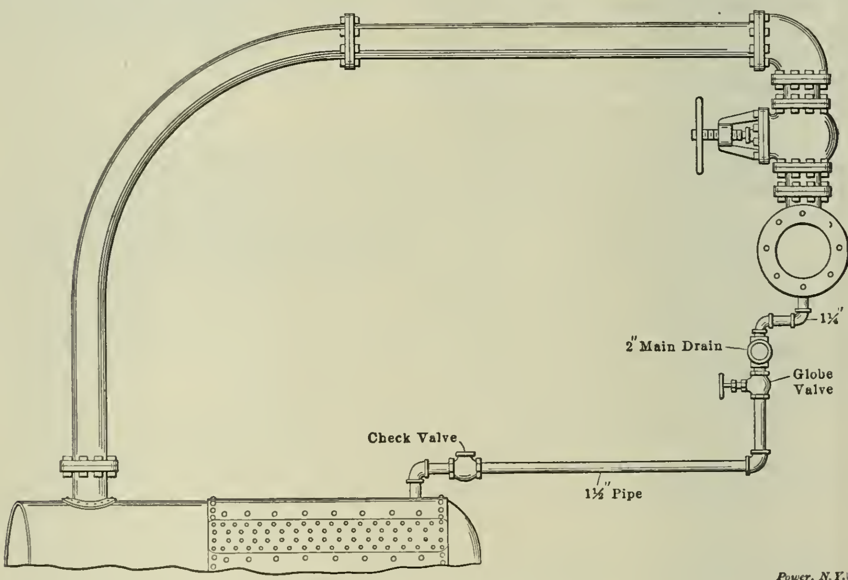
Now the second engine having a 30x42 cylinder and a piston displacement of 700 feet per minute will give 3430 cubic feet of steam into the 12-inch exhaust per minute. The first engine, with 36x42 cylinder and piston displacement of 840 feet per minute, will give 5938 cubic feet per minute into the 12-inch exhaust pipe. The first engine is all choked up, and when the condenser is off, it requires more extra coal than is required to heat the factory; and should the resistance of piping for using the exhaust be added, when the full load is put on the engine it would require new boilers to carry a higher pressure to get the work out of the engine, and the probability is that these advisers will some time succeed in getting this concern to go to all this expense, because the advisers have not the judgment to see that there are limitations to all rules.

W. E. Crane.

Broadalbin, N. Y.

Draining a Main Steam Pipe

In a certain power plant in which six water-tube boilers are being installed, it is proposed to dispose of the water of condensation from the main steam header in a manner which appears to be a somewhat novel departure from the conventional practice. Each boiler is to be connected to the header by means of a long sweep bend and horizontal lead, as shown in the accompanying illustration. It is designed to tap the tees, to which the leads from the boilers will be coupled, for 1¼-inch pipe connections, by which it is intended the water of condensation shall be carried to a 2-inch main drain pipe of the same length as the header, and running parallel thereto. This drain pipe is, in turn, expected to discharge a portion of its contents into the steam space of each boiler in service, through a 1½-inch branch pipe connecting to the drum of the boiler, on top and close to the back head; each branch being furnished with a horizontal check valve and globe valve as shown.



DRAINING A MAIN STEAM HEADER

Water accumulating above the check valve to the hight of the main drain pipe will have a head of about 20 inches, and it is expected that the pressure, due to this head, will be sufficient to compensate for whatever disparity may exist between the steam pressure in the drum and the steam pressure in the header.

A. J. Dixon.

Chicago, Ill.

Cause of Engine Wreck

After reading the article in the March 23 number, on "A Cause of Engine Wreck," by W. E. Crane, I should like to ask if, in running a Corliss engine with momentarily heavy loads and then having all the load suddenly thrown off, there would not be a checking in the speed of the engine before the governor would drop from its highest plane to the point where the intake valves would again open to admit steam?

This has been my experience, and I find a Corliss engine to be much steadier and still not get enough steam to produce motion on no load, with about 1/16-inch valve opening for small- or medium-sized engines.

The governor being blocked in its highest position on a Murray-Corliss engine with which these tests were made, the cam rods would, of course, be adjusted in reverse of the one spoken of in Mr. Crane's article, on account of the inside opening of the steam valves.

LEROY H. WHEAT.

Redfield, S. D.

The Valve Leaked

The accompanying diagrams were taken from a 14½ and 23 by 16-inch tandem compound engine direct-connected to a 200-kilowatt 250-volt three-wire generator, designed to operate at 250 revolutions per minute.

When the diagrams were taken the generator was running as a two-wire machine connected to the outside busbars. The engine was governed by a single-weight shaft governor attached to the high-pressure valve only. The low-pressure valve was connected to an eccentric on the inside hub of the wheel, having the same travel at all speeds. The engine and generator were not new, nor were they designed to operate together, but were purchased to help over the fall and winter peak loads. The engine was first sold for a condensing unit, and when first started up the speed would drop way down when any load was applied. The speed was increased to 268 revolutions per minute at no load and would drop to 230 with a small load. The exhaust was piped to the atmosphere and the usual treatment of taking off and adding weight and tension to the springs was tried, as well as new leaves in the springs, but "nothing doing." A new spring of heavier leaves was put in in place of the old one and a strip of iron ¼ inch wide was riveted to the exhaust side of the low-pressure valve, and when starting up with a light load the receiver gage would show a vacuum until the ammeter read 200 amperes. The diagram, shown in Fig. 1, was then taken.

Between the high- and low-pressure cylinders there was a brass check, grooved [illegible] inch deep, intended for packing. The low-pressure cylinder was taken off and we found that sleeve to be badly worn on the lower side. Repairs were made by putting soft packing in place of the brass, and on starting up again the diagrams, shown in Fig. 2, were taken. By comparing the diagrams in Figs. 1 and 2 an idea can be had of how much steam

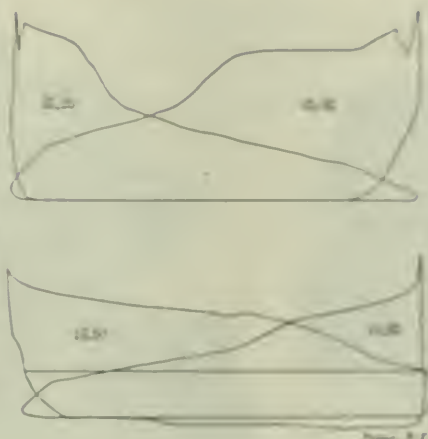


FIG. 1

was leaking through from one side of the high-pressure cylinder to the low-pressure exhaust. The valves had been set to even up the high-pressure cylinder load some time on the start.

Next we adjusted the high-pressure valve, which was some improvement, and we ran through the winter that way, when

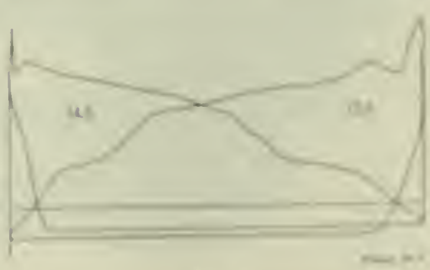

FIG. 2

the unit was disposed of. I found in running this engine that the speed would drop with the load, something I never saw in an automatic governor engine. I supposed that all automatic governing adjusted steam to match the load. The engine showed better economy at half load than full load.

[illegible]

[illegible], N. Y.

An Engine Accident

In the March 30 number Thomas [illegible] has described an engine accident and thrown a little light on a perplexing condition. Without going into a discussion of the merits of his indicator diagrams, it is safe to say that a piston rod should have sufficient area to withstand full boiler pressure when applied to the piston. The pressure applied to the piston can never exceed this point, except in case of water being trapped in the cylinder, or similar accident, and if the rod is large enough safely to handle this pressure, it is not clear how any failure of the low-pressure cylinder to carry its share of the load could jeopardize the high-pressure rod. If the engine carried steam full stroke on the high-pressure side and the low-pressure side were uncoupled entirely, the engine could be expected to make a very creditable struggle to maintain rotation, until overcome by the load. And even if blocked in one condition, and the throttle valve thrown wide open, there could not be any possibility of tearing the rod asunder.

It would be very easy to show that the one-third of the rod remaining was sufficient to pull the load, but it will be hard indeed to find an engineer who does not know that such an argument could be presented only by persons either too ignorant of the practical side of mechanics or too [illegible] to be honest.

When a blacksmith wishes to cut a piece of small bar which does not need a clean cut, he usually "nicks" or "nicks" it on the "hardy" at the point he wants it to break. A few blows on the end soon breaks the bar in two. To do this does not require any such application of power as would be required without the nick. It will be seen that the piston rod under discussion followed this same train of events, as being marked by an initial crack, each stroke of the engine [illegible] until the slight deflection of the rod on the weakened point, and if the rod were taken to pieces it would be only a matter of time before it broke.

If I were a manager, in a similar case I should give the engineer-in-charge a chance to explain. I would get from him one thing I was paying him for—expert knowledge on a special subject. If through lack of proper command of language he failed to make himself clear, I would consult with an outside specialist of established reputation. In doing so as a manager, not an engineer, I would not feel that I was illustrating a lack of wisdom with a solitary case of my line.

[illegible]

[illegible], N. J.

A New York dentist was seriously injured by the explosion of a heating boiler in the basement of his house. A considerable amount was done to the house, also.

Small Steam Turbines*

By George A. Orrok

The papers upon steam turbines which have been presented before the society have dealt with the larger types of apparatus and have been written to show the reliability, efficiency and general desirability of this type of prime mover.

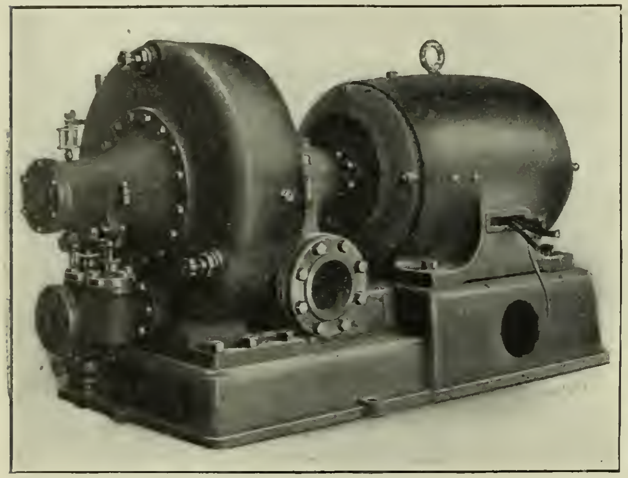

FIG. 6. STURTEVANT STEAM TURBINE, 30-INCH

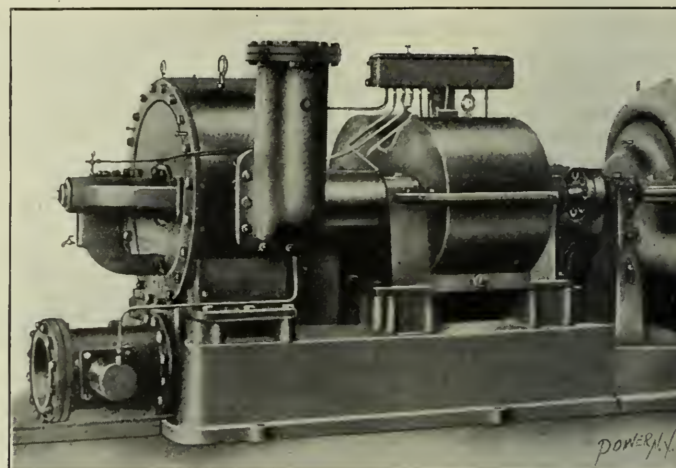

FIG. 1. HIGH- AND LOW-PRESSURE DE LAVAL TURBINE

This paper treats of the smaller sizes of steam turbine from the standpoint of the designing and operating engineer, describing the commercial machines in sufficient detail, with reference to the service to which they have been applied, and giving certain facts concerning their operation which may be of advantage to the engineering profession. Curves of steam consumption are given which show in a general way what may be expected of these machines under certain conditions.

At the present time seven machines are on the market and can be obtained in various sizes from 10 to 300 horsepower with reasonable deliveries. These are the De Laval, Terry, Sturtevant, Bliss, Dake, Curtis and Kerr turbines. Three other machines are nearly at this stage of development and patents have been applied for on several others.

Many thousand horsepower of these turbines have been sold and are in successful commercial service. The following figures as to sales in the sizes from 10 to 300 horsepower have been obtained from the manufacturers:

De Laval,	De Laval Steam Turbine Company	70,000 h.p.
Curtis,	General Electric Company.....	70,000 h.p.
Terry,	Terry Steam Turbine Company...........	15,000 h.p.
Kerr,	Kerr Turbine Company.	10,000 h.p.
Sturtevant,	B. F. Sturtevant Company.	....
Bliss,	E. W. Bliss Company	....
Dake,	Dake-American Steam Turbine Co...........	......

All of these machines are of the impulse type; that is to say, the steam is expanded in a nozzle and the kinetic energy of the jet is absorbed by passing one or more times through the buckets of the turbine rotor. In the De Laval turbine only one moving element and one steam pass are used, which necessitates a very high bucket velocity. In the Terry, Sturtevant, Bliss and Dake turbines a series of return passages are provided. The steam returns two or more times to the same rotor and the bucket speed is much lower. In the Kerr turbine the steam is used in stages with one bucket wheel in a stage; while in most of the Curtis machines two or three stages are used with two or three rows of moving buckets, separated by stationary guide blades, in each stage.

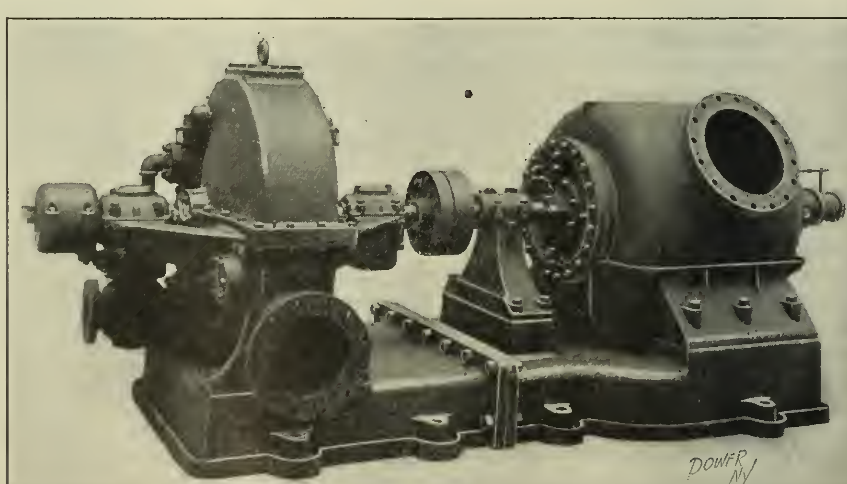

FIG. 2. TERRY STEAM TURBINE, 36-INCH

Compound machines of the other types have been made, but are not as yet produced commercially.

By far the larger number of these machines are used in connection with extra high-speed electric generators, the next application being to centrifugal fans for high pressures. Centrifugal pumps adapted to high rotative speeds have been rather generally introduced in the last few years and it is becoming usual to connect small turbines direct to these machines. The small space required and the simplicity obtainable in a 100-horsepower turbine at speeds of from 800 to 1200 revolutions per minute have been important factors in their introduction.

The first of the small turbines to be put on the market was the De Laval, made by the De Laval Turbine Company, of Trenton, N. J., and introduced in this country about 1896. This machine is of the pure impulse type; the steam being expanded in the nozzle down to the exhaust pressure, and the resultant velocity transferred to the wheel in one steam pass. The bucket speed is quite high, ranging from 600 to 1300 feet per second. Eight sizes of wheel are made, generating from 10 horsepower to 500 horsepower, with one nozzle in the smallest size and eight or more in the 500-horsepower size.

The high bucket speed necessitates the use of gears of special construction, which have been very successful. The design,

*Paper presented at the spring meeting of the American Society of Mechanical Engineers, Washington, D. C., May 4-7, 1909.

construction and economy of this type have been discussed in Volume 25 of *Transactions*, page 1056.

The Terry turbine, made by the Terry Steam Turbine Company, of Hartford, Conn., has been manufactured for about 10 years, although the commercial ma-

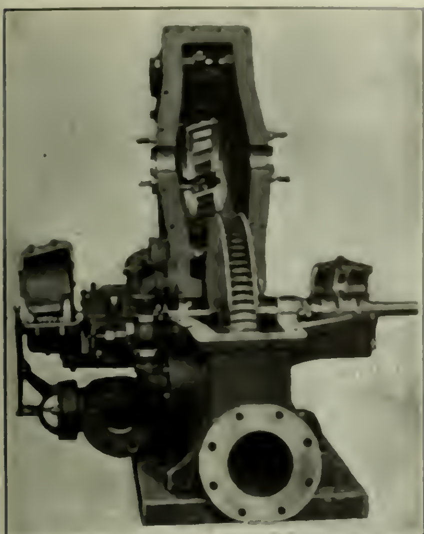

FIG. 3 TERRY TURBINE SHOWING CONSTRUCTION

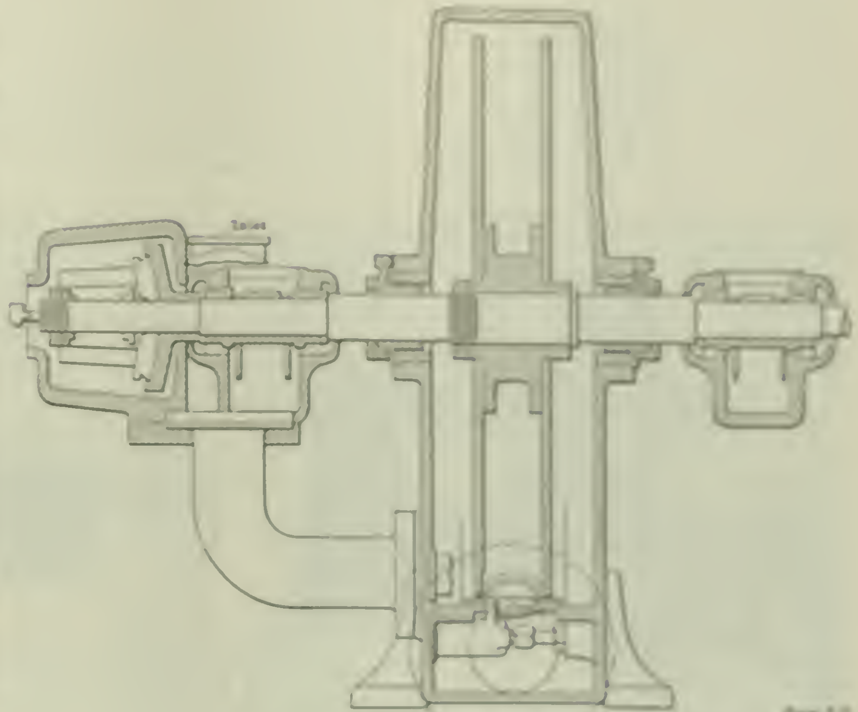

FIG. 4 [illegible]

FIG. 5 [illegible]

[illegible]

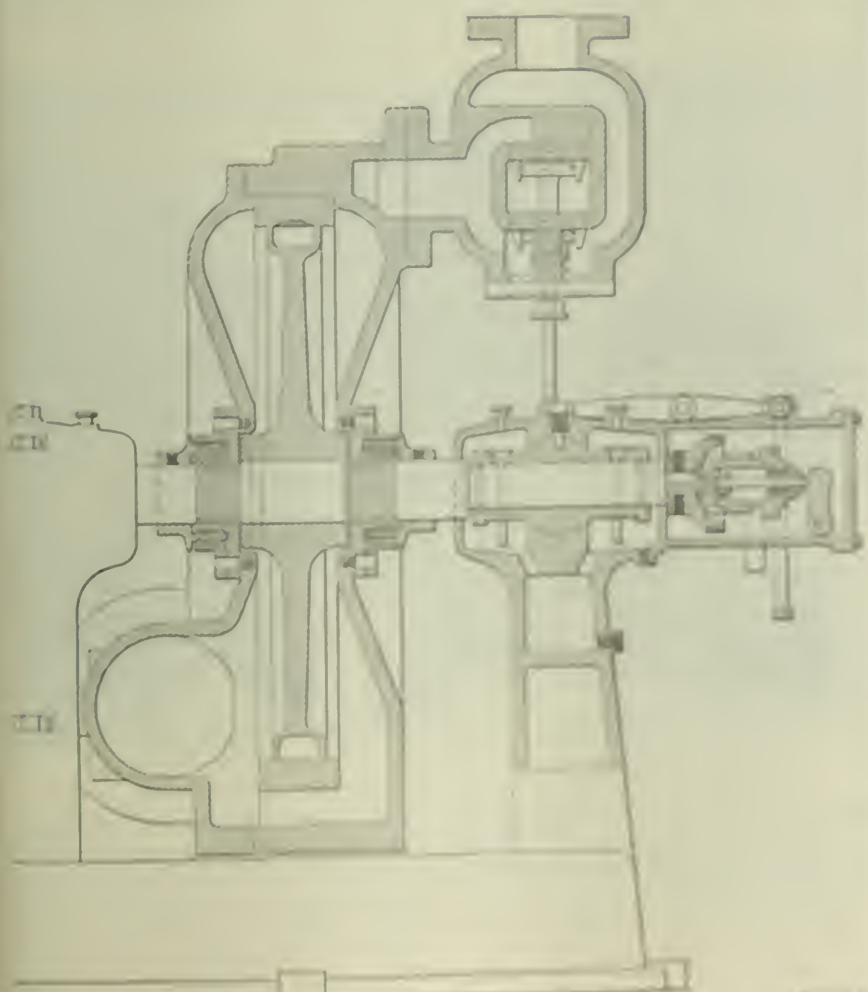

FIG. [illegible]

The sizes of wheel manufactured at the present time are 12-, 18-, 24-, 36- and 48-inch, and the number of nozzles varies from two on the 12-inch wheel to eight or ten on the 48-inch wheel.

The Sturtevant turbine, made by the B. F. Sturtevant Company, of Hyde Park, Mass., has been in the development stage for three or four years and quite a number of machines have been sold. The present type of turbine may be called "standard," however, and four sizes of wheel are built, 20-, 25-, 30- and 36-inch, developing from 3 to 300 horsepower. The turbine is of the multiple-pass type similar to the Riedler-Stumpf. The casing is cast solid with one end. The nozzle and return-chamber ring are inserted from one side and the wheel is milled from the solid. The return passages are from eight to twelve in number and are milled on the inside of the return-chamber ring. They are partitioned and are similar in shape to the buckets. The nozzle lies in the plane of the side of the wheel.

The Bliss turbine, formerly known as the American, made by the E. W. Bliss Company, of Brooklyn, N. Y., is of the same type as the Terry and Sturtevant and has been on the market only a few months. The casing and steam chamber are cast solid with one side and the nozzle and return chambers bolted in. The wheel is milled from a steel casting, or forging in the smaller sizes, and the partitions separating the buckets are inserted and held in place by three bands of steel shrunk on the face of the wheel. The return passages are peculiar in having no partitions. Two sizes of wheel have been built, the 42-inch and 30-inch, but designs have been developed for the 12-, 18-, 24-, 36-, 48- and 60-inch, covering powers from 10 horsepower to above 600 horsepower.

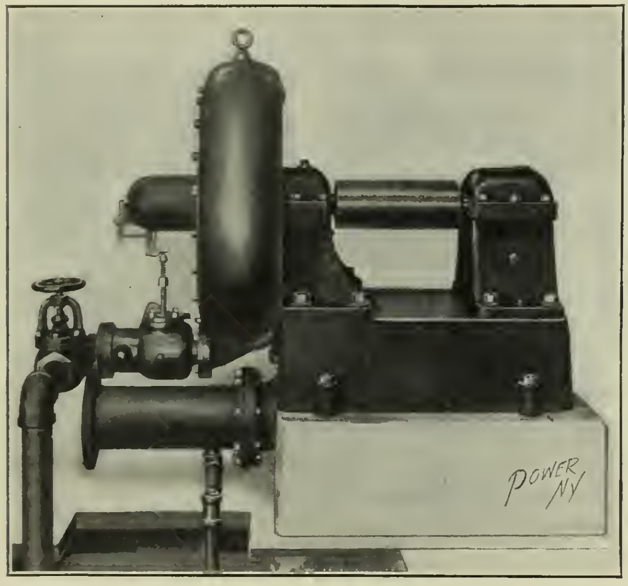

FIG. 8. BLISS TURBINE, 30-INCH

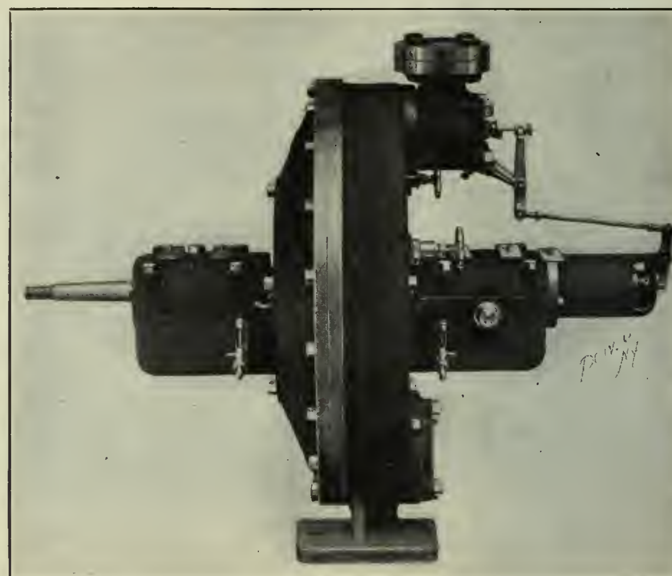

FIG. 9. DAKE TURBINE, 24-INCH

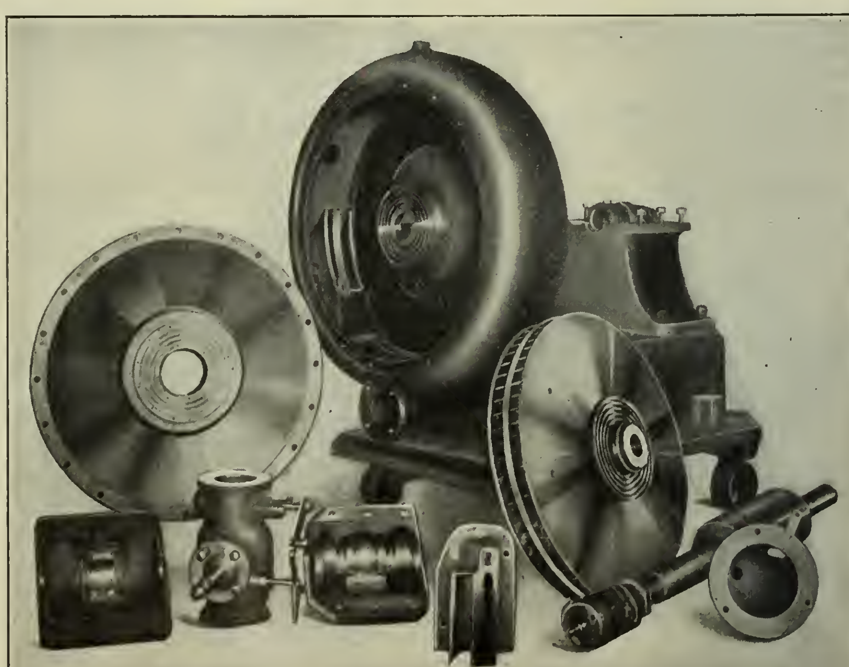

FIG. 10. BLISS TURBINE PARTS

The Dake turbine, made by the Dake-American Steam Turbine Company, of Grand Rapids, Mich., is a single-stage impulse turbine. The wheel is made of two bucket disks, with milled buckets and inserted partitions, bolted together over a wheel center. In their Headlight turbine the governor is inclosed between the sides of the wheel. The nozzles and return passages are placed between the bucket disks. The machine is built in sizes of from 5 to 100 horsepower, the diameter of the smallest wheel being 12 inches.

Coincident with the development of the large Curtis turbines, the General Electric Company, at its Lynn works, has developed and placed on the market a line of small generating sets ranging from 5 to 300 kilowatts. This range is covered by eight sizes, the smallest machines being single-stage with two or three passes per stage. The buckets and nozzles are of the well known Curtis type.

The Kerr turbine, made by the Kerr Turbine Company, of Wellsville, N. Y., is of the compound-impulse type. It is generally built in from two to eight stages. The buckets are of the double Pelton type, inserted like saw teeth in the wheel disk. Four sizes of wheel, 12-, 18-, 24- and 36-inch, are made and cover a range of from 10 to 300 horsepower. The nozzles are in the plane of revolution of the wheel and are screwed into the stage partitions and held in place by a lock nut.

As in large turbines, details of these

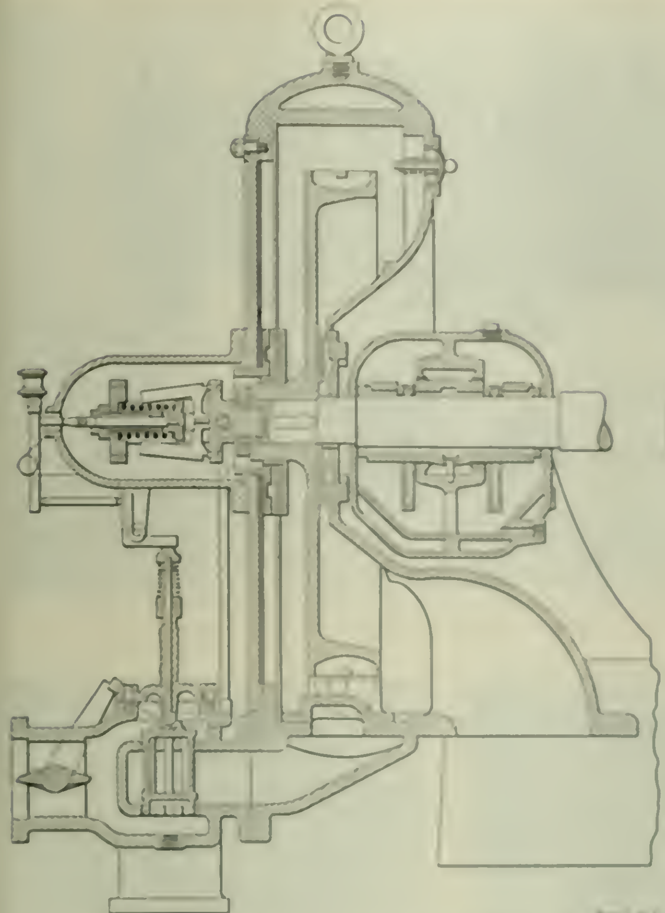

FIG. 11. SECTIONAL VIEW OF BLISS TURBINE

FIG. 13. CURTIS TURBINE, 50-HORSEPOWER

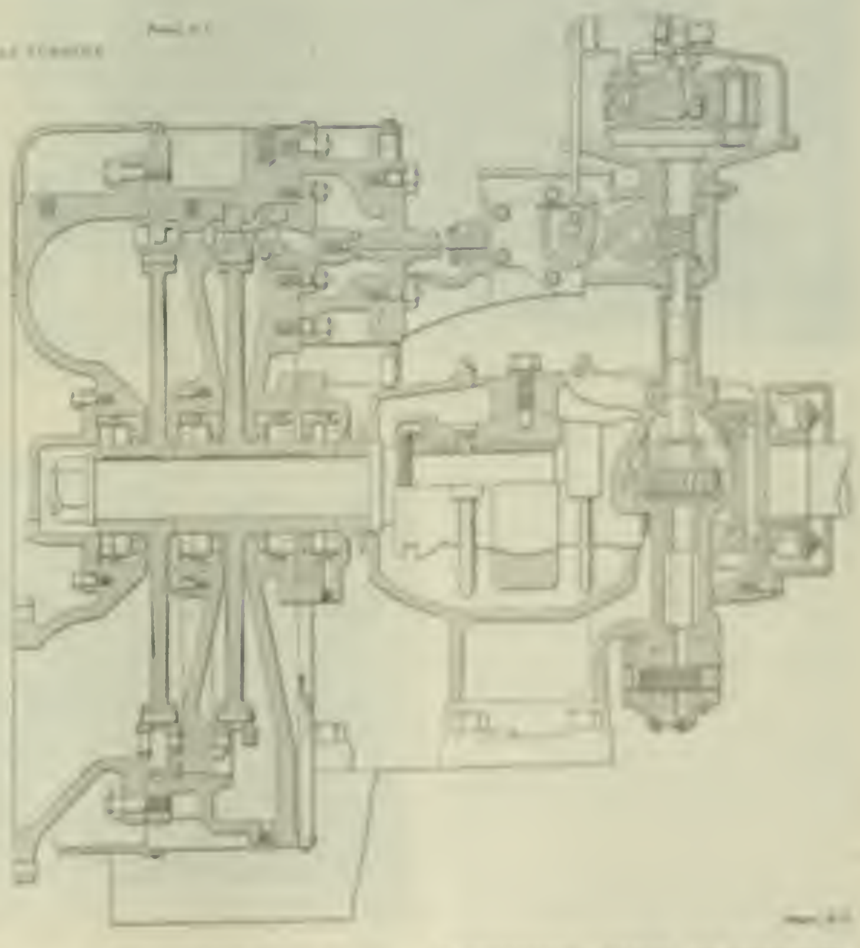

FIG. 14. SECTION OF CURTIS [illegible] TURBINE, [illegible]-HORSEPOWER

small turbines, to which reference has been made, show the skill and knowledge of the designer, and that the same problem may be solved in different ways is well illustrated by the sections here reproduced.

Description of Details

Nozzles. The diverging nozzle is used by all makers except Kerr, whose multi-speed wheel requires a converging nozzle. In the De Laval, Sturtevant and Kerr turbines the nozzles are screwed into their seats; that of the Terry is held in place by a bolt. The nozzles of the Curtis, Dake and Bliss turbines are reamed out of the solid. The larger sizes of the De Laval machine which have been put on the market lately have a large number of reamed nozzles instead of the older construction.

Buckets. The constructions employed in the Curtis and De Laval wheels are well known and have been described many times. The Terry, Dake, Bliss and Sturtevant buckets are practically semicircular in form. The Terry bucket is constructed entirely of steel punchings assembled between grooves in the two steel disks forming the sides of the wheel. The Sturtevant wheel is milled out of a steel casting. The Bliss buckets are milled out, but the partitions are inserted and held in place and steel rings are shrunk on. The Dake buckets are turned out of the solid, the recesses for the partitions milled out and the partitions inserted; the wheel is then bolted together. The Kerr buckets are very similar to the original Pelton buckets and are inserted in the wheel in a manner similar to the De Laval buckets.

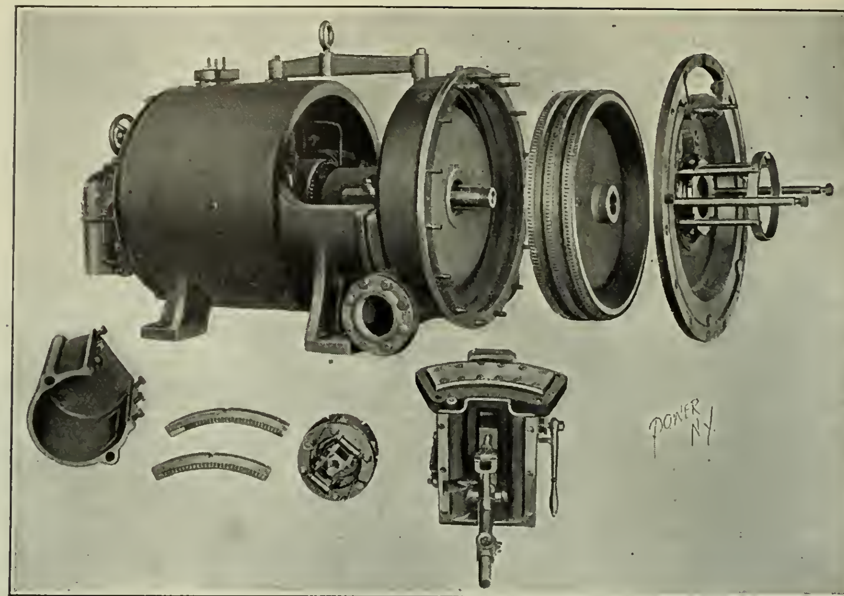

FIG. 14. CURTIS TURBINE IN PROCESS OF ASSEMBLING

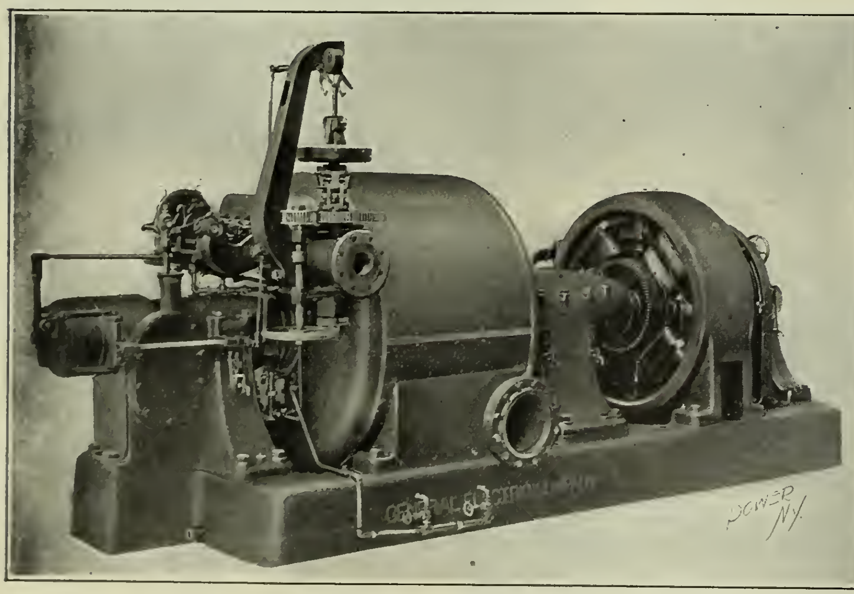

FIG. 16. CURTIS TURBINE, 200-HORSEPOWER

Return Chambers. The Sturtevant returns are milled out of the solid ring. Bliss casts them in the nozzle piece and finishes them by hand; Terry casts each one separately, finishes by hand and assembles with bolts; Dake casts the return chambers solid, mills the passages and covers them with a shrouding.

Wheel Centers. De Laval, Curtis, Sturtevant and Bliss make the wheel centers of steel castings or forgings integral with the wheel. Terry uses a steel casting, but bolts the wheel disk to it. Kerr uses a screwed coupling, the inner part cut in three pieces and keyed to the shaft with round keys, clamping the wheel disk. Dake's wheel centers are an integral part of the wheel in small sizes, but in the larger machines are steel castings, in some cases a part of the shaft.

Governors. De Laval, Terry, Sturtevant, Bliss, Dake and Kerr use a flyball governor on the shaft end, which actuates the throttle valve through a system of levers. Curtis uses the flyball governor on the shaft for small sizes and slower-speed spring-controlled governors of different forms for the larger sizes. The Sturtevant, Bliss and Curtis machines are provided with an emergency-stop governor as well as the throttling governor.

Glands. For noncondensing machines glands are not troublesome, as the difference of pressure between the casing and atmosphere is rarely more than a few pounds. Terry uses a bronze ball-and-socket gland with a long loose fit on the shaft. Sturtevant and Dake use a set of ring packing, either cast iron or bronze. Bliss has a labyrinth packing without contact. Kerr has a floating bronze bush with soft packing behind it. Curtis uses a metallic packing held in place by a gland ring, and for condensing service a carbon-ring packing, steam-sealed.

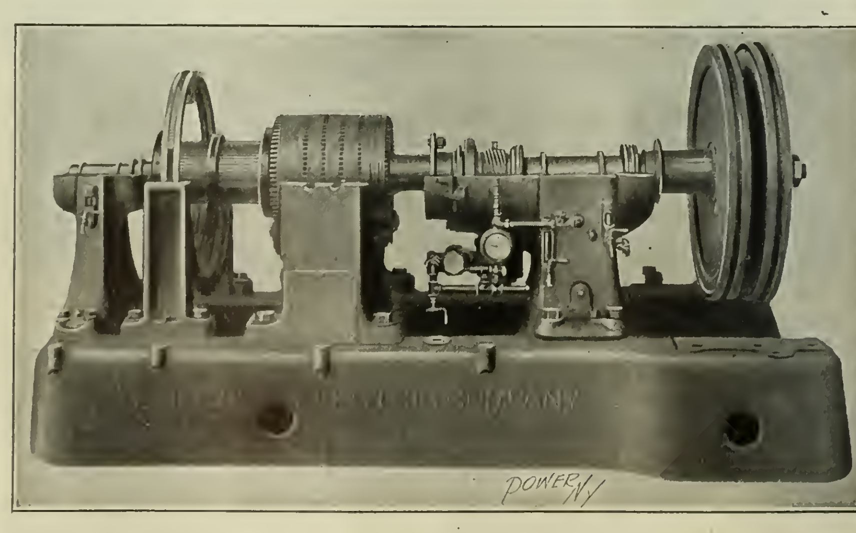

FIG. 17. REVOLVING ELEMENT OF CURTIS TURBINE IN BEARINGS

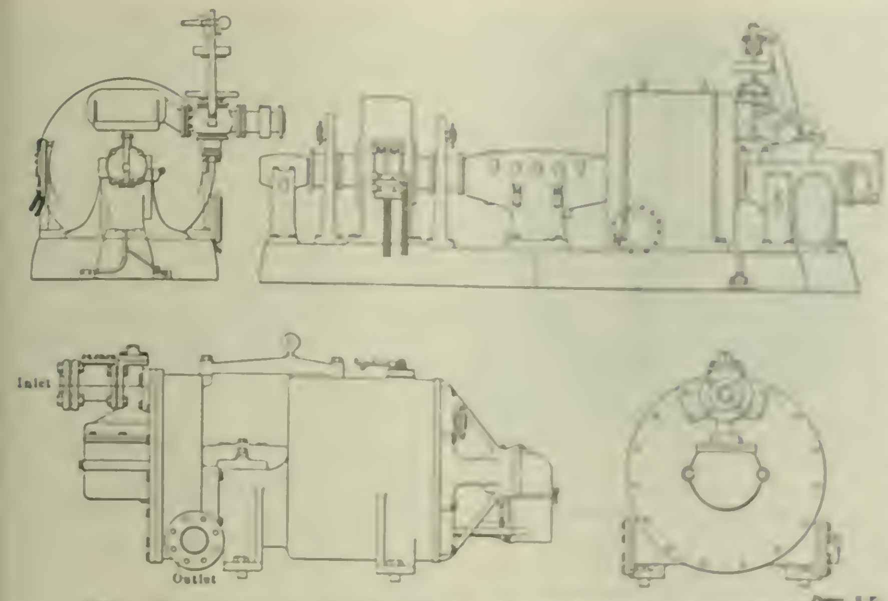

FIG. 18. DIAGRAMS OF CURTIS TURBINES, 300-HORSEPOWER AND 50-HORSEPOWER

water jackets or water-cooling pipes for an emergency cold-water circulation. The [illegible] of the thrust is [illegible] at the same time.

Operation. These machines are nearly automatic in their operation. When the turbine is once properly set, the coupling properly adjusted and the bearings supplied with oil, the machine may run for years without an overhauling. The bearings need be looked after to see that no heating takes place and that the ring is carrying the oil to the shaft. The coupling should be examined from time to time to make sure that no thrust is communicated through it to the turbine. With these precautions a three months' continuous run is common and a number of turbines have to my knowledge run more than 18 months without a cent spent on them for maintenance. Apparently there is no wear in nozzles, buckets and steam chambers. The only wearing parts are the

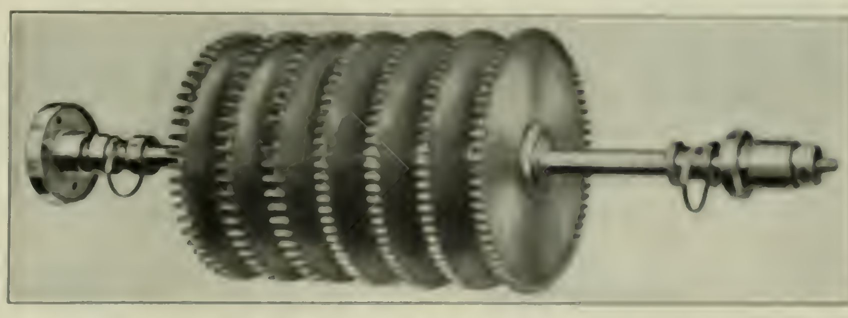

FIG. 20. COMPLETE ROTATING PART OF 18-INCH 7-STAGE KERR STEAM TURBINE

Clearance. In none of these machines is clearance an important factor. The clearance between buckets and guide passages on a 24-inch wheel is usually from 1/16 to 3/32 inch when hot. Striking or rubbing is practically unknown.

Thrust. Theoretically, there should be no thrust in any turbine of these types. Practically, there is always a very small thrust one way or the other. This thrust is usually taken care of by small thrust collars or washers next to the bearings. Thrust from the outside is prevented by the use of a flexible coupling between the turbine and the machine it drives.

Bearings. The bearings are always ring-oiled with large oil reservoirs, sometimes, on the larger sizes, provided with

bearings and these are practically permanent.

These machines may be taken apart and reassembled in half a day [illegible] in two hours. The [illegible] machines may be overhauled in an [illegible] time.

[illegible] Turbine. The [illegible] turbine made by William [illegible] & Son, New York, is a [illegible] turbine resembling in construction the Dow turbine as formerly illustrated [illegible] years ago. Some experimental machines have been built, one of which was tested at Columbia University, and any commercial machine will soon be on the market.

James Wilkinson, of Providence, R. I., has a small impulse turbine nearly in the commercial stage. A number of these machines are running, and within the next few months it is expected they will be on the market.

The [illegible] turbine, lately completed by the [illegible] Company and tested at [illegible], is another promising turbine.

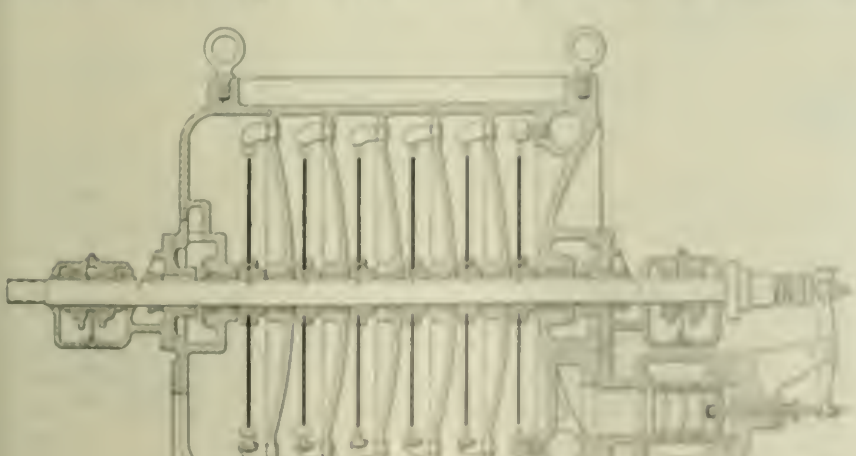

FIG. 21. SECTIONAL VIEW OF KERR TURBINE, 18-INCH

[illegible]

The success of these turbines [illegible] from the [illegible] that the Curtis turbine [illegible] and 200-horsepower sizes. These curves represent the average of a large number of tests and have been corrected to bring them to standard conditions. The averages were consistent, and the variation from the average in any case was not large.

The curves for the Terry turbine were plotted from 14 tests made at East Pittsburg by the Westinghouse Machine Company. The curves for the Bliss turbine were plotted from 24 tests made at Stevens Institute by Prof. F. L. Pryor. The curves for the Kerr turbine were plotted from tests made by the Kerr Turbine Company in its testing plant at Wellsville, N. Y.

There seems to be no change in steam economy with use. It may be too early to make this statement, but machines running regularly for three years have shown no increase in steam consumption.

The field of the small steam turbine is somewhat narrow when compared with the high-speed steam engine. The small turbine has its place, however, and with the development of a more economical machine at the lower speed ranges, will have a much wider field. The turbine-driven centrifugal fan, for both high and low pressures, will have an increasing use, and the centrifugal turbine-driven pumps have marked advantages over reciprocating apparatus because of the absence of

without doubt presages a like future for the small steam turbine.

Peat Society Meeting

There will be a meeting of the New York section of the American Peat Society, at the Technology Club, Syracuse, N. Y., May 15, from 3 to 5 and 7.30 to 10 p.m. Among the papers to be presented are the following: "Production of Ammonia from Peat," by Herman C. Woltereck; "Present State of Peat Gasifying with Recovery of Ammonia," by Prof. Charles A. Davis; "A Peat Producer with Peat Coke as Byproduct," by Dr. Otto Zwingenberger.

The first summer convention of the Society of Naval Architects and Marine Engineers will be held at Detroit, Mich., the latter part of June.

Marine Producer Gas Power*

By C. L. Straub

Only recently has such progress been made in the development of gas power for marine work as to warrant its early adoption in commercial service. Two years ago, less than 300 horsepower in the aggregate was being developed by marine producer-gas power installations; these were experimental in nature and were of the German Capitaine type. There are now installed and accepted 23 Capitaine marine plants, aggregating 2035 horsepower, a partial list of which follows:

(a) "Emil Capitaine." Launch, 60-boiler horsepower, four-cylinder single-acting, four-stroke-cycle engine; boat 60 feet long, 10 feet beam, 4 feet deep, ran an average speed of 10 miles for 10 hours on 412 pounds of anthracite.

(b) "Rex." Sea-going Swedish boat, 102 feet long, 22 feet beam, carries 340 tons on 9-foot draft; fitted with a three-cylinder single-acting, 45-horsepower engine running at 300 revolutions per minute.

(c) "Capitaine." Tow boat at Ghent; length 47 feet, beam 12 feet, draft 7 feet; fitted with a three-cylinder, single acting, four-stroke-cycle engine of 105 boiler horsepower at 240 revolutions per minute.

(d) "Duchess." A canal barge; length 71 feet, beam 7 feet 2 inch, carries 30 tons cargo on 4-foot draft; fitted with double-cylinder, single-acting, four-stroke-cycle engine of 25 boiler horsepower.

(e) "Dusseldorf." Tug at Hamburg; fitted with a four-cylinder, single-acting, four-stroke-cycle engine of 60 boiler horsepower at 240 revolutions per minute.

(f) "Leo." Tug fitted with a three-cylinder, single-acting, four-stroke-cycle engine of 45 boiler horsepower at 240 revolutions per minute.

(g) "Wilhelm." Combination freight and passenger Rhine boat, fitted with a four-cylinder, single-acting engine of 175 boiler horsepower at 240 revolutions per minute.

(h) "Badenia." Rhine freight boat, fitted with a two-cylinder, single-acting, four-stroke-cycle engine of 30 boiler horsepower.

(i) "Kattwyk." A canal freight boat, fitted with a three-cylinder, single-acting, four-stroke-cycle engine of 45 boiler horsepower.

(j) "Marie." A canal freight boat, fitted with a three-cylinder, single-acting, four-stroke-cycle engine of 35 boiler horsepower.

(k) "Hamburg." A combination freight and passenger Rhine boat, fitted with a four-cylinder, single-acting, four-stroke-cycle engine of 175 boiler horsepower.

(l) "Vorwärts." A Volga freight boat, fitted with a four-cylinder, single-acting, four-stroke-cycle engine of 60 boiler horsepower.

(m) "Nr. 26." A canal freight boat, fitted with a four-cylinder, single-acting, four-stroke-cycle engine of 60 boiler horsepower.

In addition to the above there are a number of freight boats, the dimensions and names of which I am unable to obtain; their power plants varied in capacity from 30 to 175 horsepower each.

(n) H. M. S. "Rattler." An old gun boat, 165 feet long, 25 feet beam, originally fitted with a triple-expansion engine. The gas engine is four-cylinder, single-acting, four-stroke-cycle, with cylinders 20 inches diameter by 24 inches stroke, developing 800 brake horsepower at 130 revolutions per minute. This engine is started by means of a mixture of gas and air which is pumped into the cylinders at a pressure of about 90 pounds per square inch. This installation was designed entirely by the Capitaine works at Dusseldorf. The total weight of the entire plant, including the donkey boiler for working the pumps and auxiliaries, is 54 tons, as compared with 138 tons in the case of the displaced steam engine. A consumption of 7300 pounds of coal was made for a measured distance of 95 knots at an average speed of 10½ knots per hour. The cost per mile for fuel, with coal at $30 per ton, is 8.9 cents, United States money. This boat made a maximum speed of 11.5 knots and stood against a 7½-knot current at 130 revolutions per minute of the engine shaft.

All of the above plants are, in design and construction, practically identical in operation on anthracite, coke or hard charcoal (charcoal) fuel and are made as restricted by the design to use those of fuel in commonly obtained in the scope of application. The development of a simple marine gas producer for use with any class of solid fuel is a necessity, if the subject is to be successfully realized.

The writer is fortunate in having been connected with some earlier American developments in both stationary and marine gas-power plants, which enables him to draw a comparison between a typical steam and a possible gas installation.

*Abstract of a paper presented at the Washington meeting of the American Society of Mechanical Engineers, May 4, 1909.

Three years have been devoted to the modification of the down-draft stationary bituminous producer for marine service. The work involved a reduction in the size and weight of the generators; complete revision of the scrubbing, gas-cleansing and exhausting mechanism; elimination of all gasholders, storage receptacles, mixing chambers, etc. The modified plant uptodate shows a light, compact producer, which while retaining the same rate of combustion as the stationary apparatus, has materially reduced dimensions and weight of shells, brick lining, fittings, etc. The economizer boilers which were used in stationary work have been replaced with light air-heating economizers. The gas coolers no longer contain any coke nor broken material, nor wood trays, and are built of very light, noncorrosive sheet metal, and arranged for either vertical or horizontal mounting, the latter lending itself nicely to location in space which would be otherwise wasted in the vessel. The cooled and partially cleansed gas is drawn through the producer plant by a centrifugal gas-cleaning exhauster, driven by direct-connected motor. The gas passes directly from the exhauster, under pressure, through an automatic pressure-regu-

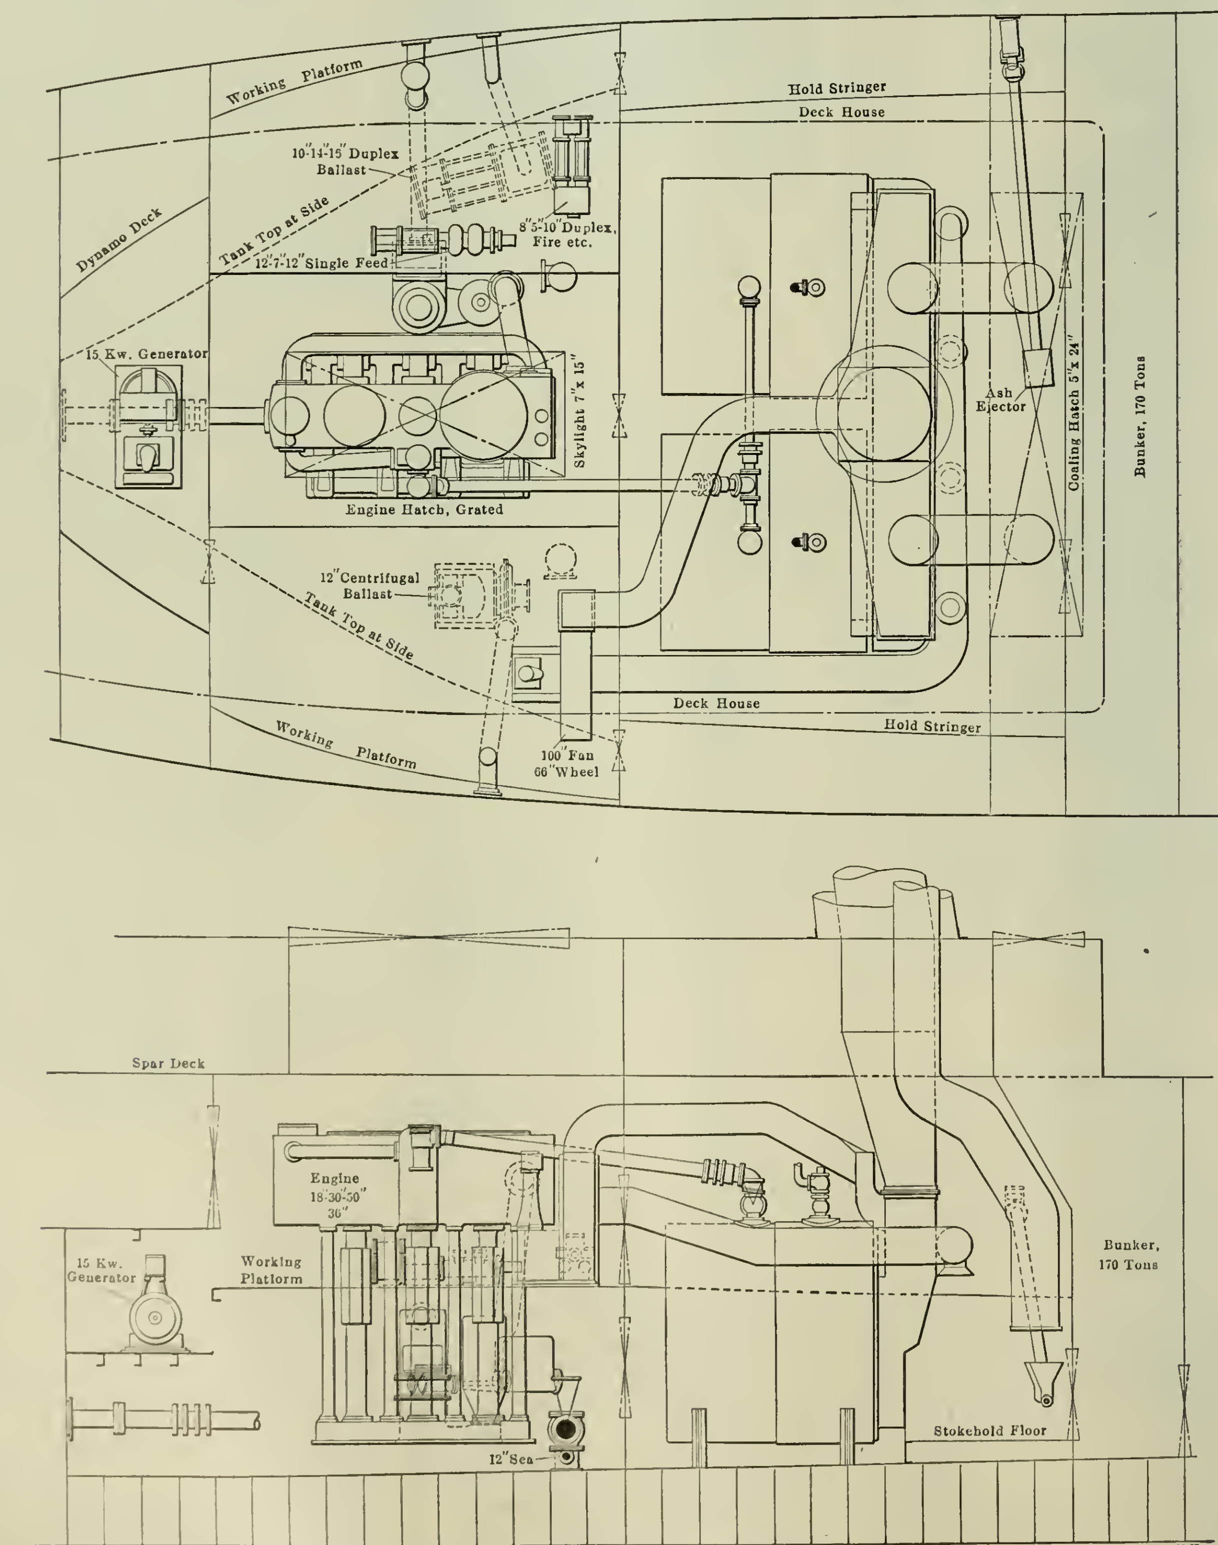

FIG. 1. PLAN AND ELEVATION OF 1000-HORSEPOWER STEAM-POWER EQUIPMENT INSTALLED IN LAKE FREIGHTER

lating valve to the engine manifold. That the plant is adaptable for marine service, with regard to space occupied and weight, may be seen from the following conservative estimate:

Plants of from 100 to 500 horsepower weigh from [illegible] to 70 pounds per horsepower, including all auxiliaries, piping, etc.

A Comparison of Producer-gas and Steam Equipments

Undoubtedly the natural opportunity at [illegible]

[illegible]

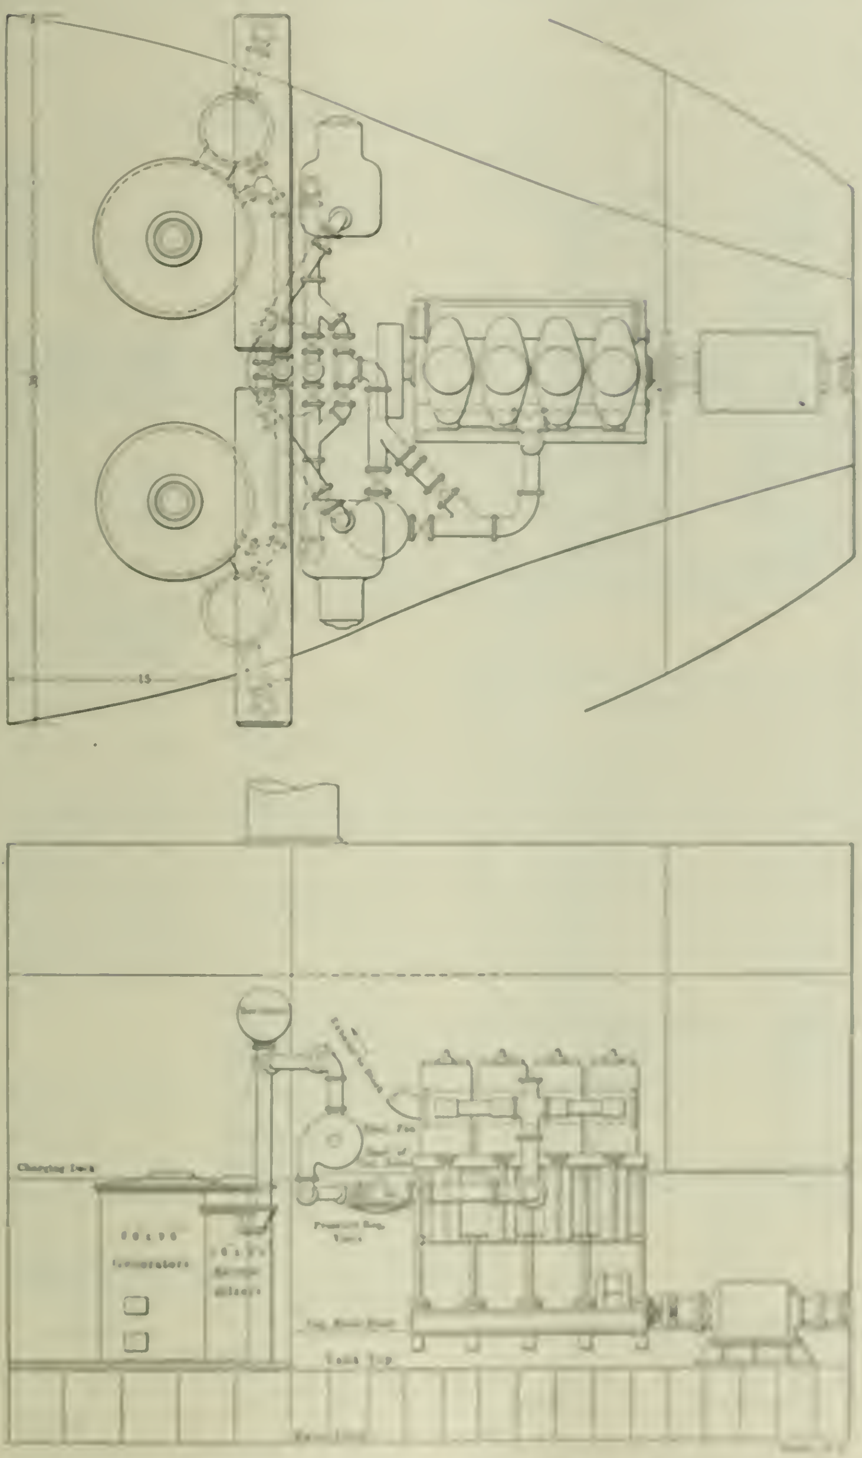

FIG. [illegible] PLAN AND ELEVATION OF [illegible] MARINE PRODUCER PLANT

each occupy from 0.4 to 0.[illegible] square foot per horsepower, and weigh from [illegible] to 90 pounds per horsepower, including all auxiliaries, piping, etc.; plants from [illegible] to 1000 horsepower occupy from [illegible] to 0.45 square foot per horsepower, and [illegible]

the present time for marine gas power lies in commercial service, in which [illegible] [illegible] [illegible] of the Great Lakes. [illegible] gine is a four-cylinder, double-acting, reversing type, having cylinders 24 inches bore by 36 inches stroke, delivering 1000 boiler horsepower at 100 revolutions per minute. The reversing is accomplished by means of compressed air, which is used to shift the cams from the head to the stern position. Compressed air is admitted to the cylinders by timed cams in proper cycle. The crank shaft of the engine is rigidly coupled to the shaft of the screw.

The illustrations show a column-framed engine. Since making this layout, the design of the engine has been modified to meet all of the present marine conditions now found in marine-engine design on the lakes. In fact, with the exception of the condenser shown on the steam drawings, the gas-engine frame will be very similar to the steam engine.

For the generation of current to drive the auxiliaries, there will be installed a double-cylinder, double-acting gas engine, direct-connected to a 50-kilowatt direct-current generator. All of the pumps and auxiliaries will be motor-driven. A smaller direct-connected unit operating on oil will be used for pumping air, blowing fires, or other service, when the gas plant is down. Allowing a distance of 4 feet 3 inches between the forward bulkhead and the engine room and the forward side of the flywheel, which distance is 1 foot greater than that in the steam installation, we have an overall distance between forward and after bulkheads in the engine room of 19 feet 6 inches.

As previously stated, two arrangements of producer equipment are shown. The four-generator plant, Fig. 3, consists of four 6-foot by 9-foot generators, each fitted with independent economizers. The forward pair and the after pair are connected independently to two horizontal gas scrubbers, which are shown slung under the main deck beams. The gas passes from these scrubbers to independent motor-driven centrifugal gas-cleaning fans, whence it is delivered, either through common connection to a purge or blowoff pipe which also acts as a bypass, or through two gas-pressure regulator valves to the air- and gas-mixing valve at the engine manifold. The 6-foot generators require only one cleaning door each. As a result a single cleaning space suffices for the four machines, allowing them to be grouped with reference to athwartship space, so as to give ample room on each side of the vessel for coal bunkers. The total space occupied by the producer plant is 21 feet 10 inches athwartship, and 15 feet between forward and after bulkheads. The producer-room weight, including generators, economizers, piping, and scrubbers, complete, of the four-generator set, is 110,000 pounds. This weight is estimated, but has been carefully checked and completely covers all the mechanism. In addition to the above mechanism, there will be a heating boiler which is shown on the main deck. This boiler will serve to furnish low-pressure steam for heating the vessel and supplying hot water for washing down decks, etc. This boiler, with water, will weigh about 8000 pounds.

The two-generator producer plant, which will undoubtedly be the one installed, will consist of two 8-foot diameter by 9-foot 6-inch generators, connected to independent air economizers and each fitted with an independent horizontal scrubber, located athwartship under the main deck beams. The gas outlet at the scrubbers will be connected with a crossover, so that either exhauster may operate either or both producer plants. The exhausters are installed in duplicate and are connected with common purge or blowoff and common gas outlets leading either through one pressure-regulator valve, or through a bypass direct to the air- and gas-mixing valves at the engine manifold.

On account of the fact that the 8-foot generators require two cleaning doors set at 120 degrees, the double-generator unit plant will require the full athwartship space in the producer room. The approximate floor space occupied, therefore, will be 30 feet athwartship and 15 feet between forward and after bulkheads. The producer-room weight, including generators, economizers, piping and scrubbers

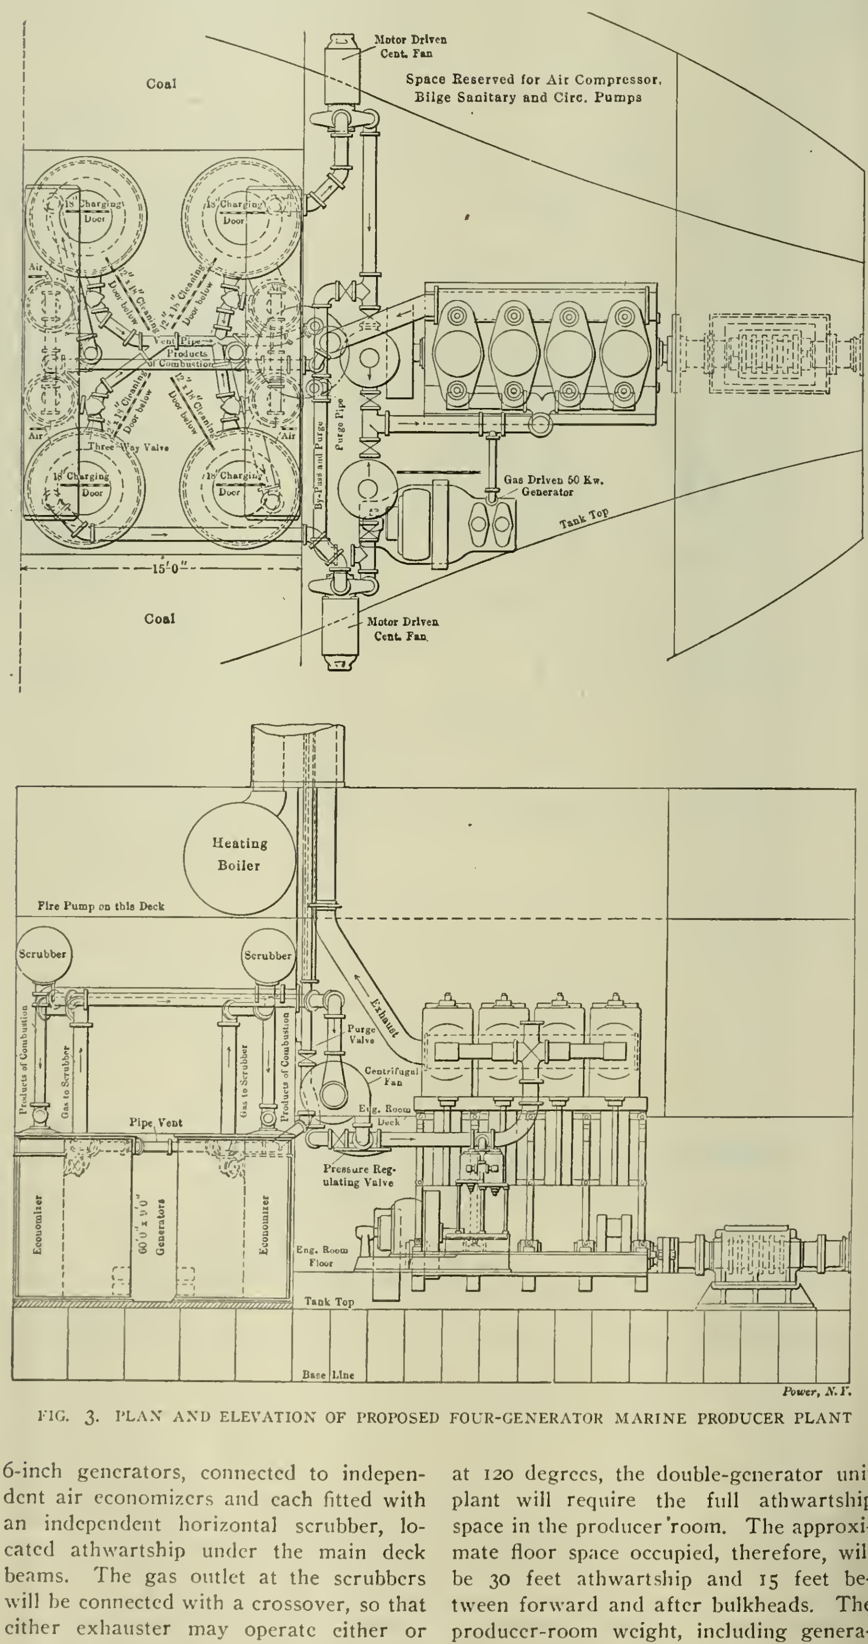

FIG. 3. PLAN AND ELEVATION OF PROPOSED FOUR-GENERATOR MARINE PRODUCER PLANT

complete for the two-generator set is 82,000 pounds. This weight is estimated, but has been carefully checked and completely covers all of the machinery. As in the case of the four-generator plant, a low-pressure boiler for heating service will be installed. In the two-generator plant, however, this boiler will be located on the producer-operating floor, that one set of firemen may suffice for both.

TABLE 1. COMPARISON OF POWER PLANTS FOR GREAT LAKES FREIGHT CARRIER.

Length overall	306 ft. 0 in.
Beam	45 ft. 0 in.
Depth	24 ft. 0 in.
Displacement	Tons gross
Cargo	4,200 net pounds at 18 feet draft
Speed	12 statute miles per hour on 900 indicated horsepower.

STEAM.	GAS.
ENGINE ROOM	ENGINE ROOM.
Three-cylinder triple-expansion condensing engine, 18&30& 50 by 36 in., 1050 i.h.p. at 90 to 95 r.p.m.	Four-cylinder, four cycle, double-acting, gas engine, 24-inch bore by 36-inch stroke 1000 b.h.p. at 95 r.p.m.
Auxiliaries steam-driven	Auxiliaries motor-driven
Length between bulkheads, 22 ft.	Length between bulkheads, 19 ft. 6 in.
Engine room weights, including auxiliaries and piping, 182,000 pounds.	Engine room weights, 105,000 pounds.
BOILER ROOM.	PRODUCER ROOM.
Two single-ended Scotch boilers fitted with economizers, forced draft. Length each boiler, overheads 11 ft.	Two down-draft gas producers and auxiliaries.
Mean diameter, each, 11 ft. 10 in.	Diameter of shell, each generator, 8 feet.
Two 42-in. furnaces each	Inside diameter of generator lining, 6 ft. 3 in.
244 2½-in. tubes, each	Height of shell, each generator, 9 ft. 6 in.
Grate surface, each, 36.75 sq. ft.	Grate surface, each generator, 20.67 sq. ft.
Heating surface, each, 1642 sq. ft.	
Boiler room weight, water in boilers, no fuel, 170,000 pounds.	Producer room weights, no water, no fuel, 82,000 pounds.
Length boiler room, 24 feet.	
Length boiler room, including bunkers, 30 feet.	Length of producer room, including bunkers, [illegible] feet.
	Square feet producer room, 430.
	Square feet per horsepower, 0.43.
Square feet boiler room, including bunkers, 900.	Square feet producer room with four generators, [illegible]
Square feet per horsepower, 0.9.	Square feet per horsepower, four generators, 0.[illegible]
Bunker capacity, 340,000 pounds.	Bunker capacity, 160,000 pounds.
Total weight of machinery and fuel, 692,000 pounds.	Total weight, machinery and fuel, 347,000 pounds.
Total length of machinery space, including bunkers, 52 feet.	Total length of machinery space, 34 ft. 6 in.
	Saving in weight, [illegible] pounds.
	Saving in fore-and-aft length, 17 ft. 6 in.
	Saving in cargo space, 17 ft. 6 in. by 42 ft. beam by 24 ft. depth = 11,[illegible] cu. ft.

The builders of this proposed apparatus are prepared to guarantee one brake horsepower hour on one pound of good bituminous coal, averaging 13,500 B.t.u. per pound.

Babcock & Penton, who have spent several years on the problem of the substitution of gas for steam, have suggested that the coal bunker, which will be placed above the charging deck of the producer, should have a capacity of about [illegible] tons of coal. The bunker will run from the charging deck to the deckfloor and will have doors opening directly adjacent to the charging doors of the generators, so that little or no coal [illegible] on the operating deck will be required.

In making the comparison shown in the [illegible] table, it is unnecessary to go into the cost of fuel, labor, hours of service, etc., as these elements vary with every class of service. In this particular proposition, it will suffice to state that the [illegible] who have been working on this problem for over two years have conservatively figured that with the saving in fuel and the increased cargo carried, the cost of the complete plant will be saved in two years of operation.

A marine bituminous gas plant, similar in construction and operation to the one described but of [illegible] horsepower capacity, has been in commercial operation driving a six-cylinder, single-acting, reversing marine gas engine for over a year. The results obtained give ample security for the statements made in this paper.

Notes on Belting

On the death of Col. Samuel Webber, the well-known New England millwright and engineer, his notebooks were left to his son, William O. Webber of Boston, who presented at one of the recent meetings of the National Association of Cotton Manufacturers some of the data therein contained relating to the measurement of power required for the operation of cotton-mill machinery. Among these notes was the following relating to the use of belting:

Good oak-tanned leather from the back of the hide weighs almost exactly one avoirdupois ounce for each one-hundredth of an inch in thickness, in a piece of leather one foot square, so that

[illegible]

Assuming an average working strain of [illegible] pounds per square inch and using the rule for velocity in feet per minute for each inch in width to transmit one horsepower:

Rule—Multiply the denominator of the fraction expressing the thickness of the belt in inches by [illegible] and divide it by the numerator.

[illegible]

If, however, we use the actual thickness as [illegible] the [illegible] as follows:

[illegible]

so that the safe working strain per inch in width would be as follows:

[illegible]

and the safe load on a [illegible]-inch belt running at [illegible] feet per minute would be:

[illegible]

of its former value, showing slight differences except in the medium, double and 3-ply cases.

Good, well-[illegible] rubber belting [illegible] will be as follows:

[illegible]

The thickness of rubber belt does not necessarily govern the strength, but the weight [illegible] as follows:

[illegible]

and the safe load on a [illegible]-inch belt running at [illegible] would be:

TABULATED RESULTS

[illegible]

Should the arc of contact on the smaller pulley be less than 180 degrees, the [illegible] should be multiplied by the following per cent.:

The "Salem's" Disability

The turbines of the scout cruiser "Salem" were opened on Wednesday, April 28, at the works of the builder, the Fore River Shipbuilding Company, and the cause of her falling off from the efficiencies attained and performances effected on her acceptance tests was revealed. It was found that the first row of buckets in the fifth stage had been battered down very badly, as by a piece of metal projecting from a steam nozzle, or perhaps by a loose piece of metal such as a nut rolling around in the space between the buckets and the nozzle. The edge of each blade was hammered to the top of the blade next to it, almost closing the passage to the steam, and it is not at all remarkable that the turbine should have lost fifteen revolutions per minute. At the time of our advices, the rotor had not been lifted out of the case; when this is done more light may be thrown upon the cause of the trouble.

The rotor appears to have been adjusted too far aft within the casing, with the result that the revolving blades rubbed against the stationary buckets, wearing the bases and shrouds nearly an eighth of an inch. Such a brake at such a radius and at the speed at which the turbine runs must have been a very serious handicap. The buckets and blading show no signs of erosion by steam. The trouble occurred in the starboard turbine and, while it is not expected that any similar condition will be found in the port turbine, that will be opened and examined before the engine leaves the works.

Economy in Woodworking Establishments

In woodworking establishments, where the problem is to get rid of waste rather than to save fuel, and the boiler furnaces serve the part of destructors, there is little attention paid to economy in the generation and use of steam. Nevertheless, there may be more economies to be had than are apparent at first thought. The fuel charge is not the only important item in the power-plant account. The standing charges for interest, taxes, insurance and depreciation, which increase in direct proportion to the investment, often approach the fuel charge in magnitude. The use of the exhaust steam in kilns, etc., means less investment in boilers, less water to pump or buy, less scale to remove, fewer furnaces to fire and rebuild once in so often, fewer boiler tubes to clean and less expense in many other ways than in the amount of fuel used.

The barbarous method of getting rid of waste by wanton burning is being outgrown. In the first place there is a good deal less waste than there used to be. Saws cut closer scarfs and the trimmings are used up to the smallest scrap that will serve even to be glued up with other scrap to make composition board. Higher prices for coal give a greater relative value to this waste as fuel, and in woodworking centers like Minneapolis it is sold quite extensively for this purpose. While its price would not ordinarily warrant going to a great degree of refinement in an effort to save it, its cheapness and availability should not lead to the neglect of possible economies.

A source of economy analogous to the use of exhaust steam in the kilns is the use of exhaust-steam heaters. Here again there is increased boiler power, less torture to the boilers by the feeding of heated water, less scale on account of the throwing down of the impurities which are removable by heat before the water goes to the boiler, and less fuel to handle and fire, with less wear on furnace and grates, even if the fuel is worth little or nothing.

This is written with a full appreciation of the fact that many of the power plants of sawmills and woodworking establishments are models of efficiency, with equipment of the highest class; and simply to offset the still somewhat prevalent notion that cheap fuel is an argument against all effort at power-plant economy.

Are Inside-Screw Valves Unsafe?

In registering a complaint against the ruling of a boiler inspector an engineer calls attention to the fact that he was compelled to replace a new nonreturn stop valve having an inside screw by one with an outside yoke and screw, causing both delay and expense.

In making his decision, the inspector was, of course, guided by what he believed to be his duty in the matter. But to one who could not be present at the time the decision was rendered, some description of the mental process by which a valve with an inside screw was proved to be unsafe or weaker than one with an outside screw and yoke would be interesting.

Valve manufacturers stand ready to guarantee the reliability of their product whether of one style or of the other, and it is not clear why one form should be prescribed when its safety in operation has been clearly demonstrated.

In one instance, several years ago, an outside screw and yoke valve failed under peculiar circumstances, where it is highly probable that an inside screw valve with bonnet would have held.

At or near the end of an eight-inch line of steam pipe carrying one hundred pounds pressure per square inch a valve of the outside screw and yoke type was put on the end of a tee instead of a blank flange, in order more conveniently to extend the pipe line at a future time. Just before steam was turned into the line the valve was closed and the dirt, scale, red lead, flange bolts, nuts and other stuff were blown out through another valve. When the pipe was clean and the blowing valve closed, after about five minutes the yoke on the valve which had not been opened broke, allowing the valve to open wide. In this valve the body and yoke were of cast iron and the stem of bronze. Heat from the steam expanded the bronze portion of the valve more rapidly than the cast iron could accommodate itself to the tension and the yoke parted.

Examination showed that the break was in clean, sound iron and that the yoke was more than ten times as strong as was necessary to resist the steam pressure, but it failed. There may, or there may not be good reasons why one type of appliance is stronger and safer than another, but the question that would most naturally arise is: Has an inspector a right arbitrarily to condemn a piece of apparatus which may be lawfully manufactured or imported?

If the inside-screw valve is unsafe in one instance are not all similar valves unsafe?

Order

In every line of human endeavor it pays to be orderly. System based on order is the underlying principle of true progress, and upon its strict observance in matters of great or small import, largely depends the issue of success. Evidences of the truth of this assertion are all about us and nowhere are they more prevalent or more abundant than in the power field.

Suppose, for instance, that the manufacturer of an engine, or perhaps a turbine, should endeavor to construct his machine without due regard to a system carefully planned and carried out, could the result of such procedure be other than failure? And, again, when the constructive process is complete, does the observance of this principle cease at the threshold of the power-plant, leaving the engine to run at any time or for any purpose, subject to the vagaries of chance? These suppositions are, of course, nonsensical and any engineer would pronounce them so, although a glance into some engine rooms shows such disorder as to imply an entire lack of system.

In building or operating an engine it is easy to see where the law of order has play, but it is the little things that so often escape attention. It may be convenient at the moment to throw a wrench in some dark corner when the work in hand is completed, but the subsequent search when it is again needed will show the false economy of such a method. A saving of present time may be effected by letting things lie where they fall and allowing a collection of odds and ends to litter the floor, or in making repairs it is often easier to patch things up with some temporary makeshift, when there is plenty of time to do the work thoroughly and as it should be done.

In the end it will be found that a strict observance of systematic order in all things will save time and money, and if the importance of doing the little things right were only realized, the number of dirty, ill-kept and disorderly engine rooms would surely be few and far between. Orderly care in the arrangement and the position of even the smallest appointments of an engine room leads to economy in the time and energy of the operator and contributes in an appreciable degree to the life of the machinery. Be orderly and systematic in the small things and the big ones will take care of themselves.

To Revise A. S. M. E. Codes

At a recent meeting of the council of the American Society of Mechanical Engineers, the committee on revision and extension of the code for testing gas-power machinery, Charles E. Lucke, chairman; E. T. Adams, George H. Barrus, D. S. Jacobus and Arthur West, made a general report and requested that they be discharged and a new committee appointed to revise, unify and standardize all the present codes of the society on their various subjects. This committee should not be confused with the gas-power standardization committee, which is a committee within the Gas Power Section, consisting of Dr. C. E. Lucke, chairman, Arthur West, J. R. Bibbins, E. T. Adams, J. E. Andrews, H. F. Smith and Louis [illegible].

It was voted that nine members be appointed by the president for the approval of the council, a committee on power tests to revise the present testing codes of the society relating to boilers, pumping engines, locomotives, steam engines in general, internal-combustion engines and apparatus and fuels therefor, and to extend these codes so as to apply to such power-generating apparatus as the present codes do not cover, including water power, and bring these into harmony with each other and with the best practice of the day.

The committee, consisting of Messrs. [illegible] and Taylor appointed to investigate the advisability of a revision of the standard code on boiler tests, reported that in their opinion it is desirable to undertake a revision of the code in view of the progress made in the art since the standard code was adopted. The application of gas-producer power, gas-producer plants, oil-fired furnaces and other important developments makes it desirable to bring the code up to date so as to include provision for gaseous and liquid as well as solid fuels. It may be desirable, also, in the revised code to give consideration to the question of a standard method for the sampling and testing of fuels.

National Smoke Abatement Conference Proposed

Through the efforts of Prof. Charles D. Benjamin, James M. Dodge, John J. Flather, Harold W. Lewis, Morris L. Cooke and others interest has been aroused in the "smoke abatement" problem to the extent of a proposal having been made to the meetings committee of the American Society of Mechanical Engineers that the society there take cognizance of the matter by holding a national conference in connection with one of its annual or semi-annual meetings.

It is believed that a symposium of papers upon the subject, contributed by eminent authorities, could be procured, beside which the contributions might profitably be selected being as follows: "The Aesthetic Side of the Smoke Question," "Legal Aspects of the Smoke Nuisance," "What Is Smoke?" "The Chemistry of Smoke," "Causes of Smoke in Power Plants and Locomotives," "Apparatus for Preventing, Detecting and Measuring Smoke," "Successful Experiments in Smoke Abatement," "Economic Side of the Smoke Problem," "The Smoke Problem as Affected by Meteorological Conditions," "Smoke in Its Relation to Public Health," etc.

One of the chief reasons that such a conference should be of immense public good, it is believed, is because of the intimate relation between smoke abatement and the conservation of the natural resources of the country.

Who Has Seen This Missing N. A. S. E. Member?

Charles L. Brandon, a member of California Association No. 2, N. A. S. E., has been missing from his home and his friends and relatives are greatly concerned regarding his mysterious absence. Mr. Brandon was last heard of in Spokane, where he was on the lookout for a position, having just left the position of [illegible] machinist with the British Columbia Copper Company, Greenwood, B. C.

Mr. Brandon is about 35 years of age, 5 feet 10½ inches in height and weighs about 160 pounds. He has dark hair, eyes and complexion, and was usually clean shaved when last seen.

Any information concerning Mr. Brandon will be gratefully received and forwarded to his wife by Jacob Thomas, secretary, California No. 2, N. A. S. E., 214 O'Farrell street, San Francisco, Cal.

Universal Craftsmen's "Chambers Night"

The fourth annual Elmer E. Chambers Night of the Universal Craftsmen Council of Engineers, tendered to the ladies, was held at the assembly rooms of the Lexington Opera House, Thursday evening, April 29. Although the night was very stormy, the hall was well filled, and the entertainment was most enjoyable. The "bunch" elicited generous applause. Following the entertainment there was dancing. The committee of arrangements comprised W. H. Armstrong, chairman; M. J. Burke, J. E. Murray, George Quelet, James Harris, George Voet, Fred Maart. Frank Martin was floor manager, assisted by Frank Corbett, John L. Wilson, Herbert Self and Robert Lawhon.

The officers of the association are: Otto Berger, worthy chief; Fred Maart, assistant worthy chief; Fred Anthony, recording secretary; M. J. Burke, financial secretary; S. S. Henderson, warden; George Quelet, treasurer; J. Wallace, guard; William Jones, chaplain; Joseph McKeown, past chief.

Mott Haven's Housewarming

Mott Haven Association No. 47, N. A. S. E., held a housewarming Saturday evening, May 1, to celebrate its removal to the new lodge rooms in Loefler's hall, One Hundred and Forty-eighth street and Willis avenue, New York City. The "bunch" entertained enjoyably. Addresses were made by Past National Presidents, Herbert E. Stone and Joseph F. Carney. Refreshments were served.

The Combined Associations of Engineers of the Borough of Brooklyn held the second annual dinner of its delegates at Feltman's pavilion, Coney Island, on Saturday evening, April 24. An appetizing dinner was served and an excellent entertainment was given by the "bunch."

Business Items

With 3800 employees on the payroll for April, the Diamond Rubber Company, of Akron, Ohio, has under way extensions to its plant which will give employment to more than 200 additional men by fall. No new lines will be taken on by the company at present, but the increased space will be used for the extension of practically all departments, including belting, packing, hose, rubber-covered wires, cables and tires. The city of Akron has lately vacated an entire street adjoining the Diamond factories to permit of the growth of the plant, and in return the Diamond company paid the entire cost of paving the remaining portion of this street not abutting upon its property, the bill for which will be not far from $15,000.

E. H. Stevens, well known among steam power-plant and central-station men as the general superintendent of plants of the Public Service Corporation of New Jersey, has become vice-president and general manager of the Bird-Archer Company, manufacturer of boiler compounds, 90 West street, New York. During his fifteen years' experience in power-plant operation, costs and management, Mr. Stevens has had complete charge of plants aggregating several hundred thousand horsepower, and is therefore well prepared to deal with questions about feed-water treatment. The Bird-Archer Company is also to be congratulated in being able to offer to its customers the advice and help of such an experienced engineer. During the past five years he has used the company's compounds exclusively and is well posted on the results that can be secured by using boiler compounds. Mr. Stevens will have complete charge of sales and will give his personal attention to inquiries from large plants which heretofore have shown serious economy losses and high operating costs on account of scale, oil deposits and other troubles caused by bad feed water.

The improvement in the business of the Westinghouse Machine Company's shops at East Pittsburg, which has been noticeable for several months, continues in the most encouraging degree. Since the first of April quite a number of orders for steam turbines, steam engines and gas engines have been booked, and the record for the first two weeks of this month shows a considerable increase over the same period of March. With the anticipated closing of quite a number of contracts for which negotiations are now pending, the indications are that the April business will make an excellent showing. Among the contracts particularly worth mentioning which the company has lately received is an order from the City Electric Company, of San Francisco, for a 15,000-horsepower steam turbine. This will be the most powerful steam turbine installed west of the Mississippi, its power capacity being about equal to ten of the largest-size express railway locomotives. This company has already installed three Westinghouse steam turbines of a smaller size. The East Pittsburg shops are also turning out at present an order from the city of Detroit, a 5000-horsepower steam turbine, and another of the same size is going to Nichols Copper Company, of Laurel Hill, Long Island, while the Saginaw & Flint Railway Company, of Michigan, has contracted for an 1150-horsepower turbine and the Alaska Treadwell Gold Mining Company, of San Francisco, has ordered two 1000-horsepower machines of the same type.

New Equipment

The York Company, Saco, Me., is to enlarge ts power hou se.

The Scotia Worsted Company, Woonsocket, R. I., will erect a new power plant.

The Hygeia Refrigerating Company, Elmira, N. Y., will build an $80,000 addition to plant.

The citizens of La Crosse, Wis., will vote on question to build a municipal electric lighting plant.

It is said the Beacon Light Company, Chester, Penn., will spend about $125,000 on improvements at plant.

Plans have been prepared for a new power house for the University of North Dakota, Grand Forks, N. D.

The Sierra Electric Company, recently granted a franchise in Red Bluff, Cal., proposes to erect two power houses.

The Springfield (Ohio) Light, Heat and Power Company will erect a large addition to its plant on West Jefferson street.

Julius A. Gebauer, Philadelphia, Penn., is having plans prepared for a four-story factory and one-story power house.

The Eldora Electric Light Company, Eldora, Iowa, will install two 150-horsepower boilers. Albert Tresner, superintendent.

The Steelton (Penn.) Light, Heat and Power Company has decided to increase output and will install additional equipment.

The Grand Rapids-Muskegon Power Com pany, Grand Rapids, Mich., is contemplating installing a steam auxiliary plant.

The Schenectady (N. Y.) Railway Company has let contract for the construction of a new sub-station for the Saratoga division.

It is reported the Southern Lumber and Ice Company, Hattiesburg, Miss., is planning to install an electric light and power plant.

The electric light plant of the Nicholville (N. Y.) Electric Lighting Company was destroyed by fire, causing a loss of about $10,000. It will be rebuilt.

The City Council, Waycross, Ga., has under consideration the question of installing an electric-light plant to be operated in connection with the water works.

The citizens of Brewton, Ala., voted to issue additional bonds for the purpose of purchasing new machinery for the municipal electric light and power plant.

The Isthmian Canal Commission, Washington, D. C., will receive bids up to 10:30 a.m., May 24, for six boiler-feed pumps, steam and vacuum gages, etc., as per circular No. 508.

The Navy Department, Bureau of Supplies and Accounts, Washington, D. C., will open bids June 1 for furnishing and installing boiler in power house at Naval hospital, Los Animas, Colo., as per Schedule 1214.

Mechanical Equipment of the Plaza Hotel

The Power Plant of a New York Hostelry Which Cost Nearly Fourteen Millions and Is Considered the Most Magnificent in the World

BY WARREN O. ROGERS

The Plaza hotel, the most magnificent structure of its kind in the world, is located at Fifth avenue plaza, Fifty-eighth and Fifty-ninth streets, New York City. It occupies an entire block on Fifth avenue, with a frontage of 250 feet on Fifty-ninth street, and 125 feet on Fifty-eighth street. It is constructed of white marble and terra cotta, contains [illegible] rooms and represents an investment of [illegible],000, the mechanical equipment costing $1,780,000.

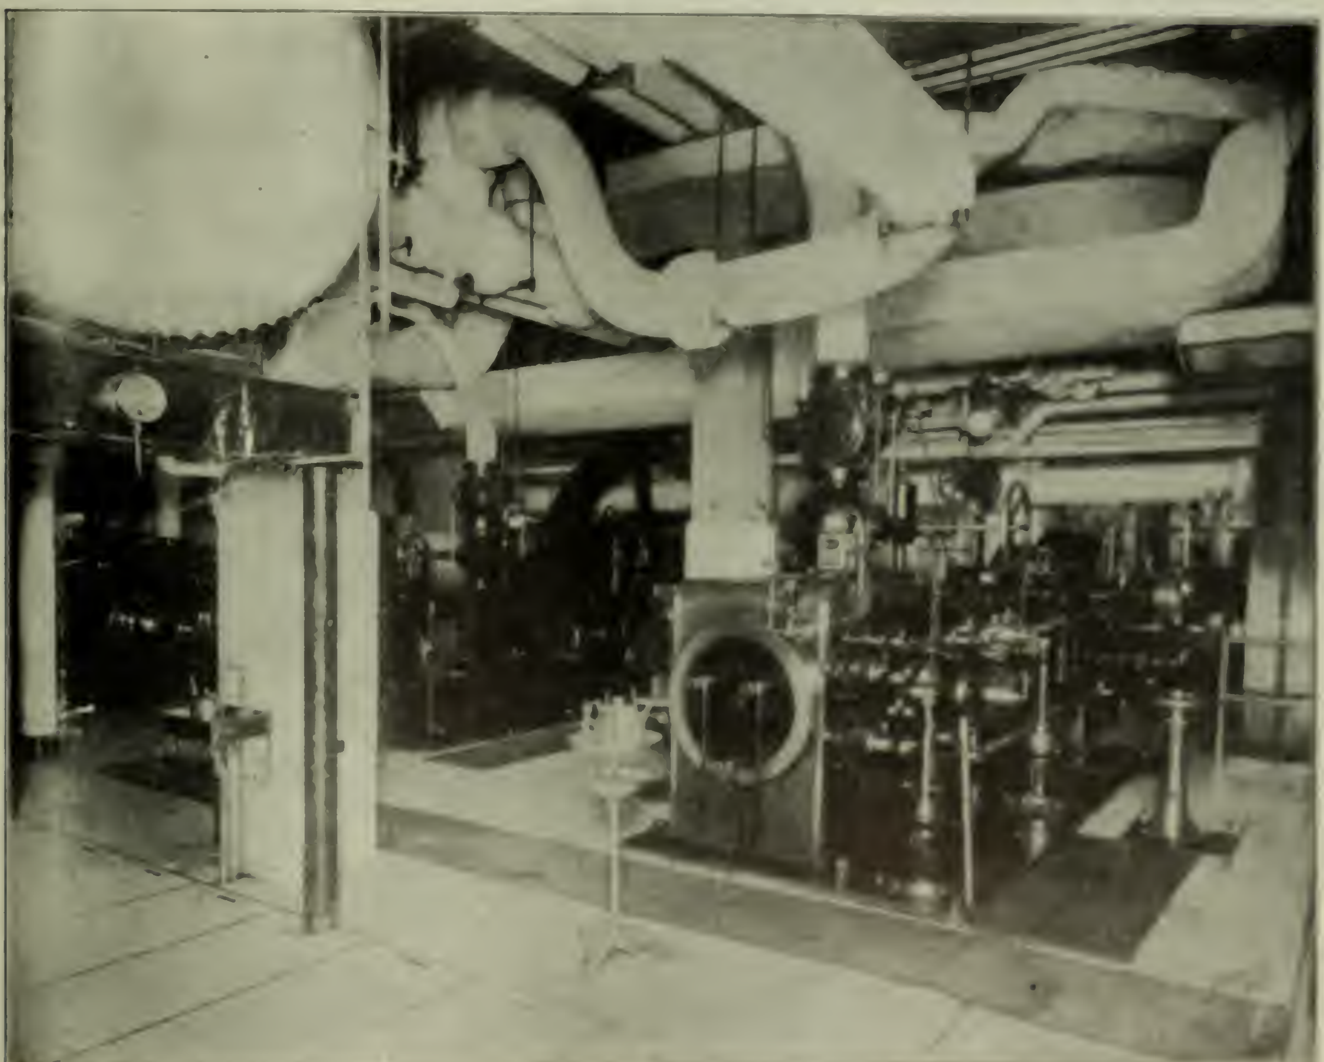

FIG. 1. A [illegible] OF THE ENGINE ROOM

Engine Room

Upon entering the engine room the visitor's attention is at once attracted by its ample proportions, occupying space practically equivalent to the floor area of the hotel. This provides abundant room for working around each machine; nothing is crowded, and the various units are arranged in an orderly manner and with considerable skill. The finish of the walls and flooring and the general appearance of the machinery add to the attractiveness of the installation. The engine room is in the subbasement and has white-enameled brick walls, while the flooring consists of white tile blocks [illegible] square.

The power equipment consists of four simple Allis-Chalmers Corliss engines, direct-connected to Westinghouse generators. Two of the engines have [illegible] cylinders, one [illegible] and one [illegible]. Besides the usual safety cams on the knock-block collars, each engine is equipped with an overspeed governor which, in case of excessive speed, cuts off the flow of steam. An automatic gravity oiling system lubricates the small [illegible] bearings. The engines are run [illegible] at an initial steam pressure of [illegible] pounds. They are painted a dark maroon, striped with gold which, together with the carefully polished bright surfaces, forms a pleasing contrast to the white floors, walls and ceiling. Figs. 1 and 2 give an idea of the arrangement of the generating units, there being two side by side at each end of the room. Fig. 3 is a plan view of the entire plant.

Refrigerating Plant

The refrigerating plant comprises two complete systems, constituting one of the most elaborate refrigerating plants in New York. It embodies a number of features not usually found in an installation of this kind. The compression and absorption systems are used, there being a 100-ton York compressor and a 100-ton York absorption machine. Two systems were adopted to insure the greatest economy during every month of the year. The absorption system is operated during the fall, winter and spring months, when the condensing water is cool and a plentiful supply of exhaust steam is available to operate the generator. The compression system is used during the summer months, when it is necessary to use live steam from the boilers, and the temperature of the condensing water is high. Either machine is capable of supplying the building with ice and refrigeration.

The compression machine, Fig. 4, is so constructed that in case either of the steam or ammonia cylinders is disabled, it can be operated by the side remaining intact. The unit consists of two vertical single-action ammonia compressors operated by a 75-horsepower cross-compound Corliss engine running noncondensing.

The condensers are of the double-pipe countercurrent type, constructed in sections, so that any section can be shut off and removed for repair without the necessity of stopping the plant. As shown in Fig. 5, the condensers for both systems are located on the grating over the refrigerating machine. The coolers are of the vertical shell type and are incased in matched lagging, the brine passing through coils of pipe in the shell.

In the absorption system the two pumps which handle the strong aqua ammonia from the absorber to the generator are of the double-acting steam-driven type, automatically governed. The generator of this system is of the horizontal type, having a vertical analyzer, the generator being so designed and containing such an amount of heating surface that it can be operated by exhaust steam at atmospheric pressure. The ammonia condensers are of the same type as those used with the compression system. They are also so arranged that by shutting suitable valves sections of the coils may be removed for repair when necessary. The ammonia coolers are of the vertical shell type of the same design as those in the compression system; the absorber is of the horizontal type and the exchanger of the vertical shell type, while the weak aqua cooler is of the double-pipe countercurrent type.

The entire refrigerating equipment consists of the brine system, the brine being pumped to the various departments of the hotel by means of four Worthington vertical brine pumps of the "Admiralty" simplex type, located in the engine room just outside the refrigerating room. There are two main brine lines, one a high-pressure and the other a low-pressure, each fed by two brine pumps. The high-pressure line consists of a three-pipe balanced system and handles all the work necessary to cool the refrigerators on all floors up to the seventeenth. Thirty refrigerator boxes are located above the ground floor, while there are 24 boxes in the basement and subbasement. The boxes are of steel, cork and glass and are practically indestructible. On the seventeenth floor is a refrigerating room for furs, etc.

In operation, the brine is cooled in the cooler and is sent up through the feed mains to the coils in the different refrigerators. The brine then passes through

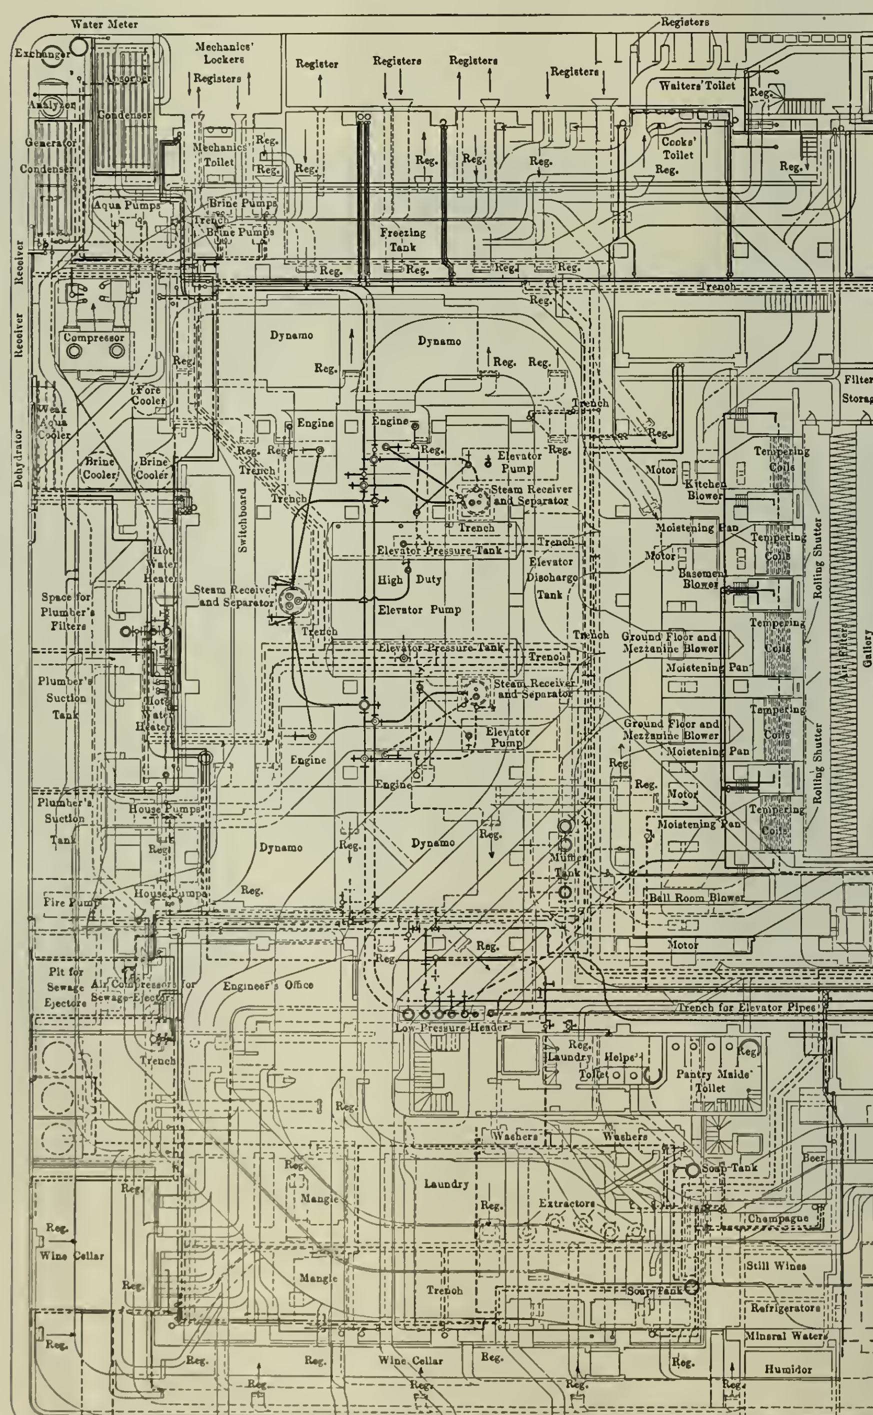

FIG. 3. PLAN VIEW OF THE ENTIRE

the return main to the reservoir tank on the seventeenth floor and is returned through the suction pipe to the pump and again circulated through its cycle.

The refrigerating boxes in the kitchen and all other places on the first floor are cooled by means of the low-pressure system, which is also used in the manufacture of ice. The suction pipe of the brine pump on this system is attached to the ice-making tanks which are located in the engine room and are shown in Fig. 6. The brine is discharged through the cooler and is then passed through the various refrigerator boxes, when it returns to the ice-making tanks.

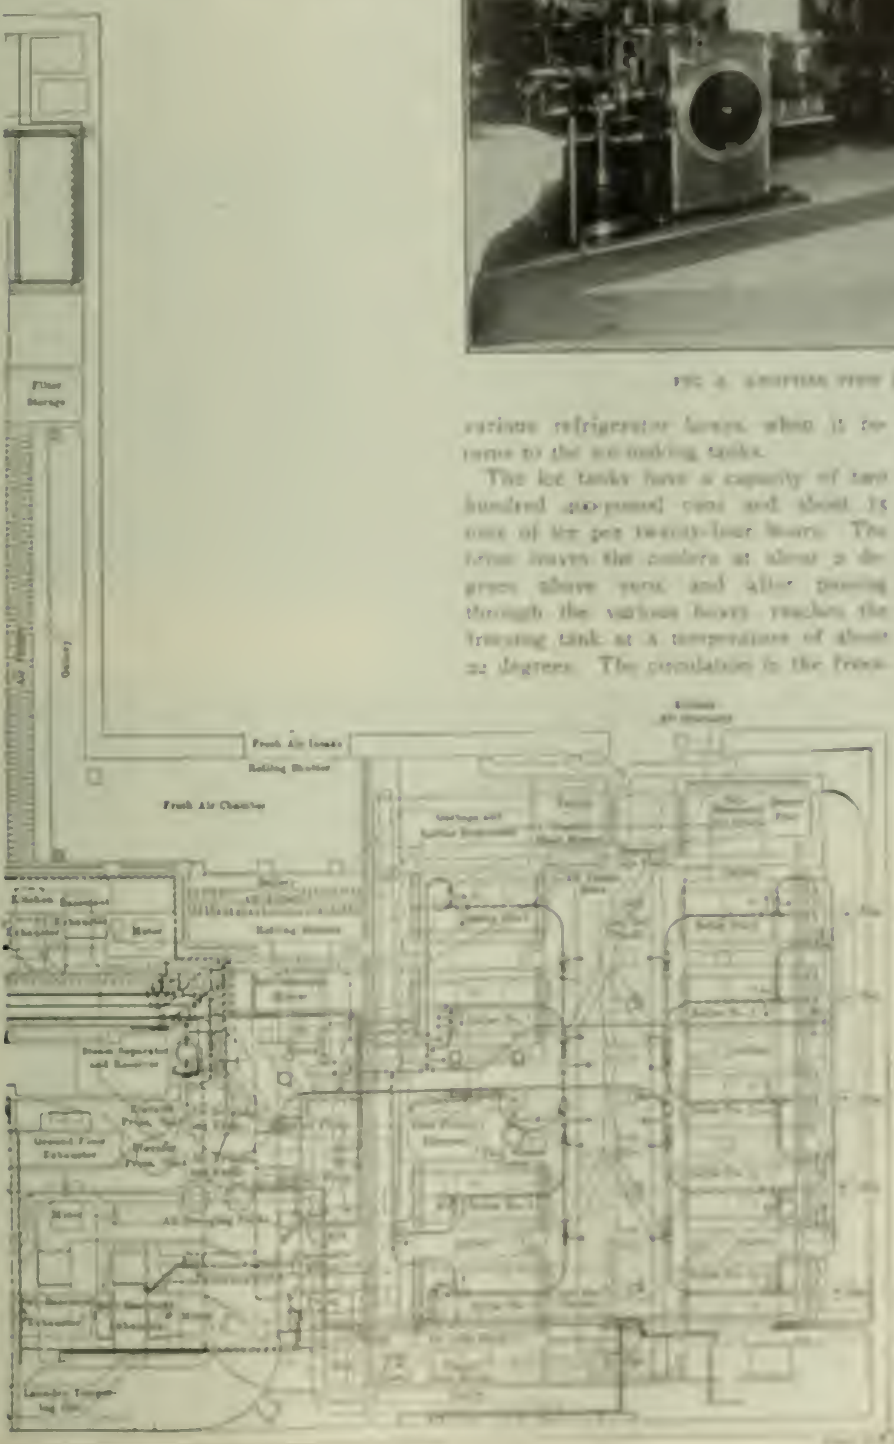
FIG. 4. ANOTHER VIEW IN THE ENGINE ROOM

The ice tanks have a capacity of two hundred 400-pound cans and about 15 tons of ice per twenty-four hours. The brine leaves the coolers at about 2 degrees above zero and after passing through the various boxes reaches the freezing tank at a temperature of about 22 degrees. The circulation in the freezing tank is accomplished by means of a vertical motor-driven agitator which keeps the brine in the tank in constant and rapid circulation. Fig. 8 shows the method of removing a can of ice by means of a hand traveling crane; also the method used in filling the cans with raw water that has been passed through a series of filtering cloths.

The entire refrigerating equipment, where ammonia is used, is placed in a room separated from the engine room by a wall partition, the only entrance being through a swing door. If an accident should occur the door may be easily shut, and a ventilating duct leading to the street opened from outside the room, thus permitting the ammonia fumes to escape and prevent them from finding their way to the hotel rooms above. The room containing the refrigerating equipment is 75 feet 8 inches long and 21 feet 9 inches wide. Both systems were built and erected by the York Manufacturing Company.

Boiler Room

A study of the plan view of the boiler power plant shows that the boilers are located adjacent to the engine room and are set in two rows facing each other with a wide working space between, as shown in Fig. 9. The nine Babcock & Wilcox water-tube boilers have a total capacity of 2700 horsepower, and supply steam not only for power but for cooking and other purposes found desirable in hotel work. The headers are made of wrought steel and are designed to carry a steam pressure of 200 pounds per square inch; the working pressure is 125 pounds



ENGINE, BOILER AND REFRIGERATING PLANT

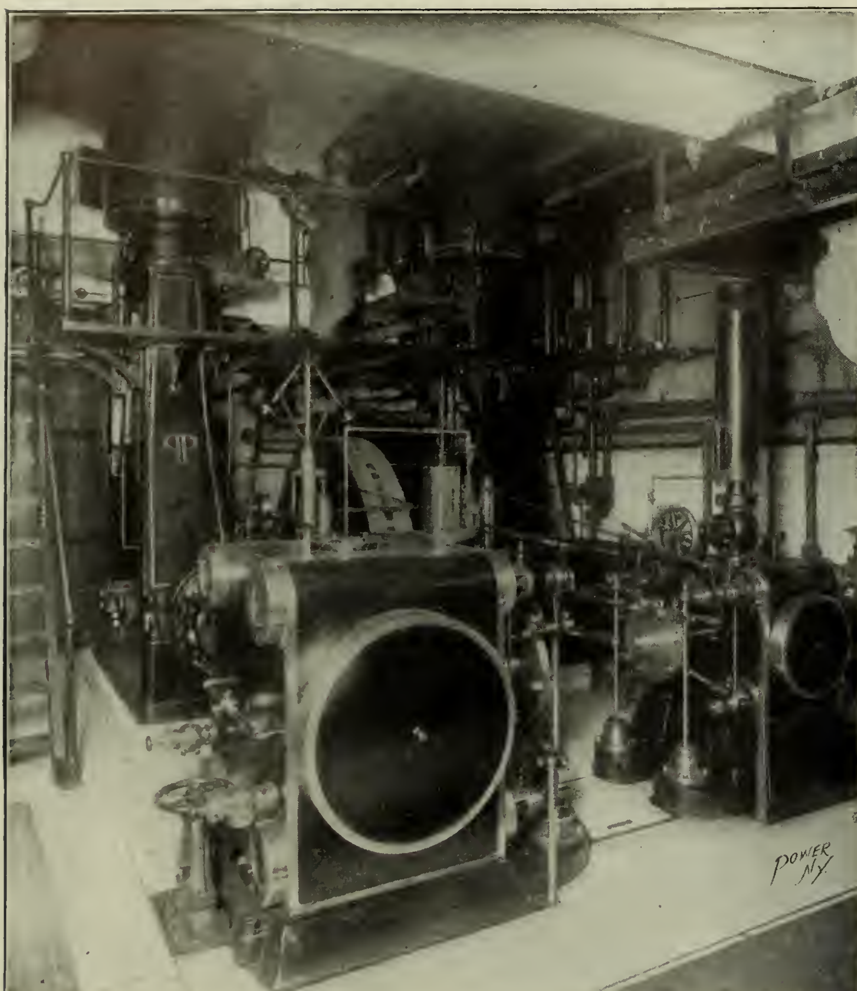


FIG. 4. THE COMPRESSION MACHINE

per square inch, however, which has been found suitable for the work required. As all boilers are not in use at the same time, sufficient opportunity is afforded for cleaning, etc.

Each boiler is fitted with a Wilkinson automatic stoker and the accompanying steam jet, two Lunkenheimer safety consolidated pop valves, and a Hubner & Mayer double-action combination stop and cutout valve, which cuts out the particular boiler it is connected to in case of accident to that boiler or piping. An unique arrangement of the boiler room is in the manner in which the firing floor separates the lower portion of the boiler room from the upper. It is made of iron gratings placed on a level with the top of the stoker hoppers. On this flooring is a narrow track over which the coal is conveyed from the coal bunkers located at one end and above the boiler room. The cars are of such design that the coal is delivered to the hopper of each stoker through a chute on the side. This is shown in Fig. 7, which also illustrates the general arrangement of the boilers.

In Fig. 8 is shown the under side of the grating floor, or the ashpit section. Here the machinery for operating the stokers is arranged; also, the steam jet, as shown. This section of the boiler room is of the same width as that above the grating floor, and is also fitted with a narrow track upon which the ash car is run. The ash and clinker are shoveled from the ashpit into the car and delivered to a Hunt steam-operated conveyer, which delivers it to the ash cart. The same conveyer is used for conveying the coal, which is dumped through a hole in the sidewalk, into a weighing hopper where it is weighed and then conveyed to an 1100-ton storage room.

Each boiler blowoff pipe is connected to a blowoff tank 4 feet in diameter and 10 feet long, made of flanged steel 3/8 inch thick; the heads have a thickness of 1/2 inch. The tank is fitted with 100 lineal

FIG. 6. PULLING AND FILLING CANS

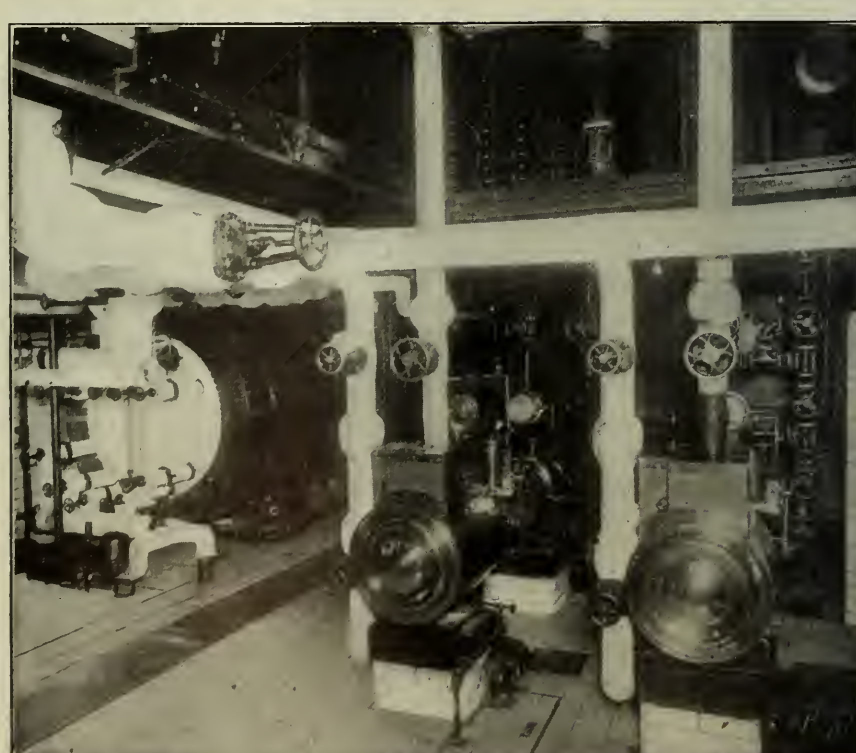

FIG. 5. THE ABSORPTION MACHINE

FIG. 8. SECTION OF BOILER ROOM UNDER FLOOR GRATING, SHOWING ASH PIT

et of 3-inch seamless brass pipe used r cooling coils.

The feed water is heated in a Goubert ed-water heater containing 600 square et of heating surface. It is 34 inches diameter and 152 inches high. There also a Goubert feed-water heater placed the 7-inch vent line, utilizing waste at from the vapor line. It is 12 inches diameter and 70 inches long and is proded with 7-inch nozzles for vapor lines d 5-inch feed inlet and outlet lines. oth heaters are designed to sustain a orking pressure of 200 pounds.

Piping

Owing to lack of head room, the 16-ch high-pressure steam header for each ttery of boilers is run along the front is a light adhesive to clear the manholes. From the headers the main steam pipes branch off and extend to the various pumps, engines and other equipment. The piping through the plant is constructed of extra-heavy and full-weight piping having gun-iron flanges and Van Stone joints. In front of the switchboard, and about central between the four engines, is a National Steam Specialty Company separator to which the engines are piped.

An 18-inch pipe conveys the exhaust steam to a receiver, from which it is distributed to 79 risers which connect with radiators through the building. Each radiator is controlled by a Johnson thermostat valve which regulates the temperature of the rooms. The returns from the heating system are taken care of by the Warren Webster system of appliances.

FIG. 10. VIEW OF SWITCHBOARD

FIG. 9. A SECTION OF THE ENGINE ROOM

One 14-inch steam separator and receiver containing 97.2 cubic feet of steam and water space is located on the main power line. One 8-inch separator and receiver containing 17 cubic feet of steam and water space is located on the auxiliary line. These separators were also made by the National Steam Specialty Company.

Pumps

Four "Admiralty" pattern Worthington boiler-feed pumps, each controlled by a Fisher governor, supply the feed water to the boilers after passing it through a Goubert feed-water heater which heats the water to a temperature of 200 degrees. In the rear of the boilers (Fig. 8) are located pumps for different services, while in the engine room are placed the pumps for hot and cold water house service. These pumps are of the

"Admiralty" compound duplex type of Worthington make.

There are two 8x12x7½x10 compound duplex steam pumps of the vertical type used for pumping out the receiver tanks and for feeding fresh water to the boilers; two 9x6x10-inch duplex steam pumps for draining the high-pressure drip tanks; two 7½x4½x10-inch duplex steam pumps used for draining the blowoff tank and low-pressure drip tank; and three 7½x5x6-inch duplex steam pumps for draining cesspools, each pump being governed by a Johnson automatic regulator, thus regulating the hight of water in the cesspools. All of these pumps are brass-lined and are of Worthington make. There is also in the pump room a 10x14x16 Knowles pump used for vacuum and feed-water heater service.

FIG. 7. FIRING FLOOR OF THE BOILER ROOM

FIG. 13. GAGE BOARD

FIG. 11. AIR COMPRESSORS

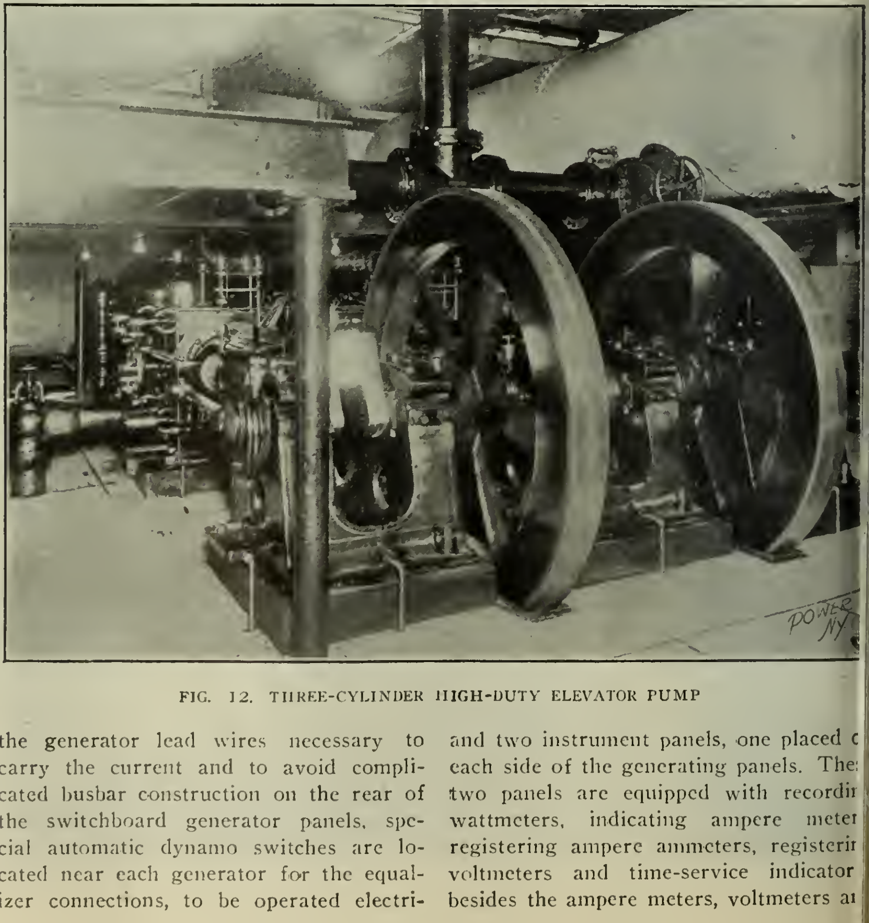

FIG. 12. THREE-CYLINDER HIGH-DUTY ELEVATOR PUMP

Electrical Equipment

The electrical equipment consists of four Westinghouse direct-current generators, one of 400, one of 300 and two of 200 kilowatts capacity. The current is generated at 120 volts, the machines being compound wound, each direct-connected to a simple Corliss engine. The speed is 90 revolutions per minute for the larger units and 100 revolutions per minute for the three smaller units. The generator circuits are extended to the switchboard by means of underground ducts. Because of the length and size of the generator lead wires necessary to carry the current and to avoid complicated busbar construction on the rear of the switchboard generator panels, special automatic dynamo switches are located near each generator for the equalizer connections, to be operated electrically from the switchboard. All of the feeders terminate near the top of the switchboard and connect to copper strips connected to the busbars and extending to the top of the board. The power feeders are connected to double-arm circuit breakers, which also answer as switches. As the switchboard is 8 feet high and 4[illegible] feet long, there is no confusion of the wiring on the back, and the different connections are arranged in a neat, compact manner.

The switchboard, Fig. 10, is made of gray Tennessee marble and is divided into 12 panels, four generating panels being in the center of the board, three feeder panels at each end of the board, each containing 26 separate circuit switches and two instrument panels, one placed o[n] each side of the generating panels. The[se] two panels are equipped with recordi[ng] wattmeters, indicating ampere mete[rs], registering ampere ammeters, registeri[ng] voltmeters and time-service indicator[s] besides the ampere meters, voltmeters a[nd]

FIG. 14. JOB TICKET

FIG. 15. ORDER TICKET

galvanometer which are mounted on the generator panels. There are 52 double-pole knife switches for controlling the lighting circuits and 26 double-arm circuit-breakers for controlling the power feeders, the latter being mounted on the feeder panel. The fuses are placed on the rear side of the switchboard. The current is used not only for the 21,000 incandescent lights in the hotel, but also to run the various motors through the building which operate the ventilating system as well as the filtered air fans.

Miscellaneous

Two mains connected with the city supply furnishes the necessary water, which is filtered through Loomis-Manning filters having a total capacity of 1,500,000 gallons per day. The drinking water is again filtered through a Hohring filter. On the eighteenth floor are storage tanks in which 75,000 gallons of water is stored for use in case of fire. The pumps in the pumping plant are so arranged that 4000 gallons of water per minute can be pumped through the fire line to the tanks.

Compressed air is used for operating a tube system designed to carry messages, etc., to various parts of the house. A vacuum-cleaning system is also installed, thus doing away with the ordinary manner of cleaning. These machines are placed in a separate room, Fig. 11. The system is operated by two steam-driven air pumps.

All of the machinery found in a well-equipped laundry is installed in the laundry connected with the hotel, all driven by electric motors. The dumbwaiters are 13 in number and are electrically operated.

There are 14 ventilating fans of the Sturtevant company's make, operated by eleven C & C motors aggregating 250 horsepower.

The Standard plunger-elevator equipment consists of 16 passenger cars and three sidewalk lifts, besides the 13 dumbwaiters already mentioned. The passenger elevators are of the hydraulic plunger type. Each car is fitted with safety devices which make it impossible for the operator to start the car until he has closed the door. The same device also prevents the door of the car from being opened while the car is between floors. The hydraulic power for these elevators is supplied by two [illegible]-inch Laidlaw-Dunn-Gordon [illegible] pumps and one three-cylinder compound flywheel-type high-duty pump made by the same company. An ingenious method of arranging the two high-pressure water tanks [illegible] connected with the elevator system is shown in Fig. 12. It will be seen that the tanks are suspended from a framework of iron beams directly over the three-cylinder engine, thus utilizing overhead room and saving that much floor space. The low-pressure tank, which carries a pressure of from 25 to 30 pounds, is located at the back end of the pump on the floor in a horizontal position.

Fig. 13 shows an attractive gage board, designed by the [illegible] Company, the gages indicating the temperatures of different [illegible], water pressure, etc.

Among other equipment is that of a [illegible] garbage cremator, the heat generated from the garbage being used for one of the boilers.

Keeping Records

A word regarding the working force and method of keeping the repair charts of this installation is of interest. There are on the average 90 men connected with the engineering force. The men in the boiler and engine rooms work in three shifts, each shift keeping [illegible] hours. This is to prevent the possibility of an accident occurring by someone neglecting [illegible] at the change of the watch [illegible]. It is less likely that an accident will occur.

FIG. 16

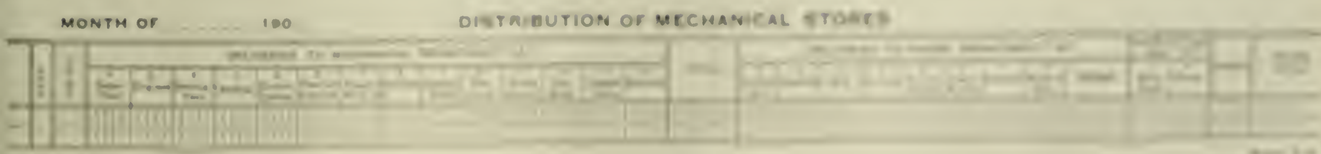

FIG. 17

The engineers' report forms were designed by the chief engineer, J. C. La Vin, and are reproduced herewith. By means of these reports it is possible to know at any time just what has been done by any workman and in what department the labor and material were used. When a man is given a piece of work to do he is given an order and job ticket similar to that shown in Figs. 14 and 15. When the tickets are properly filled in by the workman every detail regarding that particular piece of work is available, if at any time information is desired pertaining to it.

The report sheet pertaining to the distribution of labor about the mechanical and house department is shown in Fig. 16. That pertaining to the distribution of supplies for the mechanical and house department is shown in Fig. 17. By means of these report sheets the labor and material charged to each department are easily ascertained, as they are made up from the job ticket. Thus, if in looking over the report sheet of distribution of labor it is seen that boiler No. 1 had had work done on it charged to job No. 100, by referring to job ticket No. 100 the detailed report of what was done, hours consumed in doing the work and the amount and kind of material required to do it are ascertained. The report sheets on distribution of labor and mechanical stores is a tabulation of the job tickets in a condensed form.

In Figs. 18 and 19 are reproduced in reduced form the chief engineer's daily reports of the absorption and compression refrigerating plants. It will be seen that each report is most complete and that when the engineer on watch has filled in the necessary data the report enables the chief engineer to ascertain just what has been done. In Figs. 20 and 21 are shown the chief engineer's report sheets for boilers and auxiliaries, respectively.

From the foregoing it will be seen that the chief engineer is always in a position to ascertain the exact cause for any increased expense one week or month over another, as well as for one year over another.

The Curtis turbine-driven fireboats at Chicago, Ill., gave excellent account of themselves in the fire which destroyed several Chicago grain elevators on April 29. The "Graeme Stewart" promptly responded to the first alarm at 4:30 a.m., and was shortly afterward in service with full pressure on the two gun nozzles. The "Joseph Medill," although not in commission, went into action on a hurry call a few hours later with one of the gun nozzles and several hose in operation. The operation of both boats was satisfactory in every respect.

Operation of a Small Producer Gas Power Plant*

By C. W. Obert

The new Westchester market which Swift & Co., recently built in New York, at One Hundred and Fifty-second street and Brook avenue, contains an interesting producer-gas power plant for the operation of both refrigerating and electric generating machinery. The refrigerating duty at present required embraces the operation of a total cooling system containing over [illegible] feet of 2-inch pipe, which reaches a maximum of over [illegible] tons of refrigeration per 24 hours under the most severe summer weather conditions, two 65-ton refrigerating machines were installed for this service, with equipments in duplicate, owing to the great importance of continuity of refrigeration, particularly in hot weather. A maximum of nearly 90 horsepower is required for compression machines of this size and engines of 100 horsepower were selected for driving them, to provide sufficient capacity for unfavorable or overload conditions.

The electrical load, which includes the operation of several electric elevators, fluctuates ordinarily between [illegible] and [illegible] kilowatts, but occasionally reaches a maximum of over [illegible] kilowatts. For this service, duplicate 75-kilowatt generators were installed, with driving engines of 100 horsepower. This was done to secure uniformity of size and detail in all four of the driving engines.

For gas making, two producer equipments were installed. One of these is a 200-horsepower producer, intended for the supply of one refrigerating machine and one generator engine when operating at maximum capacity. The other is of 150 horsepower capacity to permit of closer adjustment of the producer capacity to the load at other times.

The plant arrangement consists of an engine room in the easterly end of the subbasement of the market building, and a producer room adjoining, the entire power equipment occupying a total space, including fuel storage, of [illegible] feet by about [illegible] feet. Headroom for the machinery and piping is afforded by the depression of the subbasement floor to a level [illegible] feet below the street, and the omission of the basement floor in this section, giving there a clear headroom of [illegible] feet. To meet the requirements of the underwriters, the producer room was separated from the engine room by a [illegible]-inch hollow-tile fire wall, forming a producer room [illegible] feet by 24 feet maximum dimensions. Under the One Hundred and Fifty-second street sidewalk there is a room [illegible] feet by [illegible] feet, containing pumps and auxiliaries for the power equipment and the building heater; and adjoining this is a room [illegible] feet by 30 feet for fuel storage; the coal is dumped into it through sidewalk coal-holes from wagons in the street.

The engines are [illegible] vertical three-cylinder units, of 100 horsepower, rated at [illegible] revolutions per minute. The two for the electrical service are direct-connected to 75-kilowatt generators and the other two through silent-chain drives to the ammonia compressors of the refrigerating equipment. They are all of the four-stroke-cycle, single-acting, inclosed type, and each has [illegible] by [illegible]-inch cylinders, designed for the above rating when operating on producer gas of not less than 125 B.t.u. per cubic foot. Throttle regulation is employed.

The gas is generated by two [illegible] suction producers. Each equipment consists of a single shell generator, a wet scrubber and a dry purifier. While the producers differ in rated capacity to permit of more accurate adjustment of their capacity to the power requirements at different seasons of the year, the scrubbers [illegible] have a maximum capacity of [illegible] horsepower, which permits the smaller producer to operate up to the maximum plant capacity of [illegible] horsepower if necessary [illegible]. The [illegible] feet and [illegible] feet [illegible] respectively, [illegible] feet in height, and their internal diameters are [illegible] feet and [illegible] feet, respectively. They are fitted with [illegible] grates for operation with anthracite. They are not fitted with attached vaporizers, but [illegible] [illegible].

*Abstract of a paper presented at the Washington meeting of the American Society of Mechanical Engineers, May 4-7, 1909.

matic attachment for regulating the amount of water vapor to conform to the power requirement and consequent rate of gasification. The wet scrubbers are vertical cylinders, each 4 feet in diameter by 15 feet high, and the dry purifiers have 4-foot shells 6 feet high.

The piping of the plant was somewhat involved by the arrangement of the engines relative to the producers and by automatic vaporizers in the exhaust connections to utilize the waste heat of the engines for the vaporization of the water. The vaporizers are located close to the engines and attached to each vaporizer is an automatic device through which air is admitted and preheated for the producers. The air is conducted to the producers from these devices by a 10-inch pipe heavily covered with magnesia insulation.

An 8-inch pipe connects the top of the generator to the bottom of the scrubber shell and each scrubber has a triplicate connection to its corresponding purifier, which is a three-part filter. From these the gas is conducted to the engines through a 5-inch main with a 3½-inch branch to each engine. The exhaust connections from the engines to the vaporizers are 5-inch pipes and from the latter, individual discharge pipes are carried up through a pipe shaft in the corner of the building to a roof outlet. This arrangement of exhaust connections is so effective in muffling the noise of the escaping gases that it cannot be heard from the adjoining street and is only barely noticeable when on the roof close to the outlets.

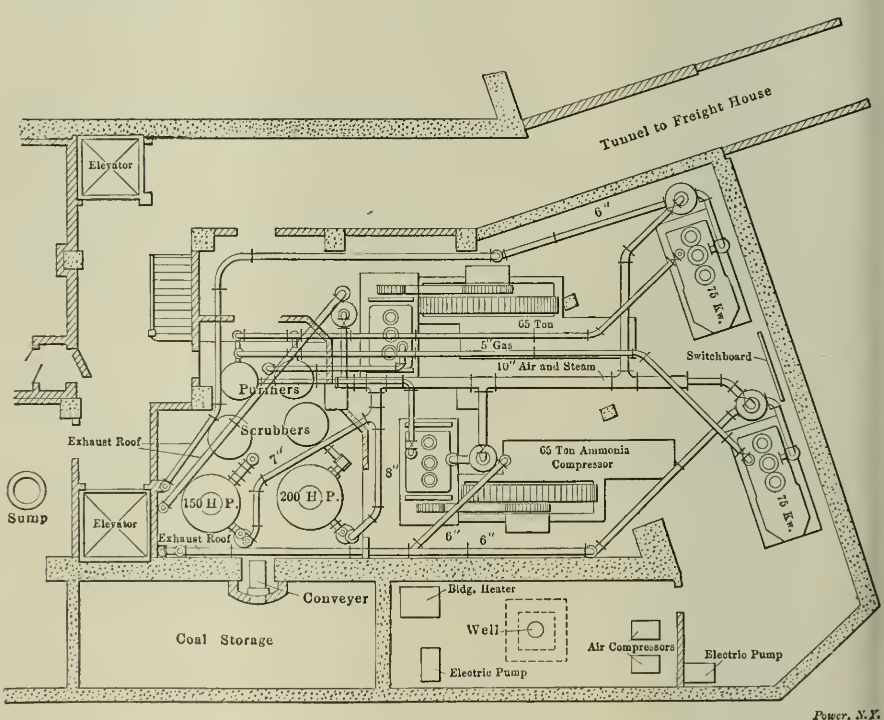
The electrical generators are 75-kilowatt General Electric direct-current 220-volt machines, each rigidly coupled to its driving engine. The distribution for both lighting and power is on the two-wire system. The electrical circuits are controlled on a three-panel switchboard which contains the usual equipment of indicating and recording instruments, field rheostats, field switches and generator and feeder switches. The building is wired separately for lighting and power circuits, and recording watt-hour meters are included in the feeder circuits. Separate busbars are provided for the power and lighting feeders, as well as a switching arrangement by which the lighting service may be supplied from a generator other than that carrying the power load, in case the fluctuations of the latter should interfere with the voltage regulation. This provision has been found unnecessary, however, as the speed regulation of the engines is satisfactory under all fluctuations of load due to elevator operation.

The refrigerating equipment is the direct ammonia-expansion system, a feature of which is the connection of all coils in the coolers in series with those in the freezers, whereby all ammonia not thoroughly evaporated in the freezer coils will be in the cooler coils (temperature, 36 degrees Fahrenheit), which permits carrying the freezer temperature at from 0 degree to +5 degrees without frosting the compressor. The compressors were built by the Hutteman & Cramer Company, and are horizontal single-cylinder double-acting machines, with 14 inches by 30-inch cylinders, each driven at 60 revolutions per minute, by a Renold silent-chain connection from its driving engine. The ammonia condenser is located on the roof of the building. The water supply for it is obtained from a well under the basement floor, and the drainage from the sprays is subsequently utilized in the scrubbers and in the engine-cylinder jackets. One of the compressor units normally handles the load alone, which leaves one equipment always in reserve.

In operation this plant has proved particularly economical, largely because of the continuous character of the service high loads to about 1 pound per horsepower-hour, but the daily average under conditions of ordinary commercial operation is usually greater.

The operating conditions during the heavy-load season are indicated roughly in the accompanying table, in which the relation of fuel consumption to load carried is shown for two weeks of similar duty. The variations in the amount of fuel charged from day to day are due chiefly to the differing conditions of the fued bed in the producer, the removal of a particularly large amount of ashes on any day necessitating a heavy fuel charge. No account is taken of cost of water used in the scrubbers and cooling jackets, as the supply is obtained from the well without cost other than that of pumping.

The fuel used is No. 1 buckwheat anthracite that has been passed over a



PLAN SHOWING LOCATION OF MACHINERY, APPARATUS AND CONNECTIONS

due to the operation of the refrigeration plant 24 hours a day, seven days a week, thereby eliminating standby losses. The average load range of the plant is ordinarily from 50 per cent. (100 horsepower) to full rated load (200 horsepower), the high- and low-load factors occurring during the summer and winter months respectively, when the refrigeration requirements are maximum and minimum. With the heavier load factor during the summer months, the fuel consumption has ranged between 3400 and 4800 pounds per 24 hours, the larger figure having been exceeded on only two days in 11 months. The consumption per brake horsepower-hour, as calculated from station fuel records and observed loads, ranged from 1.4 to 2 pounds of coal. The fuel rate has dropped during periods of continuous

⅜-inch mesh and through a 9/16-inch mesh screen, with 5 per cent. fineness, and costs $3.50 per gross ton delivered in cargo lots. It is charged only at the regular cleaning periods, at each of which from 400 to 900 pounds of coal is fed, after the fire has been cleaned down and the ashes removed from the grate. The fire is cleaned periodically twice every shift, or four times per 24 hours and requires about an hour for cleaning, on the average.

In this connection it is interesting to note the comparatively short time required to start a producer into service from the cold condition, which has been done repeatedly on short notice in about five hours; on December 12, when the 150-horsepower producer was placed in operation to relieve the larger unit, the kindling wood was lighted at 10.30 and the gas supply turned onto the engine at 2 p.m., with only about 12 inches of fire zone in the fuel bed. The reliability of a suction producer operating under a continuous and exacting service of this character is well shown by the duty of the 200-horsepower producer during the summer season of 1908. When taken out of service on December 12 this producer had been continuously in service 24 hours per day and seven days per week since April 22, a continuous run of 235 days. During that time it had received no more attention than the four cleanings and chargings per 24 hours.

The operating force for the power plant consists of a chief engineer, an assistant engineer and two producer tenders, who work in two shifts. This force is able to maintain the equipment in such satisfactory operating condition that the plant has not been shut down since it was started on February 1, 1908. In order to maintain the equipment in such condition, a thorough and comprehensive operating system has been developed which may be of interest.

The operating system involves a thorough inspection routine that keeps the force well informed as to the condition of the entire equipment and a division of duties tending to favor the maintenance work. To the day operating force is assigned the inspection and adjustments of the engines and repairs to [illegible], batteries, etc., while the night force has the work of cleaning all machinery. The regular routine of the day force in detail is as follows:

First, upon coming on duty at 7 a.m., an examination of all moving parts of the two engines in operation is made, and also of oil levels in lubricators and conditions of water jackets and ignition systems. There are always two engines in operation, one being an electrical-service engine and the other a refrigeration engine, which in the periods of heavier load in the summer time have a combined load of about 140 horsepower, of which [illegible]

7[illegible] horsepower is taken by the refrigerating system. Next the water regulation for the scrubber [illegible] and then the condition of the suction draft on the producer and also on the scrubber and purifier, there being three draft gages provided for this purpose, one connected to the gas-suction line to the engines, the second to the gas connection from the scrubber to the purifier and the third to the connection between the producer and scrubber. A [illegible] of suction of from 2 inches to 3 inches of water in these three gages indicates a proper condition of the three parts, while any unusual [illegible] in any of the connections would indicate an obstruction needing immediate attention.

Next an inspection is made of the gas generator, the temperatures of different portions of the fire being determined to ascertain the condition of the fuel bed, the existence of cracks or fissures or pockets of unburned coal. To do this a [illegible] inch iron rod is pushed into the fire [illegible]

†[illegible]

[illegible]

charged. The coal is cleaned by screening if very fine or dirty. After charging, the operator slices across the grate so as to relieve the center of the fire and again puts water in the ashpit, this time to cool off the grate after cleaning and offset the effect of any air that may have got in during the operation. The cleaning usually occupies one hour. After giving the generator time to settle down, the ashes are withdrawn from the ashpit, an average of 1½ ash cans (about three bushels) being removed after each cleaning. During the cleaning operation the operator is always on the lookout for any change in the engine speed due to weak gas on account of opening the ash doors. Should this occur he immediately cuts the air supply to the engine. The producer is now good for six hours' operation, after which the cleaning is repeated. The refrigerating engines are operated for periods of 84 hours and then gone over. One exhaust valve is taken out of an engine each week, thoroughly cleaned, and reground, if necessary, thus insuring attention to each valve once in every three months. Igniters are cleaned weekly and the batteries and ignition system checked. The temperature of the fuel bed of the producer is taken twice a day and a gas analysis is made once a week or oftener if necessary. The average calorific value per cubic foot of gas is 134 B.t.u., based on the analysis: CO_2, 8.6 per cent.; O, 0.6 per cent.; CO, 20.2 per cent.; H, 18.5 per cent. and N, 52.1 per cent.

The "Mauretania," on the trip which ended at Liverpool on April 20, made 200 miles toward the end of the voyage in 6 hours 10 minutes, or at the rate of 29 knots an hour, a feat never before accomplished by an ocean liner.

Some Properties of Steam*

By Prof. R. C. H. Heck

The purpose of this paper is to present some recent experimental results as to two of the fundamental thermodynamic properties of water and steam, and to make certain comparisons between these determinations and the older values used in our steam tables. The two properties considered are the relation between pressure and temperature of saturated steam, and the specific heat of water.

The Pressure-temperature Relation

This relation is, from the point of view of experimental determination, the simplest of the properties of steam, and with accurate instruments and adequate skill can be very precisely measured. For this reason, the results obtained by various experimenters differ by relatively small amounts, and in discussing them we take up a question in the realm of scientific accuracy rather than one concerning effectively correct values for ordinary technical use. For certain purposes, however, it is most important that this relation be truly and accurately known.

In *Annalen der Physik*, 1907, Volume 22, pages 609 to 630, is published a paper by F. Henning on "The Saturation Pressure of Steam," in which are gathered together all the determinations that have been made on this relation, from Magnus and Regnault down to that time. These are compared by means of curves, which show, to a large scale, their departures from an assumed standard of reference. This standard is the formula of Thiesen:

$$(t + 273) \log \frac{p}{760} \; 5.409\,(t - 100) - 0.508 \times 10^{-8}\left[(365 - t)^4 - 265^4\right],$$

where t is Centigrade temperature and p is pressure in millimeters of mercury. From the comparison and discussion the conclusion was reached that up to 100 degrees Centigrade this formula is to be accepted, while above 100 degrees the determinations of Regnault are best—not as set forth by his formula, but as worked over by Henning, from a selection of his more reliable observations.

A new and very accurate determination by Holborn and Henning, over the range from 50 degrees to 200 degrees Centigrade, is fully described in *Annalen der Physik*, 1908, Volume 26, pages 833 to 883, in a paper on "The Platinum Thermometer and the Saturation Pressure of Steam," while in *Zeitschrift des Vereins deutscher Ingenieure*, February 20, 1909, is given a brief presentation and comparison of results. Exceedingly close agreement is shown between these new observations, the recomputed Regnault values, and the work of Knoblauch, Linde, and Klebe (see Table 3 in *Zeitschrift* article). The final result is a table giving p for every degree from 0 degree to 205 degrees Centigrade, which follows Thiesen's formula up to 50 degrees, and embodies the author's work from that point.

This table is here reproduced in Table 1, but with pressure converted to pounds per square inch and interpolated for every degree Fahrenheit from 32 degrees to 402 degrees, or to just past 250 pounds absolute. Later the writer hopes to extend this table, carrying forward the line of the Holborn-Henning determination in comparison with the observations of Regnault and others. This can be done even

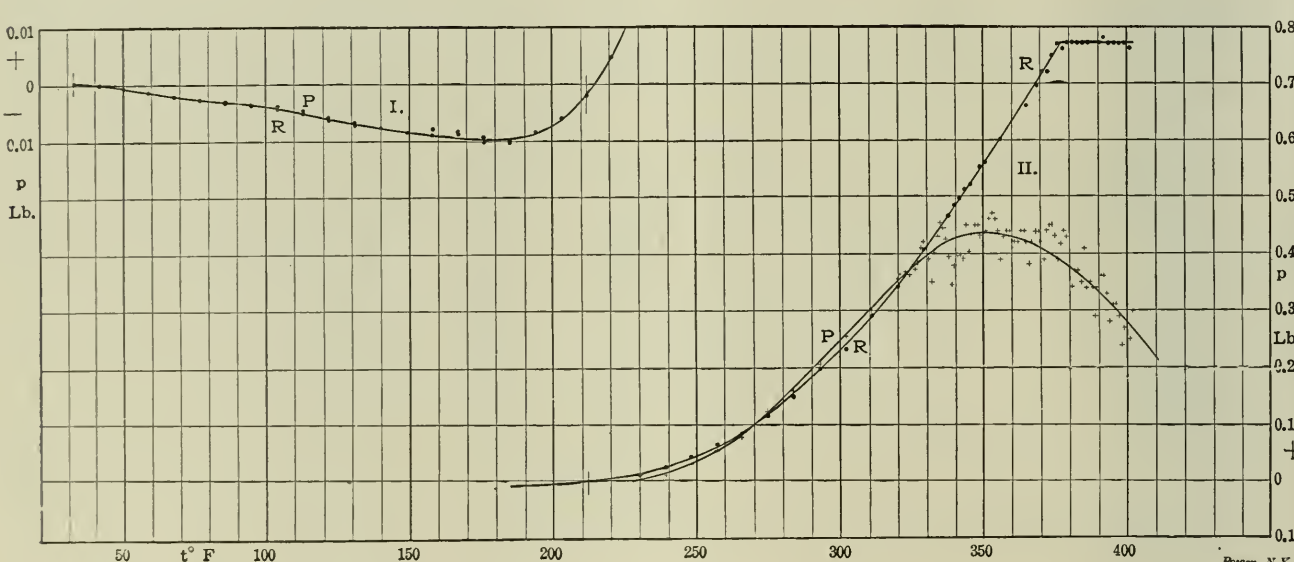

FIG. 1. COMPARISON OF PRESSURE-TEMPERATURE DETERMINATIONS

*Paper presented at the spring meeting of the American Society of Mechanical Engineers, Washington, D. C., May 4-7, 1909.

up to a pressure of 1000 pounds with sufficient accuracy for all practical purposes.

In the work of conversion and interpolation, it was necessary to carry the numbers to a higher degree of apparent accuracy, or to use more significant figures, than any experimental precision would call for. Without a mathematical formula, a function of this sort can be carried forward only by carefully smoothing out the differences until those of the second order follow a continuous rate of change. In this operation, the first differences were brought to a sufficient degree of smoothness to furnish effectively accurate values of the rate of change of p with t; and this differential coefficient, $\frac{dp}{dt}$ is also given in Table 1. It may be considered absolutely correct (as a derivative) within four or five units in the last place, while as between successive values the closeness is much better. This is less precise than might be desired, but it is accurate enough for use in calculating specific volume, since the thermal data there involved are not of any greater degree of reliability.

In Fig. 1 is given a comparison between the pressures in Table 1 and some hitherto generally used values. The base is temperature Fahrenheit, the ordinate the difference between the other value of p and that in Table 1. Curve 1, for the range up to 225 degrees Fahrenheit, is drawn to the large scale at the left, and shows how Regnault's formula drops below the new determination. The curves at 2 have the ordinate scale at the right, only one-tenth as large as that for 1. The letter R marks the "standard" Regnault rates, here plotted from the table in Rankine's "Thermodynamics," which happened to be the most convenient in its manner of expression; note the abrupt change at about 380 degrees Fahrenheit. Curve P shows Peabody's values, which are based on Regnault, but with revised computations, and depart quite decidedly from the older table above 225 degrees. The scattering of the points above that temperature is due to the coarseness of numerical expression, Peabody giving but one decimal place for the higher pressures. The curve is simply sketched through this band of points.

Holborn and Henning do not attempt to devise a formula, but base their table on a method of graphical interpolation. It will be noted that curve 1 shows a faint waviness, indicating some departure from perfect mathematical smoothness; but the extreme smallness of the irregularities is really a proof of the skill with which the original interpolation was made.

The Specific Heat of Water

In Fig. 2 are plotted several important curves for the specific heat of water—the true or instantaneous, not the mean value. Curve R shows Regnault's formula, which in Fahrenheit units is

$$s = 1 + 0.0000222\,(t - 32) + 0.000000278\,(t - 32)^2.$$

This curve differs radically from the newer and true determinations of the specific heat over the lower part of the range as shown by the other curves.

Curve B represents the experiments of H. T. Barnes and associates; these are described briefly in *Proceedings Royal Society*, 1909, Volume 82, fully in *Phil. Trans. Roy. Soc.*, 1902, Volume A 199, while in *Physical Review*, 1902, Volume XV, there is a description of the determination on supercooled water, which was carried to minus 5 degrees Centigrade, and the tabulated values for the whole range up to 95 degrees Centigrade. The body of this work was done by a continuous method, water flowing through a small tube and absorbing heat which was electrically supplied and measured; for the range below freezing a method of mixing was found necessary.

Curve P, which begins at 140 degrees Fahrenheit, shows the values used by Peabody above this temperature; below it he accepts the work of Barnes. Peabody's line—it is almost straight—is based on Regnault's experiments; but it hardly seems reasonable to make s thus an almost straight-line function of t.

Curve D shows the very important experiments of Dieterici, described in *Annalen der Physik*, 1905, Volume 16. In these a small body of water, pure and free from air, was sealed in a tube of quartz. This little cartridge was heated to a certain desired temperature, then dropped into a Bunsen ice calorimeter, where the heat given off in its cooling to 0 degree Centigrade is measured. The highest temperature reached was about 300 degrees Centigrade. The drawback to this method is the relatively large heat capacity of the quartz tube, which has to be very carefully determined. From 100 degrees Fahrenheit upward Dieterici finds that his results conform very well to a parabolic equation like that of Regnault, which for Fahrenheit units has the constants

$$s = 0.99827 - 0.0000576\,(t - 32) + 0.00000064\,(t - 32)^2$$

Below 100 degrees Fahrenheit, calculation from graphical interpolation is preferable to calculation by formula. A numerical comparison of the several curves is given in Table 2.

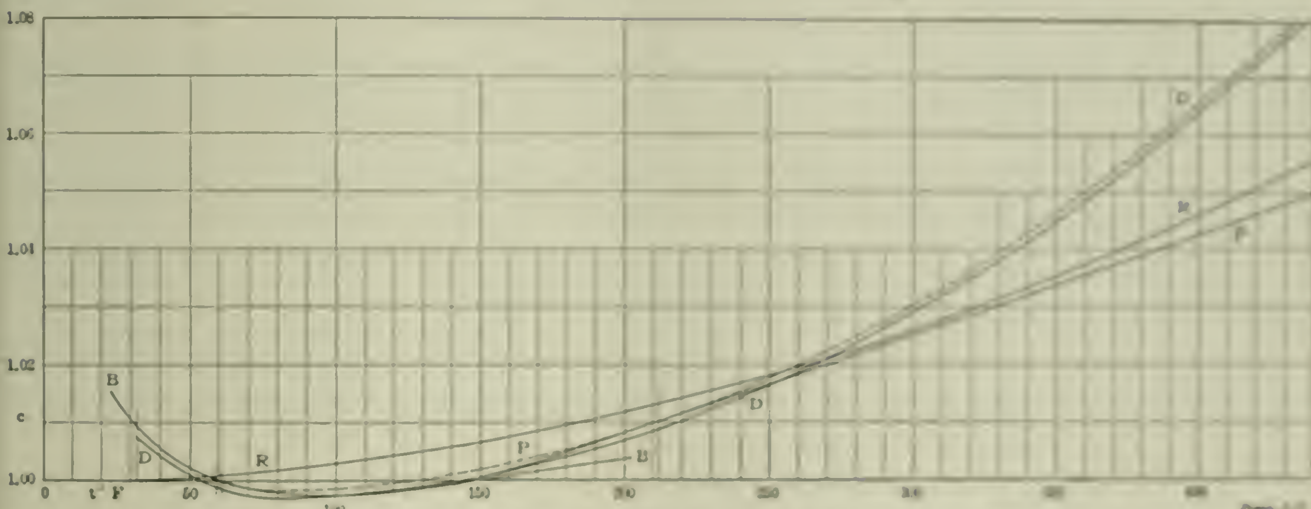

FIG. 2. THE SPECIFIC HEAT OF WATER; VALUES MEASURED OR USED BY REGNAULT, BARNES, PEABODY AND DIETERICI

[illegible] Heat Units

Before discussing these data, something must be said as to the unit of heat measurement. Regnault intended to use the heat capacity of water at 15 degrees Centigrade as the heat unit—in other words, the 15-degree calorie—but it was not until after his time that the first accurate set of measures of the specific heat over the lower range of ordinary temperatures was either clearly perceived or accurately measured. Barnes' values are based on unity at 16 degrees Centigrade, and, it will be noted that the *B* curve on Fig. 2 crosses the base line at just about 16 degrees Centigrade (the two short vertical cross-lines near 60 degrees Fahrenheit are at 15 degrees and 16 degrees Centigrade). The now generally used numerical values of the mechanical equivalent of heat, 427 meter kilograms or 778 foot-pounds are based on a heat unit at 15 degrees Centigrade or 59 degrees Fahrenheit.

Dieterici's results are expressed in the mean calorie, which is one one-hundredth of the heat required to raise 1 kilogram of water from 0 degree to 100 degrees Centigrade; and his specific heat values check up to an average of unity over this range. Graphically, on Fig. 2, his curve cuts the 15-degree Centigrade ordinate at 0.0012

Regnault: from the formula given. Above 200 deg. Cent. his formula is an extrapolation.
Dieterici: from table in original publication, computed by formula from 40 deg. Cent. upward.
Barnes: from *Physical Review*, with last value extrapolated.
Peabody: from Steam and Entropy Tables, p. 10.
Dieterici: values in mean calories (heat units), others in 15 deg. Cent. units.

below the unity base line. In a special experiment, with electrical measurement analogous to that used by Barnes, he made the mechanical equivalent of the mean calorie bear to our standard Rowland value for the 15-degree calorie the ratio of the numbers 419.25 to 418.8, or 1.0011 to 1. Disregarding some uncertainties which may exist in the minds of physicists as to the finality of this determination, it seems reasonable, for engineering purposes, to use this 0.0011 or 0.11 per cent. correction in order to change from one system of units to the other.

The amount of attention here paid to this small point is justified by the importance given to it through the introduction of the mean calorie to the society in the recent paper on "The Total Heat of Saturated Steam," by Dr H. N. Davis. Personally, I think we had better transform heat values to this unit by means of the ratio just offered, rather than change our mechanical equivalent of heat from 778 to 778.9.

Now the specific heat is the ratio of a certain absolute quantity of heat to an assumed unit quantity. If we use a larger unit, the ratio will be smaller, and vice versa. Assuming that the mean calorie is 1.0011 of the 15-degree calorie, we change Dieterici's values to the 15-degree unit if we increase them by 0.11 per cent. This would raise his curve to the dotted position on Fig. 2, and change his formula to

$$c = 0.99938 - 0.0000576\,6\,(t - 32) + 0.000000407\,(t - 32)^2$$

SPECIFIC HEAT OF WATER — CONCLUSION

It is pretty safe to say that the Holborn-Henning results for pressure and temperature, set forth in Table 1, are final, and that this relation is now known surely and accurately enough for all purposes of practical science. But in regard to the specific heat of water we are yet confronted by one of the annoying uncertainties which have so long surrounded many parts of that subject. Dieterici claims an experimental accuracy ranging from 0.1 per cent. at low ranges to 0.5 per cent. at high ranges of temperature; but his method is open to the objection that two heat capacities have to be measured and their difference used.

In spite of some small doubt as to the accuracy of Dieterici's results, and a faint suspicion that his curve may rise too rapidly, I am of the opinion that his determination is to be accepted instead of Regnault's. Further, the idea of an increasing rate of increase in c, as expressed by a second-degree equation, seems to be far more reasonable than that of a nearly constant rate of increase.

It is hardly probable that the heat capacity of water will ever be so accurately determined that the heat for the external work of expanding the water will be more than a small fraction of the probable error in heat measurement.

The Specific Volume of Saturated Steam*

By Prof. C. H. Peabody

For many years the specific volume of saturated steam has been computed from the thermodynamic equation

$$s = \frac{r}{A\,T} \cdot \frac{1}{\frac{d\,p}{d\,t}} + \sigma,$$

in which the quantities have the following significance:

s = Specific volume, for example the volume in cubic meters of one kilogram.

r = Heat of vaporization in calories.

T = Absolute temperature obtained by adding 273 to the temperature by the Centigrade thermometer.

$\frac{d\,p}{d\,t}$ = Differential coefficient of the pressure with regard to the temperature, the pressure being in kilograms per square meter.

σ = Specific volume of water ([illegible] cubic meter per kilogram).

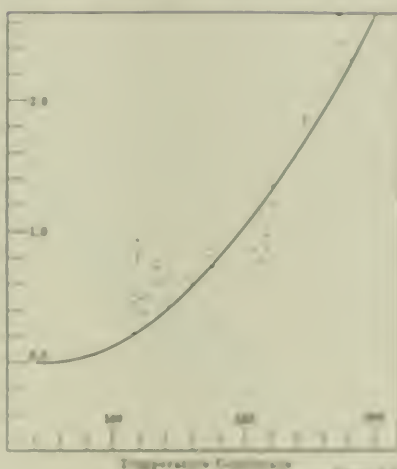

FIG. 1

For this paper French units are used because the original data are given in them and comparison with experimental values is convenient.

All the quantities entering into this equation are now determined with a certainty and precision that must be considered satisfactory for engineering purposes and a comparison with experimental determinations of the specific volume shows an exceptionally good concordance.

To make the exposition of this statement clear it is necessary to review the experimental data and to state the precision that can properly be attributed to them.

The mechanical equivalent of heat as determined by Rowland[1] may be taken as 427 meter-kilograms (778 foot-pounds) at 15 degrees Centigrade, which corresponds nearly with 62 degrees Fahrenheit. There have been some recent investigations which on the whole confirm this result, though there is some indication that it is a little small. The uncertainty may be one in a thousand or one in two thousand.

Callendar[2] gives for the absolute temperature of freezing point 273.1 degrees Centigrade, with a probable error of one in two thousand.

For the range of temperature from 30 degrees to 200 degrees Henning[3] gives the equation

$$r = 94.210\,(365 - t)^{0.31249}$$

in calories at 15 degrees Centigrade. In English units the equation may be written

$$r = 141.124\,(689 - t)^{0.31249}$$

Experiments by Dieterici,[4] Griffiths[5] and A. C. Smith[6] confirm his results and extend the equation to freezing point. The probable error of this equation is one in one thousand.

In his paper, "The Total Heat of Saturated Steam," read at the annual meeting, 1908, Dr Harvey N. Davis gives for the total heat of steam from 212 degrees to 400 degrees Fahrenheit

$$H = H_{212} + 0.3745\,(t - 212) - 0.00055\,(t - 212)^2$$

Transformed into French units this may be written

$$H = 638.8 + 0.3745\,(t - 100) - 0.00099\,(t - 100)^2,$$

provided that the constant term be taken as the sum of Henning's value for r at 100 degrees Centigrade and the heat of the liquid be taken as 100.0, according to a consideration to be taken up later in this paper. To conform with the conditions already assumed, this equation should give the total heat in calories at 15 degrees Centigrade, while Dr Davis used for his calorie $\frac{1}{180}$ of the heat required to raise one kilogram of water from freezing to boiling point. The difference amounts to [illegible], as indicated by the heat of the liquid just mentioned ([illegible]). Now the total heats at 100 degrees and 200 degrees Centigrade are [illegible] and [illegible], and their difference is [illegible] calories so that the total effect is less than [illegible] of a calorie.

As for the heat of the liquid we have the three following sources of information:

*Paper presented at the annual meeting of the American Society of Mechanical Engineers, Washington, D. C., May 4-7, 1909.

[1] Proc. Am. Acad., Vol. 15, [illegible]
[2] Phil. Trans., [illegible]

[6] Physical Review, [illegible]

(*a*) Barnes'[7] determinations of the specific heat of water from 0 degree to 95 degrees Centigrade.

(*b*) Dieterici's[8] determinations of the same property from freezing point to very high temperatures.

(*c*) Regnault's[9] determinations of the heat of the liquid.

Barnes' experiments were made by an electrical method for which great relative precision is claimed, and they showed a good concordance with Rowland's work on the mechanical equivalent, which in reality was an investigation also of the specific heat. Dieterici's investigation consisted essentially in heating water in a quartz tube, which was then transferred to the ice calorimeter. His results appear to be systematically larger than Barnes'; at 95 degrees Centigrade, the discrepancy is $\frac{4}{10}$ of 1 per cent.

In 1907 the author endeavored to join Regnault's values for the heat of the liquid to those deduced from Barnes' values of the specific heat. Now Regnault's experiments consisted in running hot water into a calorimeter partly filled with cold water and noting the rise of temperature in the calorimeter. There were 40 tests in all, scattered irregularly from about 100 degrees to 190 degrees Centigrade for the temperature of the hot water; there were in a way three groups of tests, one near 110 degrees, one near 160 degrees, and the third near 190 degrees Centigrade.

The average rise of temperature in the calorimeter for the first group was not far from 9 degrees Centigrade, which item appears to account for the considerable irregularity of results at that place. The experiments with the highest temperatures had nearly twice that rise of temperature in the calorimeter and about half the dispersion of results.

In order to use Regnault's results his values for the heat of the liquid were recomputed, allowing for the true specific heat of the water in the calorimeter, and then a diagram was plotted as shown by Fig. 1, in which the abscissas are temperatures and the ordinates are values of $q - t$.

This allows of the use of a large vertical scale which much accentuates the apparent scattering of points. A curve was then drawn to join a curve from 0 degree to 100 degrees Centigrade, from Barnes' results for the specific heat of water. This curve passes near the highest group of points, above the middle group and below the lowest group.

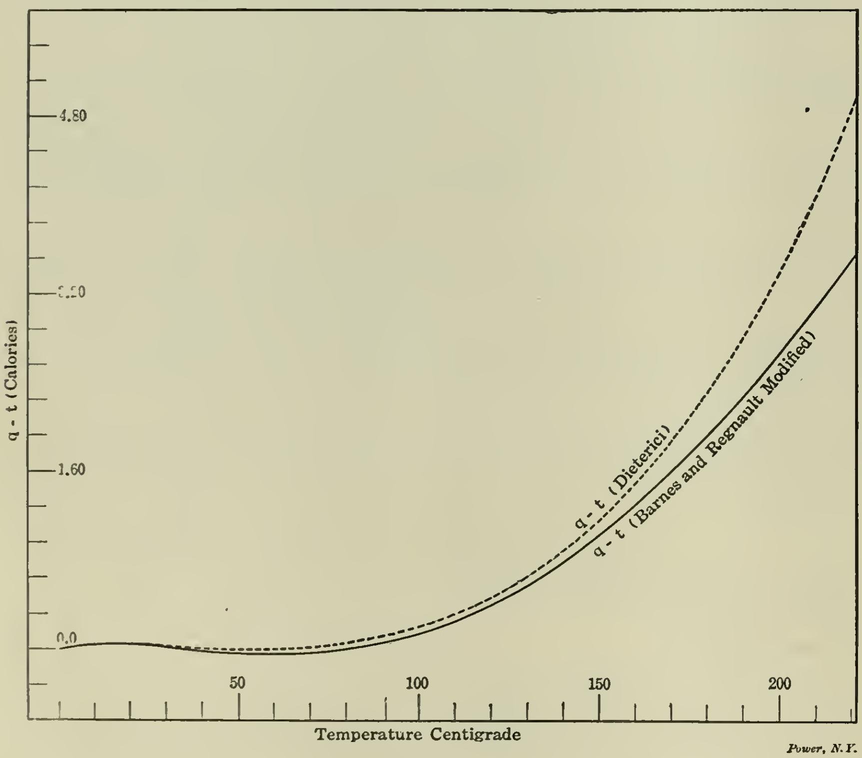

FIG. 2

It should be said that Barnes' results were first transformed to allow for the use of 62 degrees Fahrenheit for the standard temperature, instead of 20 degrees, which he had taken in his report; also that his values were slightly increased at temperatures approaching 100 degrees so as to avoid a break in the curve. The last had the effect of increasing the heat of the liquid at 100 degrees by one one-thousandth.

Finally a table of specific heats was drawn off for temperatures from 0 degree to 220 degrees Centigrade, which served as the basis of a graphical integration for the value of $q - t$. Fig. 2 gives the curve representing the final value of this quantity and also a curve representing values that would be obtained if Dieterici's values for the specific heat were excepted.

The author is of the opinion that the full curve in Fig. 2 shows very nearly the true value of the property under consideration, and he has used it to determine heats of the liquid.

The maximum deviation of a single point from the curve in Fig. 1 is 0.8 of a calorie, which amounts to ¾ of 1 per cent. of the heat of the liquid at that point. If we could consider that an error of 0.02 degree might be attributed to the temperatures in the calorimeter it would account for one-third of that deviation. But to take the most pessimistic view of the situation and charge an error of 0.8 of a calorie against the method, we may still consider that for temperatures above boiling point the heat of the liquid is always associated with the heat of vaporization, and that their sum is more than 630 calories, so that the deviation in this light amounts to ⅛ of 1 per cent.

A more just view is clearly to take the deviation of the worst group of points. This occurs at 117 degrees and is about 0.3 of a calorie, that is, 0.25 per cent. of the heat of the liquid. The most favorable view is to consider that the upper end of the curve is well fixed by Regnault's experiments, which were then under the most favorable conditions, and that the lower end is tied to Barnes' values, which have all desired precision. This matter is discussed with some detail because the original experimental results needed to be entirely recast for the present purpose.

But while important from some aspects, the quantities with which we are dealing are not affected by uncertainties that concern our main investigation, i.e., the specific volume of saturated steam, for the maximum variation between the author's value for the heat of the liquid, and a value determined from Dieterici's investigation, amounts to 0.8 of a calorie at 200 degrees Centigrade. This is only ⅛ of 1 per cent. of the total heat at that place. However, we need for our specific volume the heat of vaporization, and the discrepancy then becomes ⅕ of 1 per cent.

Recent determinations of the pressure of saturated steam have been made by Holborn and Henning,[10] with all the resources of modern physical methods including the platinum thermometer. They claim a precision of 0.01 degree in the determination of temperature and that their results reduced to the thermometric scale have a probable error of not more than 0.02 degree at 200 degrees Centigrade. Their own experiments cover the range of temperature from 50 degrees to 200 degrees Centigrade (122 degrees to 392 de-

[7] *Phys. Review*, Vol. 15, p. 71, 1902.

[9] *Memoirs de l'Institut de France*, Vol. 26.

[10] *Annalen der Physik*, Vol. 26, p. 383, 1908.

NOTE—Since these results may not be easily accessible, it may be of interest to say that they have been transferred directly to Table 3, of the author's "Steam and Entropy Tables," edition of 1909.

grees Fahrenheit), and they have extrapolated results to 205 degrees Centigrade. Below 30 degrees they have made use of experiments by Thiesen and Scheel to extend results to freezing points, these experiments were not made with the same degree of precision as those by Holborn and Henning.

In order to extend calculations to 220 degrees Centigrade, as has been the habit in computing steam tables, the author made use of a diagram shown by Fig. 3, in which the abscissas are temperatures Centigrade and the ordinates are differences between Holborn and Henning's value and pressures computed by the following equation:

$$\log p = 5.457570 - 0.4120021\,(9.997411296 - 10)^{t-[illegible]} + (7.74168 - 10)\,(9.997411296 - 10)^{t-[illegible]},$$

which was chosen as a matter of convenience and because it gave a curve which crossed the axis near 220 degrees Centigrade when produced. It is thought that the extrapolated values are not much in error, though there is no means of determining this question. Fortunately this part of the range of temperature, as well as that below 30 degrees Centigrade, is not so important to engineers.

The degree of precision attained by Holborn and Henning in the determination of the pressure of saturated steam is far beyond any direct technical requirement, since pressures are seldom determined closer than one tenth of a pound; it is, however, requisite, if the differential coefficient $\frac{dp}{dt}$ is to be determined with certainty and accuracy.

Since their results are presented in a table without attempting to represent it by an equation, it becomes necessary to replace $\frac{dp}{dt}$ by $\frac{\Delta p}{\Delta t}$, which can be most readily obtained as follows: For a given temperature, for example 100 degrees, we may compute the ratio by taking two adjacent temperatures, such as 98 degrees and 102 degrees, finding the difference of pressure, which is to be divided by the difference of temperature; and the result is to be multiplied by 13.5959 [illegible] that is the pressure of one millimeter of mercury on one square meter. This result is

$$\frac{\Delta p}{\Delta t} = 13.5959\,\frac{815.9 - 707.[illegible]}{4} = [illegible]$$

A number of elements entered into the determination to use this method and to take an interval of 4 degrees. If the relation of the pressure to the temperature could be represented by a second-degree curve, that is, if such a curve were a parabola with its axis parallel to the axis

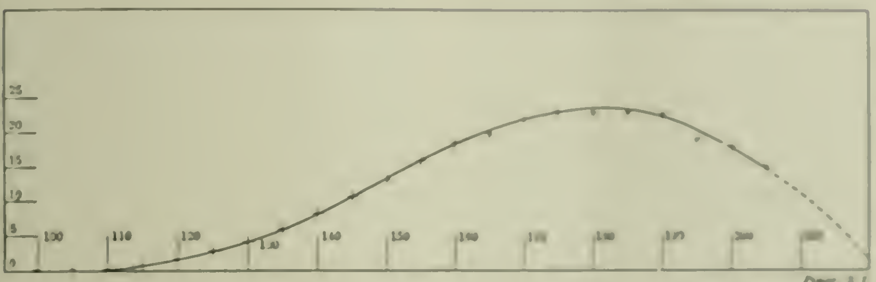

FIG. 3

of pressure, the ratio $\frac{\Delta p}{\Delta t}$ for any interval would be precisely equal to $\frac{dp}{dt}$. A table of values that could be represented by such a curve would have constant second differences; by second differences are meant the results obtained by taking (a) the differences of successive tabular values, and (b) the differences of these differences. An examination of the second differences of Holborn and Henning's values showed great regularity between 50 degrees and 100 degrees, i.e., for their own determinations. The second differences increased slowly; for intervals of 4 degrees the increase was imperceptible, for 6-degree intervals the increase was barely perceptible, but for 10-degree intervals it was very apparent.

Now the possible precision of reading the hight of a column of mercury, including allowance for variations of density, is better than the determination of temperature; consequently the probable error may be considered to be that attributed to the determination of temperature, namely [illegible] degree; consequently the probable error of a single determination of the ratio $\frac{\Delta p}{\Delta t}$ [illegible]. To diminish the effect of [illegible] errors this ratio was computed for each degree of temperature and the regularity of the results thus obtained was tested by taking first and second differences. Where the second differences showed irregularity, the values of the ratio were changed to the extent of [illegible] in order to improve the regularity of the second differences. This process is equivalent to drawing a smooth or fair curve to present physical properties determined by observation.

Having values of the ratio $\frac{\Delta p}{\Delta t}$ for each degree of temperature the specific volumes were computed by the thermodynamic equation in the first paragraph. They were in turn tested for regularity by taking first and second differences, and again the values were changed when necessary to the extent of [illegible] to improve the regularity of the second differences. The combined effect of both changes is estimated not to exceed [illegible] in any case and the author believes that the probable error of the final determinations of the specific volumes is not greater than that assumed for the range of [illegible] degrees to 200 degrees Centigrade.

It may further be said that having computed the values of [illegible] at each fifth degree and plotted the results on a large diagram, no individual values were found to vary from a fair curve more than [illegible].

Fortunately there are extant experiments on the specific volume of saturated steam by Knoblauch, Linde and Klebe,[3] made with such a degree of precision as to give a satisfactory check on the computations made by the method described. These experiments consisted in measuring the temperature and pressure of superheated steam at constant volume, and the results were so treated as to give the volume at saturation by a straight-line extrapolation, with great accuracy. The experimenters give the following equation to represent the properties of both superheated and saturated steam:

$$[illegible]$$

COMPARISON OF EXPERIMENTAL AND COMPUTED VALUES OF THE SPECIFIC VOLUME OF SATURATED STEAM.

Temperature.	Volume, Cubic Meters.			Temperature.	Volume, Cubic Meters.		
	Experimental.	Computed.	Per Cent Deviation.		Experimental.	Computed.	Per Cent Deviation.
[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

[3] [illegible]

$B = 47.10$; $a = 0.000002$; $C = 0.031$; $D = 0.0052$,

volumes being in cubic meters per kilogram. pressures in kilograms per square meter. and the absolute temperature being on the Centigrade scale.

For English units the equation may be written

$$p\,u = 85.85\ T - p\ (1 + 0.00000976\ p)$$

$$\left[\frac{150{,}300{,}000}{T^3} - 0.0833\right],$$

the volumes being in cubic feet, the pressures in pounds per square foot and the temperatures in degrees Fahrenheit.

Knoblauch claims for this equation a mean probable error of $\frac{1}{500}$, though admitting individual discrepancies of twice that amount. This equation applied to the computation of specific volumes of saturated steam shows a good concordance with results, computed by the thermodynamic equation, the greatest discrepancy being $\frac{1}{300}$ at 165 degrees Centigrade (329 degrees Fahrenheit).

Not satisfied with this apparent concordance, which after all was with an empirical equation which on examination showed somewhat larger variation from individual experimental values at saturation, the author had a diagram drawn of the 32 values of the specific volume reported by the experimenters. The diagram was drawn to a very large scale, using temperatures for abscissas and logarithms of volumes for ordinates, and a fair curve was drawn by aid of a stiff spline. From readings on this curve the volumes were determined at 5-degree intervals, and are set down in the accompanying table together with valves computed by the thermodynamic equation.

The greatest deviation of values in this table is 0.2 per cent., which is precisely the probable error assigned by the experimenters for their work. It may therefore be concluded that between the limits of temperature in this table and probably from 30 degrees to 200 degrees Centigrade (86 degrees to 392 degrees Fahrenheit), the probable error of computations by aid of the thermodynamic equation is not in excess of $\frac{1}{500}$.

This conclusion carries with it the attribution of at least the same degree of precision to all the properties entering into the thermodynamic equation. A little consideration will show that this conclusion covers all the properties given in steam tables, including the entropy. As an apparent exception we have the heat of the liquid at high temperatures which may be uncertain to the extent of ¼ of 1 per cent. of itself, but as that quantity is then associated with the heat of vaporization the influence of such an error will be of no consequence in computations.

It may therefore be expected that steam tables based on the present information will have permanence.

Increasing the Weight of Governor Balls

By A. J. Dixon

To the question, "How would a Corliss engine be affected if weight were added to the governor balls?" the following answer was made by an applicant for an engineer's license: "The balls would continue to revolve in the same plane for the same speed, and consequently the increased weight could have no effect on the speed of the engine." It is clear that the kind of governor referred to was the purely ideal revolving pendulum, involving only centrifugal force and gravity, and not taking into account the frictional and other resistances that the practical, everyday working governor has to contend with. Of course, if the governor had no work to do, no resistance to overcome, or if the energy necessary to drive it at a certain speed should always remain the same, irrespective of the weight of the balls, the applicant's answer would have been correct; for, since the two controlling influences in the action of the revolving pendulum or flyball governor are centrifugal force and gravity, the added weight would simply intensify these forces an equal amount—the balls would tend to fall lower by reason of the added weight, but they would likewise have a greater tendency to fly outward by reason of their greater mass, and the net result would be that they would remain in the same plane.

In order to accomplish regulation in actual practice, the speed of the governor must vary within certain limits, and obviously, the narrower these limits the closer the regulation. It is not feasible to regulate closer than within about 2 per cent. of a mean or average speed. This is partly owing to the frictional resistances to be overcome, but chiefly to the resistance due to the inertia of the moving parts of the governor. For example, suppose the engine is cutting off at a certain point for a certain load, and the load suddenly drops off. For a brief moment the valves will continue to cut off at the same point as before, slightly accelerating the speed of the engine, but directly the inertia of the driving mechanism and moving parts of the governor will be overcome, together with the incidental frictional resistance, the speed of the governor will increase, the balls will rise to a slightly higher plane, and cutoff will occur earlier in the stroke of the piston. This will be the succession of events only in the case of a properly designed governor, where the weight of the balls, which is naturally the principal factor in the retarding influences just noted, and the power of the driving mechanism are so adjusted to each other that the resistances can be compensated for by the aforesaid 2 per cent. increase in speed.

Since the inertia of a body is directly proportional to its mass, it is clearly evident that if the mass of the governor balls were increased without at the same time re-proportioning the other essential parts of the governor and its driving gear to correspond, the mechanism could not act as quickly in response to the accelerated speed of the crank shaft as before, on account of the increase in resistance due to the greater inertia and greater friction; consequently, the engine would continue to gather speed until a velocity would be attained sufficient to overcome the additional retarding influence. Then, this velocity of the crank shaft would probably be so great, that when the governor belt would finally take hold and impart a proportionate speed to the governor spindle, the moving parts would acquire a momentum that would carry the balls above the proper plane for regulation under the altered condition of load, with the result that the valves would cut off earlier than they should, the engine would slow down only to be speeded up again after a few revolutions, and the final outcome of the whole performance would be a badly racing engine.

The natural inference to be drawn from the preceding remarks is, that the less weight put into the governor balls, the closer the attainable regulation. But this is so only up to a certain point beyond which it is impossible to go. This limit is fixed by the amount of energy necessary to operate the releasing gear; that is, to overcome the frictional resistance between the hook plates and steel blocks with which they engage. It is quite evident that the energy necessary to do this work is present in the mass of the revolving parts of the governor, and consequently, if the balls were deficient in weight, the hooks could not be forced to disengage or slide off the studs, without a more or less serious displacement of the knockoff cams and consequently of the whole governing mechanism.

A press despatch states that Secretary Ballinger of the Interior Department has instructed the director of the Geological Survey to make an investigation of power sites under the public domain outside of national forests which are not included in withdrawals for reclamation purposes with a view to securing at the next session of Congress legislation to control and regulate their disposition.

The Great Falls Power Company, of which P. M. Gillatt, engineer of the H. M. Byllesby Company, Chicago, is one of the principal movers, is now taking contracts and proposes to supply sixty-three towns and cities in Manitoba with electrical energy.

Increasing the CO_2 Content of Flue Gases

Investigation of Combustion Conditions under Ten Boilers (8400 Horsepower) Using Bituminous Slack Saved $6500 per Year

BY A. J. BOARDMAN

The plant consists of eighteen 400-horsepower and four 300-horsepower Babcock & Wilcox water-tube boilers, with Roney stokers. The diagram of the boiler room is shown in Fig. 1. The four batteries on the north steel stack include four 400-horsepower boilers and four 300-horsepower boilers, which are the oldest boilers in the house. On the south stack are four 400-horsepower boilers, and there are ten 400-horsepower boilers on the brick stack, which is more than the stack was designed for. The last boiler is approximately 148 feet from the stack. With future extensions to the house an additional stack will be built to equalize the draft.

FIG. 1. PLAN OF BOILER ROOM

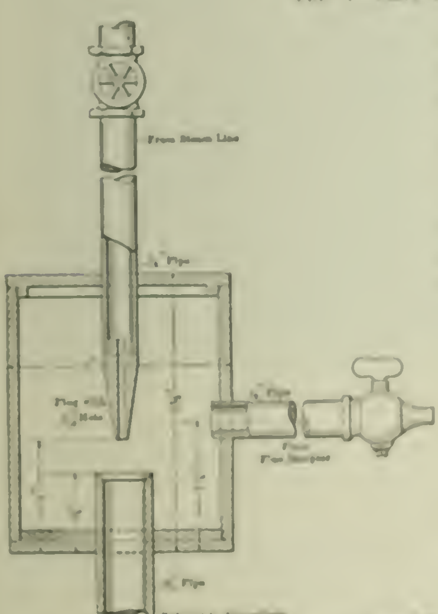

FIG. 2. CONSTRUCTION OF ASPIRATOR

The idea that prompted this investigation was to find out to what extent it was possible to regulate the boilers in order to secure the highest CO_2 at the stack and at the same time get the required capacity out of the boilers. It was deemed advisable to attempt both to regulate the boilers singly and as a whole by analysis of the stack gases. This would give a relative value of the CO_2 after allowing for the infiltration of air through leaks in the breeching.

So far most of the claims of the manufacturers of CO_2 recording instruments have been based on hard coal which gives the best possible conditions for complete combustion. An average analysis of the coal used in this plant, which is [illegible] county, Indiana, slack, is as follows:

	Per cent.
Moisture	[illegible]
Volatile matter	[illegible]
Fixed carbon	[illegible]
Ash	[illegible]
Total	[illegible]

A number of tests made have shown that the CO_2 record gives accurate information regarding the efficiency of a boiler. For a boiler that works at the highest theoretical efficiency the CO_2 record would be constant at about 20, that is, all the oxygen of the air would combine with carbon to form CO_2. In practice such results are seldom obtained, excepting for momentary jumps up to 16, 17 or 18 per cent., which are for very short periods and may be considered abnormal. When a condition exists in the grate for any length of time to give a CO_2 value of 17 or 18 per cent., the boiler capacity will probably decrease. It might be stated that the boiler in the plant under consideration which gave the highest average CO_2, 14 per cent., had the least amount of draft. A test on the same boiler showed a capacity of 87 per cent. under approximately the same conditions.

In the present case, using bituminous slack, when the CO_2 rose as high as 15 per cent. for a short time, the fire became heavy and the capacity of the boiler was seriously interfered with.

It is common knowledge that there seems to be an excess of air owing to a lack of knowledge of the existing conditions in the grate. The result is that the best efficiency in practice corresponds to about 70 per cent. of the theoretical and will generally be lower, depending upon the kind and quality of coal, amount of [illegible] grate, furnace, etc. With the coal used in this plant under the conditions described the average CO_2 [illegible] at the stack should be about [illegible] per cent. [illegible] the highest attainable practical efficiency would give approximately [illegible] per cent. of CO_2 with [illegible] average of about [illegible] per cent.

FIG. 3. ARRANGEMENT [illegible]

Apparatus Used and Preliminary Testing

The apparatus used were an Orsat-Muencke flue-gas analyzer, an Ellison draft gage and a 1000-degree thermometer. The draft was taken over the fire and at the bottom of the soot blowoff holes in the side of the boiler instead of the standard place in front of the damper. There was a difference of 0.02 inch between the damper and the bottom soot holes, but since the readings were only relative this deviation could make no appreciable difference.

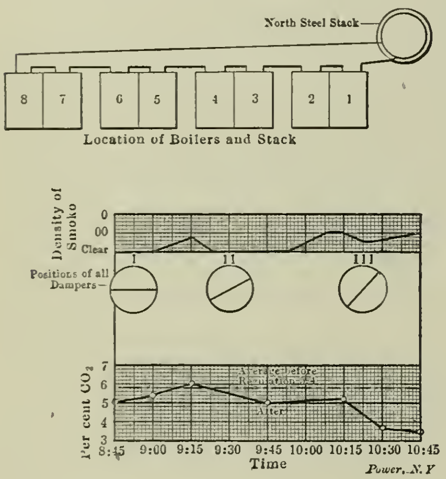

FIG. 4. OBSERVATIONS ON NORTH STEEL STACK

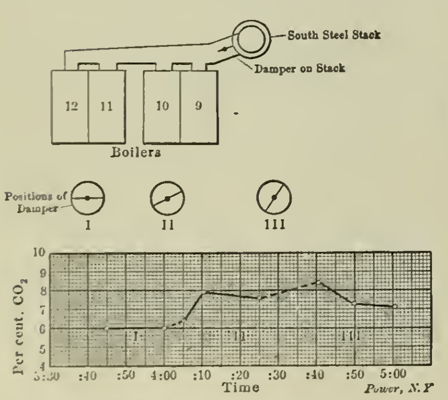

FIG. 5. REGULATION ON SOUTH STEEL STACK

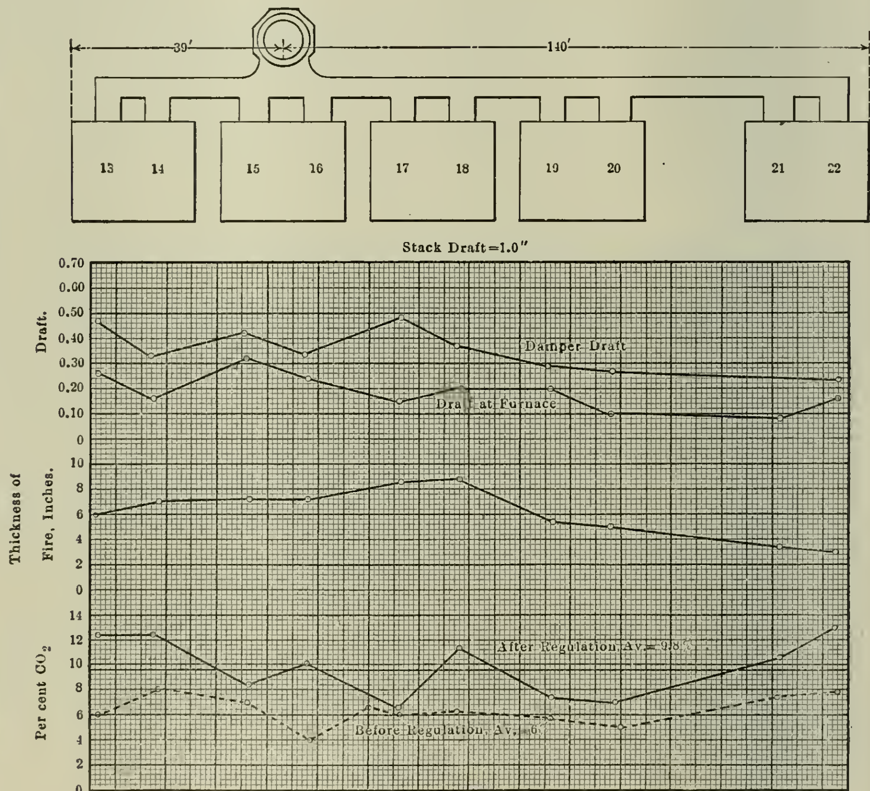

FIG. 6. PRELIMINARY TEST OF BOILERS ON BRICK STACK

The flue-gas samples were taken at the same place. At the brick stack, where it was necessary to draw the samples down into the boiler room, a distance of 40 feet, a steam aspirator, Fig. 2, made out of piping, was used, and in addition a cotton soot filter, on account of the suction that was exerted in drawing down the gas. The samples were then taken from a tin sampling can, as shown in Fig. 3.

Trials were made on several of the boilers to get extreme and average results before attempting to regulate any bank of boilers. The CO_2 varied from 3.5 to 16.6 per cent., the average being near 6 per cent. The highest CO_2 record, 16.6 per cent., was obtained on boiler No. 22, which had the least draft, 0.26 inch, in front of the damper. This extremely high reading was probably due to momentary conditions and may be regarded as abnormal.

A series of observations were taken on the north steel stack, including a smoke chart*, and CO_2 analysis. It was noted that as the load increased the smoke became more dense and the CO_2 decreased. This is explained by the fact that as the boilers were being forced an excess of air was required which increased the density of the smoke and also decreased the CO_2 content of the flue gases. The next day an attempt was made to increase the CO_2 by adjusting the conditions at the fires, that is, with the excess of air shown by the CO_2 record, either shut off the draft or carry a heavier fire, as the most economical draft is not a dilution coefficient of one, but the least amount of air it is possible to get along with.

Infiltration of Air through Breeching

With the dampers wide open the CO_2 was about 5.4 per cent. As the dampers were gradually shut off the CO_2 decreased at the stack. This showed that the breeching was full of leaks. By closing all the dampers a little, more air was pulled through the leaks. Further closing of the dampers decreased the CO_2 to 3.5 per cent., which conclusively proved this to be true. (See Fig. 4.)

On the majority of the boilers in question the baffling was in poor condition. Experiments on the defective boilers showed that it was impossible to raise the CO_2 to any appreciable extent. This is due to the fact that after the air is drawn through the fire, if there is not a thorough mixing of the free oxygen of the air with the unburnt volatile matter of the coal to produce complete combustion, the gases then pass out of the flue at a very high temperature, which lowers the efficiency of the heating surface. Owing to the high temperature and slagging action of the gases, it is difficult and expensive to keep the baffling over the bridgewall in good shape, and the result is that some boilers have about one-half the effective heating surface of others.

The results obtained on the south steel stack, serving four boilers of 1600-horsepower capacity, were somewhat better. Allowing for the infiltration of air in the breeching, the average was raised from 6 to about 8 per cent. (See Fig. 5.) This represents a saving of 9 per cent. of the heat lost up the flue. High temperature readings showing poor baffling on boiler No. 11 interfered with better results. A different method was followed with the boilers on the brick stack. Flue-gas analyses were made for the greater part of one day to ascertain the average CO_2, Figs. 6 and 7. It was thought desirable to attempt individual regulation on each

*The chart used is similar to the Ringelman chart with the exception that the densities are designated as clear, 00, 0, 1, 2 and 3, instead of 0, 1, 2, 3, 4 and 5.

boiler to find the best conditions for each boiler, draft, thickness of fire, etc., then try to approximate the conditions before running a test with the boilers on that stack. As the work proceeded the necessity of a recording device became more apparent. It was easy enough to take

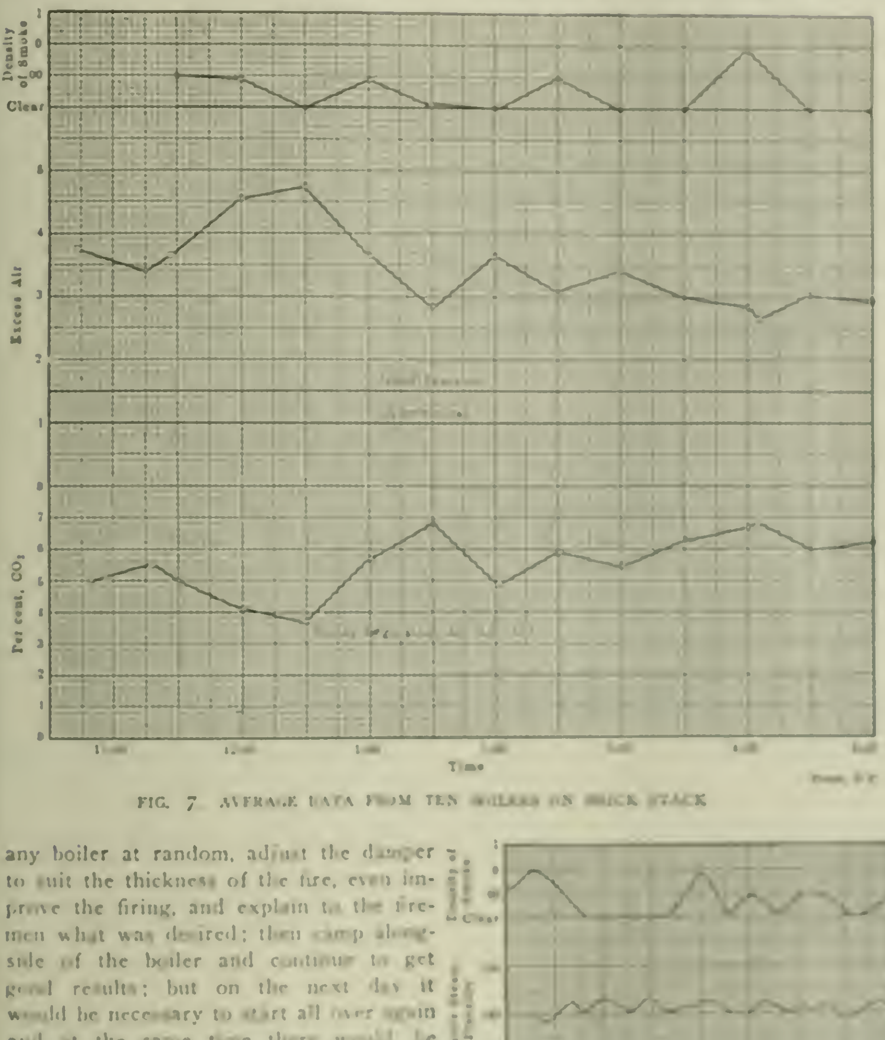

FIG. 7. AVERAGE DATA FROM TEN BOILERS ON BRICK STACK

any boiler at random, adjust the damper to suit the thickness of the fire, even improve the firing, and explain to the firemen what was desired; then camp alongside of the boiler and continue to get good results; but on the next day it would be necessary to start all over again and at the same time there would be twenty-one other boilers, each wasting heat up the stack. There was nothing that could be told the firemen that would be of any permanent value in firing.

Effect of Damper Regulation

Experiments were then made on all ten boilers connected to the brick stack with special reference to damper regulation. The series of observations extended over one day. Although the experiments on the separate boilers and stacks had given an idea of what might be expected, it still remained to prove out a few of the theories that had been advanced by the previous tests.

The graphical logs, Fig. 8, show, first, that the maximum attainable CO_2 with the coal used is in the neighborhood of 10 per cent.

Second, that the increase in CO_2 corresponding with the decrease in draft showed a decrease in steam pressure and boiler capacity.

This checks up with the results of the steaming tests at St. Louis, i.e., if the oxygen is decreased simultaneously with the rise of CO_2 content, the completeness of combustion* decreases.

Third, that the density of smoke increased with the raising of the CO_2. This

FIG. 8. [illegible]

is explained by the fact that by decreasing the air supply with the thickness of fire constant, it became necessary to make frequent use of the slice bar, which resulted in an increase in the density of the smoke.

About 3 o'clock in the afternoon the load had started to peak and it became necessary to open up the dampers to get capacity out of the boilers.

In the following data Column 1 gives average results before regulation and Column 2 average results after regulation.

This table is correct for the values given. It is impossible to compute a table that will show the heat loss for any case, owing to the number of varying factors that influence the result.

A Peculiar Accident

On the afternoon of Saturday, March 20, Peter H. Bullock, chief engineer of the Concord Reformatory, Concord Junction, Mass., was passing through the engine room on his way to his office and paused near the cylinder of a 20x48 Harris-Corliss engine. As he glanced from the valve gear to the governor, by the hight of which he saw that the load was light, there came the sound of water slapping in the cylinder. Signaling his assistant to go to the boiler room, he partially closed the throttle, slowing the speed of the engine, when almost immediately there came the pound of solid water in the cylinder.

Mr. Bullock immediately closed the throttle and, as the engine continued to pound hard as it slowed down, unhooked the motion plate, hoping to stop the engine more quickly. At the third stroke following, as the crank was passing the forward center, the side of the throttle valve burst, steam and hot water striking him in the face and on the upper part of the body and throwing him to the floor. Bruised and scalded, and with eyes and mouth closed, Mr. Bullock crawled as rapidly as possible toward a window seventy feet away, running into the flywheel of a high-speed engine *en route*, which bruised him more. But in less than thirty seconds from the time he placed his hand on the throttle lever he was safe outside the building.

In this plant steam is generated in three vertical boilers, with induced draft controlled by a Foster fan-regulating valve, and in two horizontal tubular boilers with natural draft. At the time of the accident shavings and waste lumber were being burned under one of the horizontal boilers and, as the fire was burning fiercely, it is thought that the Foster valve in the fan-engine steam pipe practically stopped the fan engine and water was carried over into the steam main from the horizontal boiler. From the horizontal boiler the steam pipe passes across the boiler room and, making a right-angle turn, leads along the side wall which separates the engine room from the boiler room. At the end of this pipe steam for the engine is taken from the bottom, compelling all water in the pipe to flow to the engine.

It would seem that after the throttle, which was of the sliding-cover lever-operated type, was closed water collected in the pipe and as the water in the cylinder was rapidly forced upward through the steam chest, lifting the steam valve of the engine and the valve in the throttle from their seats, when the water from the cylinder met the column of water in the pipe above the throttle, the pressure required to start this column was greater than the body of the throttle would stand.

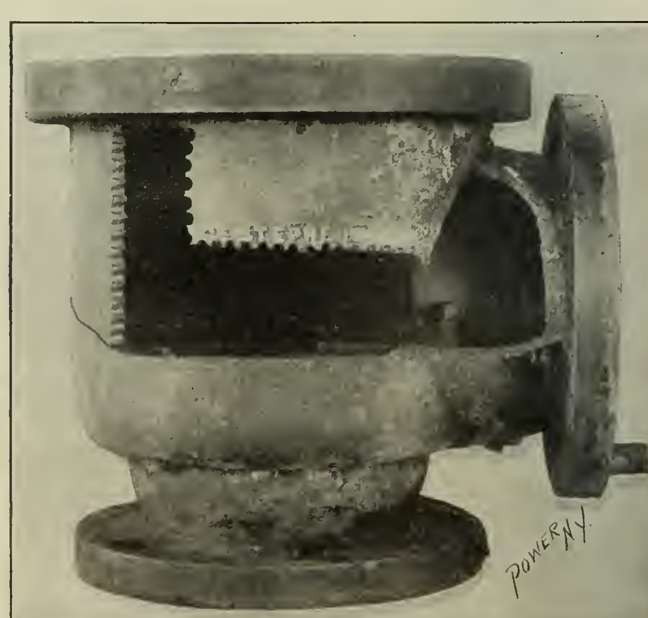
It is assumed that the break in the valve was caused by water from the cylinder of the engine rather than by that from the boiler, because at no time was there any sound that would indicate what is known as water hammer in the steam pipe. A piece of the casting was blown out and could not be found.

Test pieces were cut from the body of the valve casting and sent to the mechanical laboratory of the Massachusetts Institute of Technology, where they were found to have a tensile strength of more than 20,000 pounds per square inch.

Critical examination of the fracture showed that possibly a crack about six inches long existed in the iron for a long time, as most of the way around the edge it looked bright and clean, while for the rest of the circumference it appeared dull, as though oil had seeped into a very small crack and carbonized.

At one place the thickness of the metal in the shell was reduced to about 1/4 inch, but calculation shows that even at the reduced thickness a sound valve casting would be safe for a working pressure of more than 200 pounds per square inch. It is probable that the body of the valve had become weakened, or it would not have failed in time to save the engine from a serious wreck. Inside the largest

VIEW OF VALVE BODY, SHOWING FRACTURE



SHOWING PORTIONS CUT FOR TEST PIECES

diameter of the valve body was 9½ inches, with a thickness of 7/16 inch, except where reduced by the spot-facing tool to about 5/16 inch at a single point.

After steam had been shut out of the pipe and the excitement had somewhat subsided, it was observed that the water in the horizontal tubular boiler was a little lower than normal, showing that it was not unlikely that it had at no time been unusually high, but had primed during the fierce firing just preceding the accident.

Mr. Bullock has been chief engineer at this plant for nearly thirty years and this was his first accident of any kind in which anyone was hurt.

The engine has been in constant operation about sixteen years and has never before had a dose of water.

Practical Points in Electric Crane Work

By R. H. Fenkhausen

A certain make of radial arm crane controller was for the first few years of its manufacture equipped with the type of brush holder shown in Fig. 1. A holder of this type was mounted on each end of the controller arm but insulated from it. The path of the current was from brush to brush in each holder and fiber buttons F were used to insulate the springs at one end and thus prevent the passage of current from destroying their temper.

As no pigtails were employed to carry current to the brushes, and they could not be easily attached, the current was forced to travel from brush to holder and thence to the other brush. The brushes were necessarily loose in the holders to allow them free play, which resulted in heavy arcing that soon destroyed brushes, springs and, eventually, the holders themselves.

There being some seventy-five of these holders in the plant under my charge, the maintenance charges were very high and the shutdowns of cranes numerous, so that it became necessary to design a better brush holder. The result is shown in Fig. 2. In the new holder it will be evident, the brush holder has no part in the carrying of current. All current is carried by the brass plate X and the holders proper could be made of any convenient material. It was, of course, easier to convert the old holders to the new, simply by cutting off the bridges D, Fig. 1. The change described increased the life of the brushes over fifty times and entirely stopped crane shutdowns due to this cause.

As many hundreds of these holders (estimated at 2000) were placed on the market before the makers changed the design, it is hoped that this description of the simple alteration will aid some readers of Power into whose hands the old brush holders have gone.

Many cranes are equipped with a limit switch to prevent overtravel of the hook, and most of these are operated by a weighted arm traveling on a rod [illegible] from the end of the drum shaft. This limit switch is [illegible] [illegible], but careless operators [illegible] [illegible] to stop the hook [illegible] and [illegible] disturb the setting of the weight A, Fig. 3, in order to save themselves the trouble of resetting the switch. As several [illegible] had [illegible] a [illegible] [illegible] alteration of the [illegible] [illegible] the [illegible] as follows: A plate B, Fig. 3, was attached to the frame of the crane under the weight A. Studs E E were tapped into the weight, holes having been drilled through their heads, and a lead wire was passed through the said heads and around the bar B, as shown, and the ends sealed with a lead seal closed with a sealing tool having the initials of the company engraved on the face. The cap screws F and G were also sealed to prevent tampering.

When a hook overtravels the seal must be broken, and as the crane inspector is the only one having access to the sealing tool, every case of overtravel is recorded against the operator.

This plan is also useful to prevent unauthorized alteration of the setting of circuit-breakers, relays, etc.

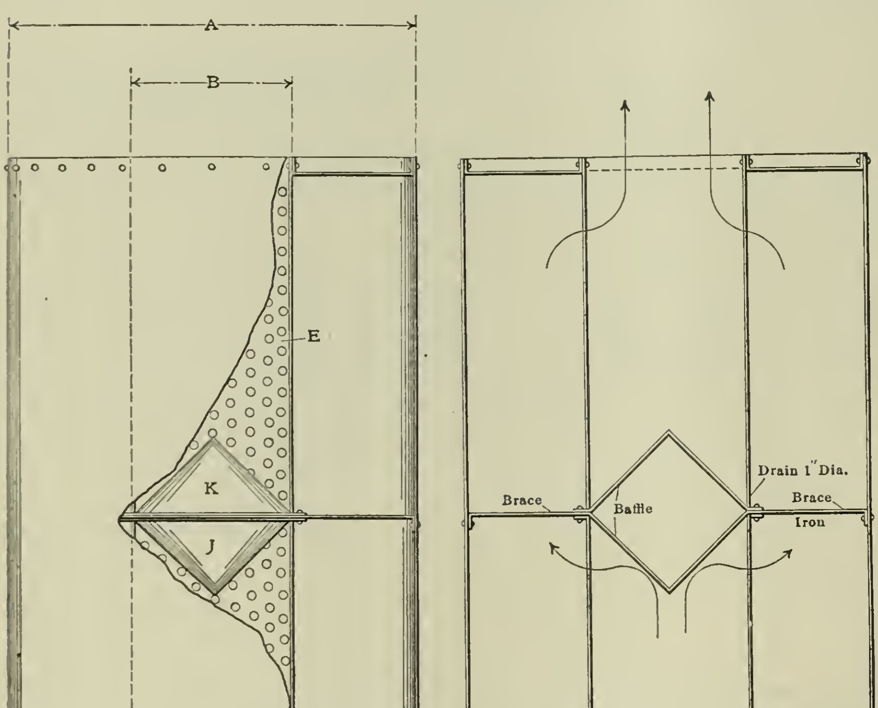
Homemade Exhaust Head

The accompanying sketch is of an exhaust head. It is very simple and inexpensive and so efficient that it has been adopted by the company with which I am connected. We have used them on exhausts on from 2- to 16-inch pipes, with entire satisfaction.

The head is made of galvanized iron with riveted and soldered joints, making it water-tight. It consists of two cylinders *A* and *B*, *B* being only a continuation of the exhaust pipe which is divided into two sections by the conical baffles *J* and *K*, the upper section *E*, being perforated the entire length, while the lower section is perforated down to the point *D*. The remaining part *H* forms a catchbasin for the water and oils separated from the steam. The perforations are staggered and vary in direct proportion to the area of the exhaust pipe. The outer cylinder *A* forms a condensing chamber around *B*. This is stiffened in the center of the large heads by a light brace. At the bottom is a flange into which is screwed the return pipe. The large internal area of this chamber overcomes any possible chance of back pressure on the engine, while giving the best conditions for the expansion, condensation and separation of the water and oil.



A HOMEMADE EXHAUST HEAD

I have also used the device with success as a muffler on a high-speed engine.

H. M. Nicholls.

Chicago, Ill.

Arrangement of Air Pump and Heater in a Mine Plant

On beginning my work in my present plant I found two slide-valve engines installed to run the mill, one a 13x16, the other an 18x24. These engines can be run simple, both at one time or separately, with or without vacuum; or, by changing two valves, they can be run compound with or without vacuum. I usually have 120 pounds of steam pressure.

The air pump and jet condenser are located 40 feet from the low-pressure cylinder of the mill engine, which has an 8-inch exhaust pipe. This is rather small for that distance and reduces the vacuum a little. I averaged 17 inches of vacuum, at the condenser, which is not so bad for an altitude of 7200 feet. A perfect vacuum at this altitude being about 22¾ inches, 17 inches is equal to about 24 inches at sea level.

In order to get a vacuum on the mill engines when the compressor was not running, I connected the air pump to the mill by means of a shaft, having a crank on the end connected to an arm on the rockshaft of the air pump. By slipping off the connecting rod from the rocker arm on the air pump, and the pin on the compressor, adjusting this arm for the mill connection, the mill drives the air pump at 50 revolutions, very satisfactorily.

We have a pond, about 100 feet square, 350 feet from the condenser, and draw the condensing water from it, through a 5-inch pipe, directly by the air pump, which makes a lift of 15 feet besides the friction in the pipe. This pipe runs under the mill through a tunnel which conveys the warm water back to the pond for cooling, discharging at the farther end.

As the water from the mine is bad for the boilers, I made a surface condenser to furnish condensed water for them, connecting the condenser to the air pump and drawing the water from the pond with a common steam vacuum pump. This pump circulates the water over the condenser tubes, the hot water dropping back into the same canal, and returns to the pond to be cooled. I get the same vacuum with the surface condenser that I do with the jet condenser. This reduces the power required to operate the air pump almost to nothing, and puts the power it requires when running the jet condensing onto this circulating pump. But I make use of all the heat in the exhaust of this pump to raise the temperature of the feed water, which water comes from the surface condenser at about 120 degrees temperature, by running the exhaust to the heater.

The heater has no outlet for the exhaust steam and other inlets, except a ¾-inch pipe at each end to drain out the water of condensation. These pipes are connected to one leading to the hotwell. In addition to the exhaust steam of the circulating pump entering the heater, the trap which drains the receiver and reheater (which are one) between the high- and low-pressure cylinders of the compressors also discharges its water into the heater. On account of the variable temperature of the feed water entering the heater, there is a fluctuating back pressure on the exhaust of the circulating pump, but this does not interfere to any disagreeable extent with the regularity of the pump.

This same heater is connected to the receiver of the mill engines by a 1-inch pipe having a valve. When the mill is running there is more water to be heated (which water comes from the same feed pump) and consequently requires more heat. This is obtained from the receiver of the compound mill engines, which receiver has an average pressure of about 25 pounds, and the heater is always exposed to this pressure. The 1-inch pipe is so located that it takes all the water of condensation from the receiver. No steam from any other source enters the heater except that mentioned.

I introduce the feed water at the top and deliver it to the boilers from the bottom, as the water going out at the bottom leaves the oil at the top of the heater, which is blown out at intervals from the top. I am making a settling tank, however, to further the extraction of the oil, and shall locate this tank to catch the water as it falls from the air pump and let the feed pump take it from the tank, thus making less deposit of oil in the heater.

L. D. [illegible]

Los Angeles, Cal.

Compression

Are we not inclined to railroad this question of compression with so much theory that the most is lost sight of? Few will dispute that it is good engineering to entrap sufficient exhaust steam ahead of the advancing piston to absorb the inertia of the moving parts to such a degree that the crank will pass the centers as quietly as possible and, incidentally, warm up the cylinder walls and reëvaporate what condensation may be present rather than to have these useful functions performed by the incoming live steam.

Calculating the right amount of compression for each case may be shorn of a lot of perplexity if we are content to deal with the question in the abstract. If a reciprocating engine is operated at its normal load, speed, initial and back pressures, with the crank-pin box loosened up for the occasion, that setting of the valve or valves with regard to exhaust closure that enables the crank to pass the centers with the least jar settles the question of compression for that set of conditions, does it not?

With the four-valve, double-eccentric type of engine, valve setting is a simple operation, but when dealing with the single-valve engine, either throttling or automatic, difficulties are sometimes met with that afford an opportunity for a little mental exercise.

Inasmuch as equal lead, cutoff and exhaust opening and closure cannot be attained in a single-valve engine, that is, equal as between the two ends of the cylinder, a middle ground must be sought that will give the best net results.

To illustrate, attention is called to Fig. 1, showing the results of setting a slide valve by the eye. The cutoff is fairly equal, but the exhaust release on both ends is poor and the admission at the left is distinctly bad, and the engine knocked badly on that end. Fig. 2 shows the lead compensation, which carried the crank over the centers beautifully, with the box loosened up, and while the cutoff is unequal to a marked degree the exhaust opening leaves little to be desired.

FIG. 1

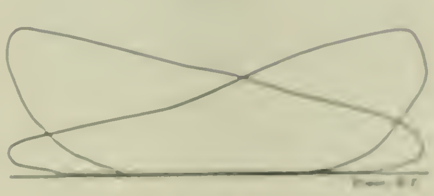


FIG. 2

It is obvious that unequal cutoff has a tendency to make the governor less [illegible], but with a fair-sized balance wheel this difficulty is more apparent than real. In handling single-valve automatic engines under ordinary conditions it is pretty safe to [illegible] and attention to keeping the valve in its proper place with reference to eccentric or valve-stem length; that is, when taking up wear, take it up equally on both sides.

There are occasions, however, when testing the governor when on the shaft, by means of an offset key, enables an engine to cope with unusual conditions that the designer had no opportunity to figure on.

In one case, an abnormally high load caused such early exhaust closure that the slack in the moving parts was taken up with a slam before the crank passed the centers. We had no way of adding to the load nor lowering the steam pressure, on account of other units, so we cut off enough inside of exhaust lap to enable the engine to run quietly under existing conditions.

In another case a single-valve automatic engine was overloaded to such extent that the high terminal pressure obliterated the effect of what little compression was realized from late exhaust closure. Long, [illegible] the reciprocating parts of this engine approaching the centers "all steamed out," only to be brought up with a steam-hammer jar when the steam valve opened.

The engine cylinder was about 12x24-inch; ⅛ inch was added to the inside lap and the knock disappeared.

A novel theory, so far, was carried out. Instead of trying to bring the face of the added pieces flush with the working face of the valve, no attempt was made to do so, with the idea that a steam-tight joint would be useless until an appreciable pressure had been raised in the cylinder, by which time the valve would have time to get over onto the old part that was already steam-tight; in other words, the added pieces acted only as obstructions or chokes. While there was not enough difference in the pressure to make it very [illegible], the scheme worked and saved a lot of useless timing.

E. G. TILDEN.

Downers Grove, Ill.

Pump Valves

In the March 23 number, page [illegible], D. T. [illegible] says he cannot see why springs are required on the valves of a boiler-feed pump. While I should not care to do without springs, I do think we often apply more pressure than is necessary.

In the plant of which I have charge, there is a duplex steam pump for feeding the boiler, taking water from an open heater, which could not very well be placed so high above the pump as it should have been. However, we had no trouble so that with a few springs [illegible] when the pump began to [illegible] the results we [illegible] it was not getting water [illegible] enough to fill the cylinder. It would run nicely up to a certain speed, also after stopping the engine, when the water in the heater would begin to get cooler.

Thinking that the spring might be set tighter on the end giving trouble, I opened up the valve chamber, but could not detect any difference. I decided to ease up on all the springs on the suction deck, although I did not consider them too tight, but on starting up again I found that my trouble was over.

THOMAS WHELPTON.

Rosthern, Can.

Puzzling Transformer Action

The trouble with a series circuit operated from a constant-current transformer, recently reported by E. L. Mason, is quite unusual. It is difficult to make positive statements in the absence of statistical data of the apparatus, but I believe the accompanying diagrams and reasoning constitute a plausible explanation.

In Fig. 1 (drawn from memory) is shown the apparatus; the constant-current transformer at the left, the boosting transformer in the center, and the terminals of the lamp circuit (with the

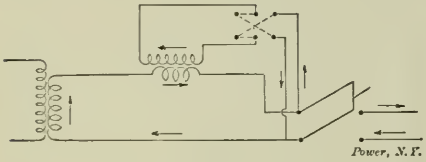

FIG. 1

switch shown open for clearness) at the right. Arrows have been added to show the direction of current in the several parts of the circuit during the half cycle in which the current plows upward through the constant-current transformer secondary.

The arrow heads show that both transformer secondaries carry more current than the lamp circuit, which is said to take 3.5 amperes. If we assume in the absence of any definite data that the voltage is about 2000, then the booster transformer has a 2000-volt primary and a 100-volt secondary. With the connections as given, the transformer primary absorbs power from the circuit, which is returned by the secondary, increasing the voltage (this is the normal conditions of boosting). When everything is balanced the product of volts boost times current in the (booster transformer) secondary is approximately the same as that of the volts and amperes in the primary. This arrangement, Mr. Mason says, operated satisfactorily.

Let us now throw over the reversing switch on the booster transformer. We shall then have the connections shown in Fig. 2. We may note here that the constant-current transformer is more powerful than the booster, so that the directions of the currents are the same, except between the booster primary and the main circuit. We now have the booster transformer primary operating in parallel with the constant-current transformer to furnish current to the lamp circuit. When balance is again obtained, the functions of the booster primary and secondary have been interchanged and the power absorbed by the secondary, which is equal to the current times the volts drop, reappears in the primary and is delivered to the lamps. The product of volts and amperes in both

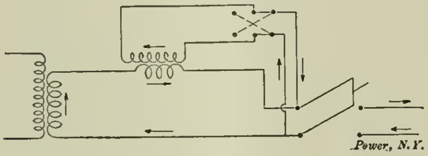

FIG. 2

circuits of the (booster) transformer is again nearly the same.

There is one important difference in the current relations in Fig. 1 and 2, which we must now take into account. In Fig. 1 the constant-current transformer carries the sum of the lamp and the booster-transformer currents; in Fig. 2, the difference. The excess of current in one case over the other is about twice the booster-transformer current, as the current will not be exactly the same in both connections. When the current in the (constant-current) transformer secondary decreases, there is a prompt change of position of the secondary coil, because this is exactly the condition which the transformer is designed to handle. The voltage rises so as to increase the current in the circuit.

We must not forget, however, that both transformers are in parallel, so that they have the same voltage at their terminals. This requirement regulates the drop through the booster-transformer secondary. The final condition of equilibrium will be increased voltage and more current to the lamp circuit, provided these

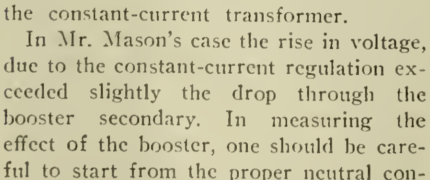

FIG. 3

are within the limitations of movement of the constant-current transformer.

In Mr. Mason's case the rise in voltage, due to the constant-current regulation exceeded slightly the drop through the booster secondary. In measuring the effect of the booster, one should be careful to start from the proper neutral condition, which is with open-circuited primary and short-circuited secondary (of the booster transformer). If the secondary is not short-circuited when the primary is open, it acts as a choking coil and causes a considerable voltage drop.

In order to realize the purpose of this booster, it will be necessary to block the secondary of the constant-current transformer, which converts it into a constant potential transformer. If the connections are then changed as in Fig. 3, the booster transformer will either boost or buck, as desired, but the constant-current regulation will be lost.

Local conditions must be peculiar to require such unusual connections. As a general thing, sufficient adjustment is obtainable in a constant-current transformer by changing the amount of counterbalancing weights to take care of any probable requirement.

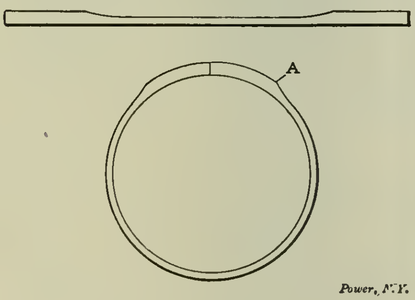
Schenectady, N. Y.

Joints for a Boiler

According to the best practice a triple-riveted butt joint has a theoretical efficiency of about 85 per cent. of the sheet. Whether the efficiency of the joint is that high under actual working conditions is



SUGGESTION FOR BOILER PLATE

an open question. Conceding that it is, and that the efficiency of a double-riveted butt joint is about 82 per cent. of the strength of the sheet, to get the increased efficiency of about 4 per cent. an additional row of rivets is necessary; the slight increase in width of the covering plate required is not worth considering, as far as increased cost is concerned.

Is there any reason why boiler plates cannot be made as shown in the accompanying sketch, and in that way compensate for the reduction in the section of the plate due to the rivet holes?

A plate so rolled would allow a riveted joint to be made exceeding in strength the body of the plate.

It might be a little difficult to bend the plate just at the point where the full compensation begins, as shown at *A*.

There may be a reason for not using the style of plate I suggest, as the grain or fiber of the plate caused by rolling would run the wrong way. I have been unable to learn the strength of steel plates "with" and "across" the grain. I find that iron plates show 6 per cent. more strength with the grain. When I say iron plates I refer to the very best grade of boiler plates.

A. H. HALE.

Denver, Colo.

Limitations of a Pump Lift

Replying to Frank L. Walls' letter in a recent issue, I differ with him regarding the statement that the limitations of a pump are a 27-foot raise, as I have several times raised water 30 feet and one time even as high as 31½ feet.

In this latter instance there was a shaft 42 feet deep at which depth were two tunnels, each 200 feet long. Their purpose was to get at the different artesian wells to cut them off at that depth, also for a header to connect up a nine and a half million 500-foot lift Dow pump, the pump to be set in a pit 42 feet below the surface on a level with the flow of the wells.

I put a duplex pump so that the cylinders were just above the water level and started up. Everything worked nicely until I got the water down 29 feet, when the pump refused to lift water. The only trouble we had was with the packing in the pump cylinders, which had to be renewed every two weeks or so.

W. Ellerbrock

Honolulu, Hawaii

A Siphon Discussion

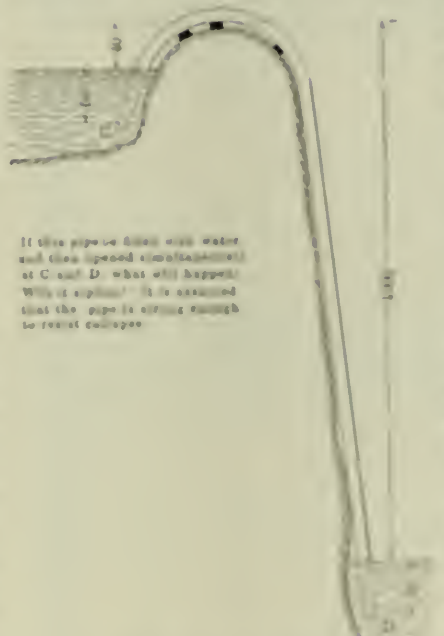
The chief engineer and a packing salesman were smoking in the fire room and chatting about the weather, politics and machine diseases, when the salesman, fishing in his pocket, produced a piece of paper with a sketch similar to the one shown herewith. Handing it to the chief, he said: "Here is something that the engineer down at the rubber works put up to me this morning. I wasn't quite sure about it and want you to post me. He wanted to know if it would siphon."

"It certainly would not," replied the chief, after looking over the sketch, "because the atmospheric pressure at sea level will not support a column of water more than 34 feet high, and consequently the water would not flow over the neck of the siphon."

"I told him that," said the salesman, "but he then asked me what would actually happen when the water was released at both ends of the pipe, and that put me 'up a tree.' I told him I was sure that the water would flow out of both branches of the siphon until it reached a point in each about 34 feet above the surface of the water in the respective reservoirs, and he then wanted to know what would take the place of the water. That was too deep for me, but I am curious to know just what would happen."

The chief looked at the sketch again and pondered deeply. "Well," he said, "there is something queer about that after all. That 1000 feet of water trying to go down the pipe would certainly give an almost perfect vacuum in the neck of the siphon;" and he pondered some more. Finally, after applying a fresh match to one of the salesman's deceptive-looking cigars, he said: "I think I have it. You see, water will boil in a perfect vacuum at any temperature down to 32 degrees Fahrenheit, so the neck of the siphon would become filled with vapor, rising from within the liquid in both its branches. This would reduce your vacuum and the water would begin to drop down the tubes, continuing until a point was reached where the vacuum would not be sufficient to cause ebullition (or boiling), when it would remain stationary."

The salesman was still scratching his head when the inquisitive mind of "Jimmy," the oiler, who had been standing by taking in the whole conversation, began to see trouble ahead, and he stepped up to the chief saying: "Now, I don't want to 'butt in' and am only looking for information (Jimmy always was a curious kid). If what you say is true, about water boiling in a vacuum, how is it that we can hold such a good one in our condenser?"



WILL THE PIPE SIPHON?

"That's right, Kid. If you don't know, find out," replied the chief. "I'll explain it for you, but the best way is to consider such things is to 'dope' them out for yourself. According to the steam tables, water will boil at 32 degrees Fahrenheit in a vacuum of 0.089 of a pound, absolute pressure, which is a prohibitive vacuum to maintain for a condenser. You have at times some [illegible] a 28½ inch [illegible] inches, which is as much as you get as a steady thing. This would give an absolute pressure of about [illegible] pounds per square inch and a boiling point of nearly 126 degrees Fahrenheit.

"Now the water in the condenser [illegible] cooling water having a constant circulation. If such a thing should happen it would mean a great deal more work for your dry-vacuum pump."

This ended the discussion, and the salesman, after handing the chief another of his "El Ropo" cigars, wended his weary way, while "Jimmy" went back to his engine, thinking of the long years ahead of him before he could master the knowledge the business seemed to need.

Brookdale, N. Y.

Economy of Different Speed Engines

In the issue of March 30, page 600, William E. [illegible] seeks by use of a chart to show the economy of an 8x10 engine over one 8x8. There is an old saying that figures don't lie, but I don't know about that chart.

I will not go into lengthy details, but assume [illegible] that figures lie, and if he cares to go into it he can [illegible]. I assume that these engines make the same number of revolutions per minute. We will say, for sake of illustration, that the piston rods are the same diameter, 1½ inches in round figures. The 8x10 engine cutting off at one-third stroke on its [illegible] uses 223 cubic inches of steam at each complete revolution. The 8x8 engine cutting off at [illegible] stroke, or [illegible] inches, uses [illegible] cubic inches of steam at each complete revolution. According to [illegible] there is a difference of [illegible] cubic inches of space to be filled with steam at each revolution in favor of the 8x8 engine. Assume that these engines are running 250 revolutions per minute, which, according to my figures, would make [illegible] cubic inches per minute in favor of the 8x8 engine. What this would amount to in pounds of steam per day, I have not figured. In [illegible] of the economy we find that it takes [illegible] of [illegible] to run engine [illegible] and [illegible] make the [illegible] of [illegible]. If these two engines are what I am [illegible], I should be pleased to have him [illegible].

[illegible]

[illegible], Mass.

Steam Engine Experiment

At the artisan school we have been doing a cranky thing in steam-engine business that may be good, and surely will astonish the steam-engine engineers. We have at the school a center-crank shaft-governed 6x12 engine which is three or four times too large for the job. On cold days we have to have a lot more steam to heat the building than we need for power, but on warm days we are not getting our power economically. We had slowed down the engine as much as we could and have it govern, and it occurred to me to try this experiment: We shifted the valve so as to have it take steam only at one end of the cylinder when running light, but at both ends when starting.

The only thing now was to see that the governor ball could go out far enough to cut off the working end and not allow the engine to run away when running light. The thing is working all right, and the boy says he does not have to shovel as much coal. One experiment does not prove much, and maybe this will inspire someone else to try it.

My notion was that by so doing we would cut the initial condensation and clearance, two main sources of loss, in the middle; and against that the excess of work in punching the exhaust steam out of the idle end of the cylinder. The first thought was to stop off the crank-end part, but if we did that, leaving the engine the same, water passing the piston might accumulate and cause a smashup; or, if we took out the packing, or opened the pet cock, we would have no compression to stop the noise at that end of the engine.

When circumstances justify repeating this experiment it would seem to be worth while. Our coal bill at the end of the month will prove results, as so far the weather has been about the same. The coal is uniform, and the same boy is fireman.

A Power Plant Layout

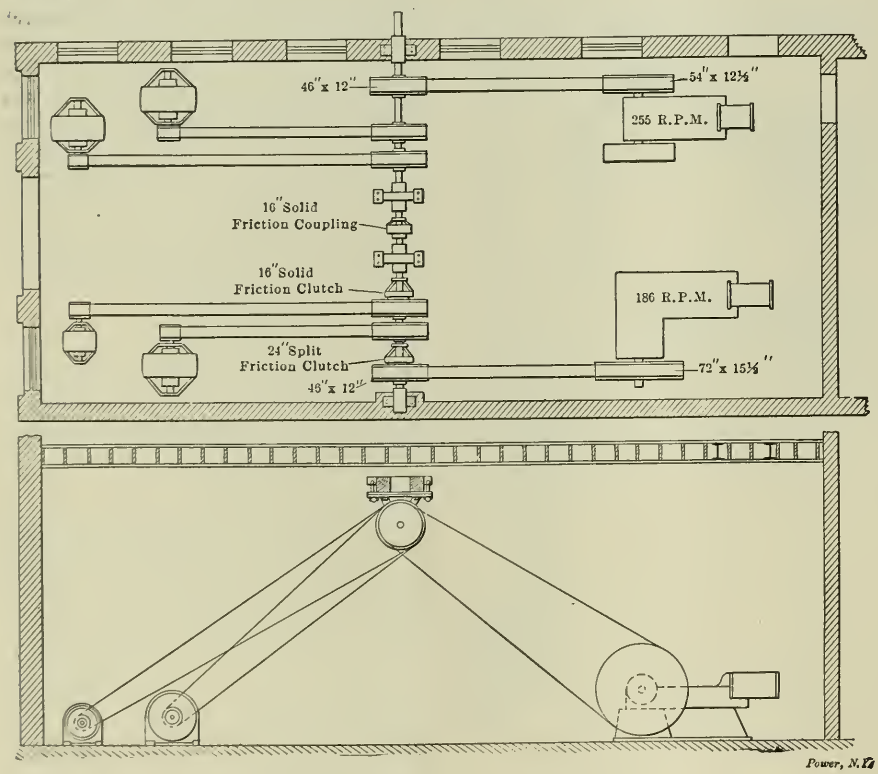
The accompanying illustration shows the layout of the engine room of a factory. There are two engines, one of 85 horsepower, running at 255 revolutions per minute, the other of 50 horsepower, running at 186 revolutions per minute. Both are belted to the same jack shaft, running at 300 revolutions per minute. The 50-horsepower engine may be thrown in or out by means of a friction clutch.

The 85-horsepower engine is sufficient to run the factory during the forepart of the day, but in the evening, when the heavy load comes up, the engine will not pull the load, and the 50-horsepower engine is thrown in by means of the friction clutch. The combination of the two engines seems to take care of the load all right.

Which engine carries the load, or does each take its portion?

C. L. Wilson.

Louisville, Ky.



LAYOUT OF FACTORY ENGINE ROOM

Gas Burns in Smoke Flue

One of the boilers in my boiler room persists in burning gas in the front connection and in the stack. It is a horizontal tubular boiler, 20 inches long and 60 inches in diameter with 4-inch tubes.

I have examined it carefully, and seen that the tubes were properly cleaned, the combustion chamber emptied, and all holes in the brickwork stopped, still the trouble persists, and requires the opening of the fire doors to stop it. This occurs mostly on quiet days when the draft is poor. It has done this ever since I have been here and, I am told, ever since it was installed. Others, of a different make but same type, working alongside, cause no trouble.

I have had my men try light and heavy firing, but nothing seems to improve the condition. Any suggestions as to remedying the trouble will be appreciated.

E. A. Adams.

Lujane, Colo.

Keying Flywheels

H. Wiegand gives some very good points concerning the keying of flywheels on shafts, in his letter which appears on page 608, of the March 30 issue. It is essential that a wheel should fit the shaft so that not the slightest lost motion or, rather, looseness, exists. If the wheel is loose, no arrangement of keys will make it entirely satisfactory, if the operating conditions are severe.

The object of a key is to prevent the wheel from turning on the shaft, not for the purpose of making it fit the shaft. If a wheel properly fits the shaft, the key need not fit tightly, top and bottom, but should fit snugly sidewise, and simply "fill the hole," top and bottom; thus, no strain is given the wheel as referred to by Mr. Wiegand, yet it will be perfectly secure and will never turn, nor will there ever be any tendency for the key to work out.

Driving in a key that is fitted top and bottom only, simply being a sliding fit sidewise, would tend to ease the part of the bore of the wheel near the keyway, from the shaft, and so destroy what was at first a good fit. Many a propeller wheel have I worked upon where after the wheel had been fitted on the taper shaft, the key was fitted to drive nearly all the way—tight sidewise—until it just "filled the hole," top and bottom, without putting any undue stress upon the hub of the wheel. The key could not get out, even though it should ever get loose, which if properly fitted is not possible to happen.

Probable Cause of Air Compressor Explosions

In a recent issue Mr. Richards took exception to the suggestion that leaky discharge valves may cause very hot air to be discharged from the compressor, the argument being that the re-expansion of the air leaking back will cause it to be cooled again.

In practice it has been found that free expansion of air does not cause the air to be cooled anywhere near the theoretical temperature, or the temperature obtained when this expansion takes place in a working cylinder. A leaky valve would not be like a specially designed nozzle, by any means. There would be considerable friction which would have quite an influence upon the temperature of the leaking air. Perhaps Mr. Richards has noticed a small pipe will get hot when cold air is blown through it at a very high rate.

As to 5 per cent. being a large amount of leakage, that would depend upon the type of compressor. I think 5 per cent. would be easily exceeded when a valve or two "go bad." I have heard of cases where the leakage was enough to be noticeable in the amount of opening which the suction valves were operating with.

F. W. HOLLMANN.

Baltimore, Md.

Improve the Diagrams

In answer to Linden A. Cole, I would say that the admission lines in the high-pressure diagram are good, yet if the crank end took steam a little earlier, it may rid the diagrams of the round corners. The expansion line in each case is fair, but the exhaust valve is slow in opening. The expansion line of the head-end diagram indicates leakage of steam through the admission valve; the cutoff is also unequal, the head end doing the more work.

In the low-pressure diagrams the steam lines are poor, as the piston travels some distance before full pressure is shown. The cutoff here is also unequal, the crank end doing most work. The steam valves probably leak, as shown by the expansion lines. The exhaust valve in the crank end starts to close before the head-end valve, but less compression is shown, which is probably due to a leak.

The boiler pressure is 150 pounds and the scale of spring for the high-pressure is 80, yet the steam line is only 1 1/4 inches above the atmospheric line, denoting a pressure in the cylinder of 100 pounds. What became of the other 50 pounds? Scaling the diagram, we have about 10 pounds back pressure, but how about the receiver pressure of 15 pounds? Is the steam throttled or passed through a reducing valve between the boiler and engine?

E. G. HARRIS.

Burlington, Ia.

Two Commutator Devices

The accompanying sketches are of two appliances that I have used quite a while and found very useful. In Fig. 1 is shown a commutator clamp. It is very often necessary to take out the end rings of a commutator on account of internal grounds, and by having a clamp that will hold the segments firmly and perfectly

FIG. 1

round, it becomes an easy matter and also saves turning up in a lathe. I have tried numerous kinds, but the trouble with them led me to make the one herein described. It is made of 2x1/4-inch steel, with a 1/2-inch screw. The drawing clearly shows the adjustable fastening. The bending is around rivets on one side of each fastening, which can be moved by removing the two cotters. The clamp is made loose or taut by screwing the bolt in the nut.

A sandpaper holder for commutators is shown in Fig. 2. The sandpaper is made fast on top by a clamp and screw. The two face blocks are pivoted and adjust

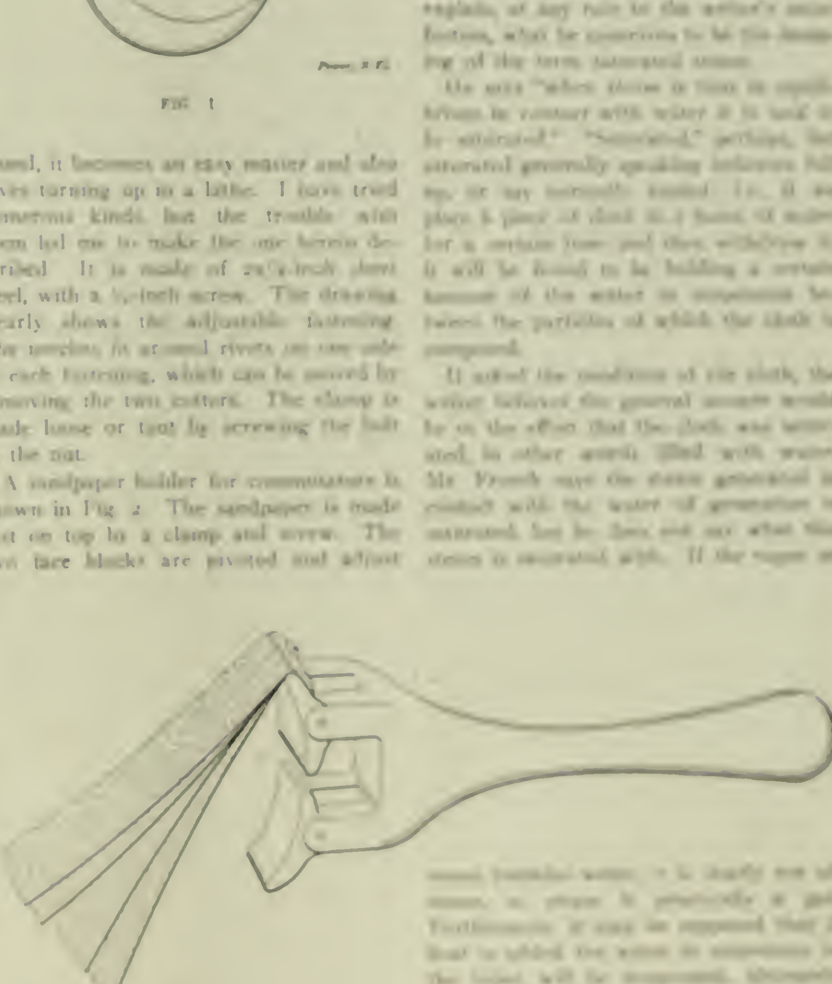

FIG. 2

themselves to the commutator, and will fit any size of commutator. If it has been [illegible] the heavy block will go in between the brushholders. It always keeps the commutator level and smooth, and is absolutely indispensable around an electrical shop. The one I have been using has [illegible]-inch face blocks.

Hygrometry

In the issue of February [illegible], page [illegible], J. French, in a not very gentle manner, gets after the writer's contribution in January. Mr. French's suggestion has referred to a handbook dealing with steam problems, written by a well known authority, and strangely enough, perhaps, finds his views confirmed by at any rate one authority.

The book referred to is "Condensers," written by F. M. Low, and the confirmation mentioned is found at the top of page 18. The writer is fully aware of the rather general definition given in the majority of steam handbooks, but at the same time would suggest that this, as also Mr. French's attempt, is somewhat ambiguous. Even now, Mr. French does not explain, at any rate to the writer's satisfaction, what he conceives to be the meaning of the term saturated steam.

He says "when steam is [illegible] in equilibrium in contact with water it is said to be saturated." "Saturated," perhaps, but saturated generally speaking indicates full up, or say naturally loaded. I.e., if we place a piece of cloth in a basin of water for a certain time and then withdraw it, it will be found to be holding a certain amount of the water in suspension between the particles of which the cloth is composed.

If asked the condition of the cloth, the writer believes the general answer would be to the effect that the cloth was saturated, in other words filled with water. Mr. French says the steam generated in contact with the water of generation is saturated, but he does not say what this steam is saturated with. If the vapor or

[illegible] water, it is clearly not all steam, as proper, is practically a gas. Furthermore, it may be supposed that if heat is added, the water in suspension in the vapor will be evaporated, ultimately giving us all steam, which the writer believes Mr. French would call "dry and saturated steam."

Once again, be it noted, the expression "saturated steam" still appears, although all moisture has disappeared, but no indication is given as to what the steam or vapor is saturated with. Still further, if we allowed all the water in the boiler to be evaporated, we would obtain a boiler full of steam or vapor, and as there is now no water in contact with the steam it would be of interest to learn what kind of steam Mr. French would call it. The latter condition approaches somewhat to that existing in a steam pipe remote from a boiler, generally *superheated steam*, inasmuch as we may suppose the radiation losses sufficiently great to cause the steam to lose all its vapor, or extra heat, above that normal to saturated steam of a given pressure, and then we have the condition as suggested by the writer of steam just saturated with heat units. Any further loss of heat would mean that the steam would not be saturated with heat and that it would contain less heat than the quantity as given in the steam table for any given pressure. Moisture would then appear, but the steam would not be saturated with water or moisture until a much greater heat loss was made, so what is it saturated with?

The writer is quite aware that this is not, strictly speaking, a practical point, but is really a theoretical one, and therefore most important that it be thoroughly understood.

W. Vincent Treeby.

London, England.

Making Improvements in a Small Power Plant

A certain power plant consisted of a 100-horsepower horizontal tubular boiler, a feed pump, a closed feed-water heater and a 50-horsepower high-speed engine for driving a dynamo for electric lighting and a line shaft for power.

In the dyehouse proper were eleven wooden tanks, 10 feet long, 4 feet wide and 4 feet deep, each filled with about 1000 gallons of water, heated by live steam. There were also two dyehouses containing coils of 1-inch iron pipe, using live steam at 80 pounds boiler pressure.

Exhaust steam could not be used directly in the tanks, on account of the cylinder oil which it contained, the slightest amount of which would spoil the dyestuffs. Neither could a steam coil be put in the bottom, as the steam had to boil the water thoroughly to dissolve the dyes and chemicals used. The best plan seemed to be to heat the water before putting it in the tanks. The feed-water heater was too small to supply both the boiler and tanks with hot water. Two of the eleven tanks were seldom used, however, so they were raised about 10 feet above the others, on suitable supports and coils of pipe set in one of them in a horizontal position. After making connection with the exhaust line, after leaving the feed-water heater, exhaust steam was turned into the coils and the water was quickly brought to a high temperature. A valve and float regulated the cold-water inlet.

The tanks were connected so that when the first, in which the cold water entered, was about two-thirds full, it overflowed into the second, from which a connection was made about 1 foot from the bottom for filling the dye tanks. The object in connecting the tanks this way was to keep one always filled with boiling water, and kept boiling by a steam coil placed in the bottom, while the other was filling with cold water. After these changes were made it was necessary only to use live steam for from 5 to 10 minutes to boil the dyes, instead of from 3¼ to 1¼ hours, as before, and not only was the live steam saved, but also the time, which in a day's run amounted to considerable.

The next thing to get at was the dyehouse, where there was an enormous waste of steam. Instead of connecting the coils to a good steam trap, and returning the condensation to the boiler, a 1-inch valve was screwed on the end of the coils, and as this valve was usually kept about one-half open, an enormous amount of steam and water was continuously blown out and wasted. I had noticed that when the water was used freely, the temperature often went down to 150 degrees, and even lower, and more live steam had to be used, while at other times the temperature was usually about 200 degrees.

Another steam coil was put into the second or storage tank, laid flat about 6 inches from the bottom, and the steam and water from the dyehouse coils passed through it, and after passing through a steam trap the water was discharged into the cold-water tank supplying the boiler-feed pump. After putting in this coil the temperature of the water in the storage tank was always from 210 to 212 degrees. When the tanks were working at their capacity there was no sign of any exhaust steam escaping, only a continuous stream of water running from the drain pipe to the sewer.

To force the exhaust through the coils a back-pressure valve was made and weighted to about two pounds. This valve was about the simplest thing imaginable, and consisted merely of a round piece of cast iron, about ¼ inch thick, and large enough to cover the exhaust pipe. It was covered on the bottom with a piece of sheet lead riveted on to form a seat on the end of the exhaust pipe, which was filed off flat and even. The valve was hinged to an iron clamp around the pipe, and a small chain running down to the engine room with a weight attached. On the hinged side, the iron clamp was turned upward so that when the exhaust steam opened it wide open it could not fall completely back, but rested against this upward projection, and could always be closed again from below.

Before these changes were made the amount of coal used per week was 12 tons, and after the change eight tons, or a difference of four tons per week, which at $2 per ton, the price at that time, made a saving of $8 per week, just one-half the engineer's salary.

Although this saving may seem small, it must not be forgotten that this was a very small plant. The total cost of making these changes including pipe, valves, fittings and labor, was $100. In three months it had paid for itself, and the saving in one year was $416.

Trouble with a Dynamo

If Mr. Baker will take a piece of clean cloth, wipe his commutator, and rub a wax candle on the commutator two or three times a day it may help him to overcome his trouble with sparking.

William F. Taylor.

Frankfort, Penn.

Knock in the Engine

In a recent number, Mr. Bryan tells of a pound in his engine. I should say that the pounding was caused by water in the cylinder. I suggest that if he has no steam trap in his header line he put one in. Also give his engine time thoroughly to work the water out of the cylinder.

H. R. Williams.

Chanute, Kan.

Will the Load on the Bolts Change?

I should like to ask Mr. Fischer who, in the May 4 number submits an answer to Mr. Glick's cylinder-head bolt problem in the issue of March 30, page 609, how a bolt can be extended without an increase of the tension in it. What stretches the bolt except an increase of tension? And if the bolt stretches enough to relieve the pressure on the cylinder flange or the gasket a given amount, is it not only by the imposition of an equivalent force producing tension and consequently stretch in the bolt?

Julian Ralph.

Easton, Penn.

Centrifugal Pumps

In the March 16 number there was another article on centrifugal pumps, by George B. Pearce. He does not seem to have decided one way or the other, as to whether the pump requires more or less power with the discharge valve closed.

I am operating three 12-inch motor-driven centrifugal pumps, which will lift water 20 feet after they are primed. If I close the discharge valve the motor requires only 30 amperes, while with the discharge valve wide open 45 amperes is required, a third more than when it is closed. We operate the pump with the discharge valve closed so as to give 40 amperes on the motor, which furnishes all the water we require for the condenser under any load.

Some Useful Lessons of Limewater

A Test for Water; Importance of Marsh Gas as Related to the Chemistry of Carbon; Table of Carbon Compounds; What Carbon Monoxide Is

BY CHARLES S PALMER

We will go right on with the study of carbon and its compounds; but right here I will mention a test for water which will be very convenient to know and to use. Get an ounce or two of common "blue vitriol," or sulphate of copper ($CuSO_4 + 5H_2O$). You will note that the formula is C-u-SO_4, plus five molecules of water. By the way, "Cu" is the chemical abbreviation for the Latin word *cuprum* for copper. This water, which is always found in blue vitriol, seems to be a part of the crystallized form, for the blue crystals always take up five molecules of water for one molecule of the copper sulphate they contain. If you powder an ounce or so of this blue vitriol and then put it in a saucer and heat it, stirring it now and then, it will lose most of this water at a temperature a little above 212 degrees Fahrenheit, that is, on the common thermometer. On the Centigrade scale, which is used by nearly all working chemists, this temperature, that is, the temperature of boiling water, is 100 degrees Centigrade.

Now, if you heat the powdered blue vitriol, carefully, a little above this temperature, it will lose most of the water and will change from a bluish powder to a light gray, almost white. This is "anhydrous," that is water free, or almost so, for it still contains a little water. Do not heat it too high, for, if you do, the white anhydrous copper sulphate will decompose still farther and will be useless for the test for water. Now take a knife-pointful of the white or grayish anhydrous copper sulphate and lay it in a clean saucer, afterward touching it with a drop of water, when it will at once become blue. Of course, you can see that when water is added to the anhydrous copper sulphate it takes up the water again which it lost on heating, and passes back to the hydrous or blue form of copper sulphate, that is blue vitriol; and so this adding of a mere trace of water to the white anhydrous copper sulphate, whereby it becomes blue, makes a very delicate test for the common substance, water.

This anhydrous copper sulphate can be used for testing not only large quantities of water, but also, if one is careful, for the merest trace. Thus, we mentioned in one of the previous lessons that the steamy layer formed at the bottom of the inside of a lamp chimney when the lamp is first lighted and when the lamp chimney is cold is water, and this can be proved by taking the lamp chimney off the lighted lamp while the chimney is still cold and dusting a little of the white anhydrous copper sulphate upon the steamy layer on the inside lower part of the chimney, when one can get a faint but distinct bluish or greenish-blue tint due to the presence of water. Your common sense will teach you how to use this test in dozens of cases as we go on; and it will be very handy to test the appearance of water as it presents itself now and then, without depending alone on the statement that it is water. You want to be sure and get this *blue* vitriol or sulphate of copper; do not confound it with *green* vitriol, the sulphate of iron, nor with *white* vitriol, the sulphate of zinc.

The Importance of Marsh Gas

The next point in the chemistry of carbon which we will consider is the importance of methane or marsh gas. This is the most important hydrocarbon of all the many hundreds of compounds of carbon and hydrogen. Theoretically in all cases, and practically in many cases, the other hydrocarbons can be obtained, directly or indirectly, from marsh gas. Therefore, if one can obtain marsh gas he can go, by various chemical changes, to any of the other compounds of carbon. Now this is a very remarkable fact: it means that if one can obtain marsh gas, he is practically in command of the whole chemistry of carbon; if one can obtain marsh gas, he has practically at his command all the compounds of carbon, and that means most of the thousands of compounds in organic chemistry. It is interesting to know that this substance, marsh gas, is found not only in natural gas and gas from wood, but it can also be made artificially from purely inorganic sources. Among the many interesting compounds which the late French chemist, the great Moissan, produced by means of the electric furnace is a carbide of aluminum, Al_4C_3. This aluminum carbide is a gray or dark-brown powder, and is decomposed with water, giving off marsh gas, and leaving behind aluminum hydroxide, according to the equation:

Aluminum carbide		Water		Aluminum Hydroxide		Marsh gas
Al_4C_3	+	$12H_2O$	=	$4Al(OH)_3$	+	$3CH_4$

It is not necessary for you to memorize this equation, but it will be a good thing for you to remember that marsh gas can be obtained by the action of water on aluminum carbide, a product of the electric furnace.

Now, the point at which we are aiming is this: Marsh gas is fundamental to and typical of the organic compounds; and the organic compounds are found very commonly in the living tissues of plants and animals. Consequently, some have argued—perhaps rather hastily—that if marsh gas and the organic compounds can be made artificially from inorganic sources, living organisms, like plants and animals, can be made artificially from inorganic compounds without the go-between of any living egg or living tissue to help the process. This may be true, but you must bear in mind that it is no proof that chemists could make living plants or animals just because they can make methane and many other thousands of organic compounds from inorganic sources.

Chemical action is one thing, and the life process (which makes plants and animals, although it uses chemical action) may be quite a different thing. My own opinion is that the life process uses chemical action and is largely controlled by it, and yet the life process is something entirely distinct from and, in a large sense, superior to chemical action. But this is only my opinion, and the opinions of others who may differ from me in this respect are certainly worthy of consideration. The trouble is that at the present time we have little knowledge of the real nature of chemical affinity, and still less of the nature of the life process as found in living plants and animals, and it is really rather premature for anyone to have a very strong opinion on either side of this much-discussed subject. Indeed, it is much safer to hold all such questions in your mind in what is called "suspended judgment." Then, whenever these questions do come up, one ought to remember that marsh gas itself, and from this many thousands of organic compounds which are found in connection with living plants and animals, can be made artificially from inorganic sources; but notice that though we have made the substances we have not, at least, [illegible] made the living process. This also is one of the things over which you may like to ponder now and then.

The Carbon Compounds

Just here I want to ask your attention

for a few minutes while we study together the accompanying remarkable table of some carbon compounds. It will look to you at first like a long, stupid and blind affair; but if you will note a few things about it—I should not think of asking you to memorize it—it will give you some very clear notions regarding the simple relations between hundreds and thousands of compounds. Thus, you will notice that, in the first column of this table are given the hydrocarbons of the marsh-gas series; and you will notice that the constant difference between any hydrocarbon and the next higher is measured by two atoms of hydrogen and one atom of carbon, or "CH_2"; that is, starting with methane, CH_4, if you add "CH_2" you will get the next higher hydrocarbon, C_2H_6, or ethane; and so on. Now the next column of the table gives the first oxidized form of the hydrocarbon, that is, the "alcohol"; and so corresponding to methane we have methyl alcohol; and corresponding to ethane we have ethyl alcohol; and so on. You will also note that between any two of these alcohols we have the same numerical difference, "CH_2," that is, one atom of carbon and two atoms of hydrogen, that we had between any two of the hydrocarbons. Thus, if you add this constant difference, "CH_2" to methyl alcohol, CH_3OH, you get the next higher alcohol, ethyl alcohol, which has the formula, C_2H_5OH; and so on through the list.

Reduced.	TABLE OF SOME CARBON COMPOUNDS.		Oxidized	
Paraffin Hydrocarbons.	Alcohols.	Aldehydes.	Acids.	
Methane, CH_4.	Methyl Alcohol, CH_3OH.	$H\,CHO$.	Formic.	$H\,CO_2H$.
Ethane, C_2H_6.	Ethyl Alcohol, C_2H_5OH.	CH_3CHO.	Acetic.	CH_3CO_2H.
Propane, C_3H_8.	Propyl Alcohol, C_3H_7OH.	C_2H_5CHO.	Propionic.	$C_2H_5CO_2H$.
Butane, C_4H_{10}.	Butyl Alcohol, C_4H_9OH.	C_3H_7CHO.	Butyric.	$C_3H_7CO_2H$.
Pentane, C_5H_{12}	Pentyl or Amyl Alcohol, $C_5H_{11}OH$.	C_4H_9CHO.	Valeric.	$C_4H_9CO_2H$.
Hexane, C_6H_{14}.	Hexyl Alcohol, $C_6H_{13}OH$.	$C_5H_{11}CHO$.	Hexoic.	$C_5H_{11}CO_2H$.
And so on.	And so on.		And so on.	

Now, be patient a few moments because the rest of the table will clear itself up just as easily as this part has done. You will note that the next column of the table, representing the next oxidation stage from the alcohols, is the "aldehydes" (put the accent on the first syllable thus, *al*-de-hydes). You will note that although each hydrocarbon and each alcohol has its corresponding aldehyde, yet these aldehydes are named in anticipation of the compounds of the fourth column, or the acids. You will also note that between any two of the aldehydes, there is this same numerical difference, "CH_2," which we found in the hydrocarbon and alcohol columns. Thus, corresponding to methyl alcohol we find formic aldehyde; and corresponding to ethyl alcohol we find acetic aldehyde; and so on. The fourth, and last column, of this table represents the corresponding acids, and between the formulas of any two successive acids you will note there is this same numerical difference, "CH_2."

Reviewing briefly the last paragraph, we find in order from reduced extreme to oxidized extreme (that is, as far as this oxidation goes) the hydrocarbon, the alcohol, the aldehyde and the acid.

It is not my intention to frighten you by loading this table on your memory; but merely to call your attention to the wonderful simplicity in the apparent complexity of the table; and also to the wonderful completeness of the table. If there were any simpler way by which I could give you a notion of the wonderful variety and completeness of the carbon compounds, I would gladly do it; but a little attention to this table will not hurt one, especially as we want to use the substance of this table in explaining the chemistry of many compounds of carbon.

In the first place, a little close attention and a little close thinking are good for all of us, because they help to make "gray matter;" and in the next place, when we try to explain the chemistry of such things as wood, paper, cotton fiber, starch, dextrine, sugar, etc., it will be very helpful to know that all of these things just mentioned are very close cousins to one another, and that they are all only so many complicated alcohols, and in some cases aldehydes (or ketones—pronounced key-tones—which are closely related to the aldehydes).

One can read of hard times or of good times, but these remarks do not mean much unless one himself has seen and lived through some hard times and some good times. One can talk flippantly of working 10 or 12 hours a day, or of walking 40 or 50 miles in a day; but one does not really appreciate what that means unless he has himself done some of these things. So when we read that, of all the elements, carbon is vastly superior in the number, the variety, the completeness and the simplicity of these compounds and these series of compounds—if one reads all this without studying a little over such a simple table as that just given, of the hydrocarbons with their alcohols, aldehydes and acids—he cannot understand easily just what is meant; but with the help of this series of hydrocarbons, with their alcohols, aldehydes and acids, one can get a clear mental picture of something of what is meant by this.

Of course, each of these hydrocarbons, or alcohols, or aldehydes, or acids, is a definite substance; each of these may be a gas, or it may be a volatile liquid; it may be a heavier nonvolatile liquid, or it may be a solid; but each compound, represented by each formula, represents a distinct substance, worthy of study and attention; and all of these substances have had much attention from chemists.

Among the higher compounds in this table there are several varieties, caused apparently by the fact that the atoms, as they increase in number, can arrange themselves in different ways; and the one fact which seems to come out is that among the higher compounds, the backbone of the molecule is made up of a chain of the carbon atoms, and these chains may be straight or branching, and so on. Take the column of acids, for instance. Every acid can form a salt with every base; and so, if lime is a base, then lime can neutralize formic acid, making calcium formate; and, similarly, lime can neutralize acetic acid, forming calcium acetate; likewise, calcium proprionate from pripionic, calcium butyrate from butyric acid (the acid characteristic of butter) and valeric acid, forming calcium valerate; and so on. Furthermore, if sodium, potassium, ammonium (NH_4 the hypothetical but really make-believe imitation of sodium and potassium found in ammonia compounds), if iron, zinc, copper, lead, barium, strontium, silver, aluminum, magnesium, etc., if these metals all make basic compounds, then any one of them can neutralize any one of the acids mentioned in the table, forming the appropriate salts; and there you have an illustration, both of the wonderful richness of the chemistry of carbon, and also of the danger in this richness.

But we will not get lost in this table; simply, we will use the table as an illustration of the marvelous completeness of the oxidation products of the alcohols, aldehydes and acids going out from each hydrocarbon. I am afraid that some of the readers will want to skip this table and this chapter; but do not do that; treat it honestly and fairly, and take comfort from the fact that no other element can put up such a number and variety of compounds as carbon does. I do not hold myself responsible for the chemistry of carbon; Mother Nature made it, and she gives you and me the chance to study it. If a few hard things come up now and then, it may be worth our while to tackle each one in order and do the best that we can with each subject as it comes along.

There is one other point here that I want to mention and that is the way in which some of the formulas are written. Look at the formula for formic acid, $H\dot{C}O_2H$. Now, there are two hydrogens in formic acid, and they are entirely different from each other. One atom of hydrogen is open and active; if we should treat formic acid with zinc you could drive off this hydrogen and collect it, just as you did the hydrogen that you got from hydrochloric acid and zinc, or sulphuric acid and zinc. But the other hydrogen in formic acid is of a different kind from that which can be driven off by zinc. This other hydrogen is hidden away behind the carbon and shows little affinity; consequently, it is a kind of latent or "paraffin" hydrogen. This subject cannot be discussed fully at this time, but this fact is enough to show that in the study of these compounds of carbon there are many new and peculiar points arising which do not come up in the study of the other elements.

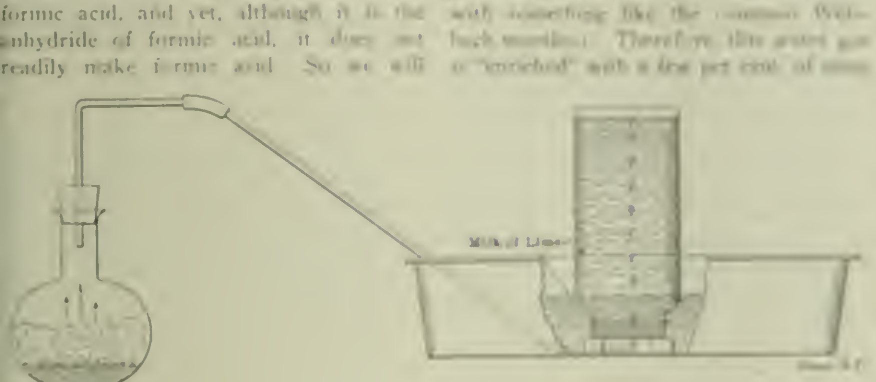
Carbon Monoxide

The next substance to study is carbon monoxide. You want to go back and read the last paper and note where carbon monoxide lies in the table of carbon compounds given in that lesson. You will see that it lies between carbon on the one hand and carbon dioxide on the other, and you will see that it is also related to formic acid in the same way that carbon dioxide is related to carbonic acid. This carbon monoxide can be obtained from formic acid, and yet, although it is the anhydride of formic acid, it does not readily make formic acid. So we will drop the theoretical relation of carbon monoxide to formic acid and will study it simply as itself. It has been mentioned already that this carbon monoxide is found in common city gas, "water gas" so-called, because it is obtained by blowing water in the form of steam on glowing coal, according to the reaction:

$$\text{Coal} + \text{Water} = \text{Hydrogen} + \text{Carbon Monoxide}$$
$$C + H_2O = H_2 + CO$$

If you go through the modern gas plant where this water gas is made, you will see a furnace filled with coal, usually hard coal, which is blown up hot by a blast of air. The gas formed during this process of getting the coal hot is waste gas, consisting largely of carbon dioxide, and is thrown off into the air. When the coal is blown hot, the air blast is shut off, the steam blast is turned on and the action of the steam on the glowing coal results in producing a mixture consisting mostly of hydrogen and carbon monoxide. But in two or three minutes this action begins to chill the coals, the steam is then shut off and the air blast is turned on again until the coal is again hot, when the steam is turned on to make water gas consisting mainly of carbon monoxide and hydrogen, and so on. Of course, this old process of making water gas is a very wasteful process on the one hand, and yet a very cheap process on the other; there are modifications and improvements of this which you will find in some modern gas plants; but, on the whole, the preceding description will apply fairly well to the processes used in many, perhaps most, of the city plants.

Now, this process of making city gas, or water gas, from steam and hot coal, results in a mixture running perhaps 45 per cent., perhaps 40 per cent., of both hydrogen and carbon monoxide. The mixture makes a very hot gas, but one which burns with an almost colorless flame. Therefore, it does not make a good illuminating gas when burned alone (unless it is used with something like the common Welsbach mantles). Therefore, this water gas is "enriched" with a few per cent. of some



MAKING CARBON MONOXIDE

hydrocarbon which will give it illuminating properties. There is one important fact which you want to note about this water gas and that is that carbon monoxide is a very poisonous gas to breathe. The old-fashioned coal gas contained only 5 or 10 per cent. of this carbon monoxide; but the modern city gas, consisting mainly as it does, of enriched water gas, will usually contain from 20 to 40 per cent. of carbon monoxide. Consequently, as compared to the old-fashioned city gas, with its 5 or 10 per cent. of carbon monoxide, was not nearly as dangerous as is at present and a small leak in the modern city water gas.

An exposure of 10 to 20 minutes to the modern water gas, especially in a small closed room, is liable to prove fatal. The reason for this is that the carbon monoxide has a very strong affinity for the coloring matter, hemoglobin, of the red corpuscles of the blood. The red corpuscles of the blood are the substances which carry the oxygen of the blood to all parts of the body; a poisoning by the carbon monoxide of city water gas means a chemical poisoning of the red blood corpuscles. Suffocation from carbon dioxide or hydrosulphuric gas is a different thing, but suffocation from the carbon monoxide is [illegible] very dangerous, as it is so subtle and so hard to overcome. Consequently, considering the [illegible] of human beings, it might be a good idea to follow [illegible] for the pipes of city water gas [illegible] a [illegible] [illegible] [illegible] [illegible]. Of course, such a law would be difficult to enforce; however, it suggests at least a remedy [illegible] of the great danger to which thousands of lives may be exposed every in our houses. The carbon monoxide, therefore, although a very poisonous gas, has a very feeble odor; but it happens that the hydrocarbons which are used to "enrich" the city water gas contain [illegible] compounds which have a very strong and penetrating odor; and this very fortunately is what gives warning of [illegible] in the gas pipes or [illegible] [illegible].

Before we leave the subject of carbon monoxide you will like to make a little of it, using the simple apparatus illustrated by the accompanying illustration. This consists of a flask, provided with a cork, a delivery tube and the pneumatic trough. The flask contains an ounce or two of common oxalic acid mixed with strong sulphuric acid. These two are heated, as shown. The mixed gases pass over to the pneumatic trough, which in this case is not filled with common water, but both the pneumatic trough and the inverted jar for the collection of the carbon monoxide are filled with milk of lime. The gas coming off from the generating flask (containing the oxalic acid and sulphuric acid) is a mixture of carbon monoxide and carbon dioxide, and the milk of lime will absorb most of the carbon dioxide, leaving the carbon monoxide in the flask jar.

From the milk of lime well stirred, as [illegible] there will be plenty of chemical to absorb the carbon dioxide. You will want to collect several jars of this carbon monoxide, which you will test very much in the same way that you did the hydrogen and the marsh gas, for it is a combustible gas, burning with a blue flame. [illegible] the jars from the pneumatic trough [illegible] [illegible] [illegible] the carbon monoxide, it doesn't matter very much whether you leave the jars [illegible] [illegible] [illegible] [illegible] [illegible], because the carbon monoxide gas is almost as heavy as the atmosphere. You will note that it burns with a blue flame and that the [illegible] [illegible] [illegible] [illegible] [illegible] in the jar, unless the gas burns [illegible] [illegible] mouth of the jar in the [illegible] [illegible]. The reaction for the production of the carbon monoxide [illegible] the decomposing action of the sulphuric acid on the oxalic acid will be as follows:

[illegible]

POWER
AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for April, 1909, *was (weekly and monthly)* 153,000.

May 4	42,000
May 11	37,000
May 18	37,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents PAGE

The Engineer in the Navy

Rear-Admiral Melville, in his address to the American Society of Mechanical Engineers, at the Washington meeting, conveyed very decidedly the impression that the engineer in the navy had not profited as much as was expected by the consolidation of the line and the staff. "The only justification," he said, "for the personnel law adopted ten years ago was the statement made by former President Roosevelt that 'on a modern war vessel every officer has to be an engineer;'" and yet the admiral in command of the fleet on its recent cruise had boasted that he had brought the fleet to San Francisco without a single engineer aboard. In true concordance with the spirit of the personnel act he would have said that he got the fleet there as he did because every officer on board was an engineer. If present tendencies are followed the real engineering of the navy will be left to a class of warrant machinists, insufficiently paid and without official recognition or prestige.

There should be no conflict between the line and the engineering staff, neither should there be any attempt to merge the one into the other. There must always be the courtly authoritative executive officer skilled in tactics, and in diplomatic usages, fitted becomingly to represent his Government in any position in which he may be placed; fitted, should occasion require, to fight his vessel or his fleet with all the grim and determined purpose for which it has been constructed and maintained and drilled and manœuvered through years of peace. There must always be the man who represents the muscle of the organization, who wins his laurels at the designer's board in the construction shops and among the mechanism which makes the fleet an effective instrument in the commander's hands. The world is learning the worth of the latter class. The term, "engineer," is becoming to mean something more, as Professor Hutton aptly put it, than a greasy individual with a bunch of waste in one hand and an oil can in the other, and when honors come to be divided the man who builds and engines ships and is responsible for the design and operation of their motive power will receive as much credit for a successful cruise as the man who walks the quarter deck and classes him with the man who peels the potatoes.

In this connection it is interesting to reread an editorial which appeared in POWER for December, 1897:

A conference has been held by a board consisting of seven line officers and four engineer officers, presided over by Assistant Secretary of the Navy Roosevelt, to endeavor to conciliate the differences which have existed for years between the engineer corps and the line. From the public reports of their conclusions, they appear to have sacrificed the efficiency of the service to peace and goodfellowship in the ward room. The line has taken the engineer corps unto itself. The engineer officers will hereafter, if the plan carries, be required to do line duty, and will acquire the long-coveted actual rank and title. The line officers will also be required to do engineering duty to the end that every officer upon the ship may be able to serve either upon the bridge or in the engine room. In order that the engineering duties may not be too onerous for this hermaphrodite functionary, it is proposed that the "machinists" who are enlisted men "shall have more to do with running the engines." This seems to be a case of the lion lying down with the lamb—inside of him. The line has always maintained that the actual care and operation of the engines required only practical mechanics, and that they could do what "bossing" was needed.

"Success lies in limitation." Efficiency comes from specialization. Perry and Farragut labored and shone in an altogether different field from Ericsson and Isherwood. The engineering of a man of war is a department of itself. It should be made to include and control the care and operation of all the machinery in the vessel. No possible excuse can be offered for making a distinction, for instance, between the engines which run the dynamos and any other of the auxiliaries and placing them and the men who run them under the command of a line officer, over whom the chief engineer has no control. The chief engineer should have absolute authority in his department, should be responsible only to the chief officer or his direct representative, and not subject to annoyance nor interference from petty officers of the line. The number of engineer officers should be increased to meet the demand of the more numerous, more powerful, and more complicated vessels which the navy is acquiring, and the officers of the engineering department should have a positive and well-defined standing as regards rank and priority in keeping with the importance and responsibilities of their position. They are not, as it is often made to appear, men from civil life employed to assist in operating the vessel, but a part of a military organization matriculated from the same institute as the officers of the line, and their course is no less difficult, the requirements no less severe. They do not, as we understand it, wish to be known as that which they are not. To be chief engineer of a man of war is a position of responsibility and importance. To be known and recognized as the Chief Engineer is honor enough among those who understand the requirements of the office. It is a position to be proud of, not to be hidden under a meaningless title. But what is the position of the Chief Engineer relatively to the other officers? Some of them have the relative rank of captain, others of commander, lieutenant-commander, etc.; but this does not mean that they have an authority even in their own departments commensurate with those titles, or that they assume among the other members of the personnel positions in accordance with their relative rank. What they ask is positive rank with appropriate titles.

Anonymous Communications

Letters asking for information are frequently received to which the writer has failed to add his signature, or in some other way made a reply except through the columns of the paper impossible.

Questions are often asked which while not of sufficient general interest to be published are of special interest and importance to the individual, and if possible these are answered by mail.

Communications which are anonymous by intention or accident cannot be answered or placed on file and the questioner and the paper are both losers, because someone did not identify himself with his letter.

It is usually assumed that the omission of the signature or a place of residence is accidental, but when a correspondent uses the stationary of his employer and carefully tears from the top of the sheet all printed matter, except the date line, and affixes one, two or three initial letters to the end, it may be taken for granted that he intends to conceal his identity.

All letters received are treated confidentially and are accessible only to those who have a moral and legitimate right to their contents, but the signatures are required for two imperative reasons, either of which is sufficient in itself—as a guarantee of good faith on the part of the writer, and for the purposes of filing for future reference.

A third reason, although perhaps not as important, is that it is not always possible to reply by mail to a correspondent whose name or address is hypothetical.

While on this subject, it may as well be intimated that there is much more satisfaction derived from a letter which is written upon one side of the paper only than from one which jumps from the first to the fourth and then to the third page and finally finishes on the second page of society notepaper.

Grammar, spelling and penmanship are matters of secondary importance and even the English language is not imperative, for correspondence is received from India, China, Japan, Russia and, in fact, from all parts of the world, and Choctaw, if legibly written and properly signed, will receive the same prompt and courteous attention that is given to the most elegantly typewritten and carefully edited letters that reach the office.

In conclusion, it is urged that correspondents write upon one side of the paper only, leave a generous space between the lines and write signature and address as legibly as possible, thus coöperating with the paper to make it satisfactory to all interested.

Decision on Anthracite Case

On May 3 the Supreme Court of the United States, in the case of the Government against the anthracite roads, handed down a decision to the effect that the commodities clause of the Hepburn rate act was constitutional. On the surface this decision, which was a reversal of the finding of the Federal Circuit Court for the Eastern District of Pennsylvania, was a sweeping victory for the Government, but by the court's interpretation of the law victory actually rests with the coal roads.

It is generally understood that the original purpose of the Hepburn act was to prohibit railroads from carrying commodities which they own or in which they were financially interested, and in this particular case the Government was endeavoring to enjoin the anthracite roads from violating the law by transporting coal owned by them or by coal companies in which they owned stock. The court decided that such ownership of stock in coal companies by the railroads was neither direct nor indirect interest in the commodity, within the meaning of the law, so that the railroads are permitted to continue their coal business through other corporations and even to own the mines, provided the coal is sold in good faith before it is transported. In short, the law is constitutional but is limited to such an extent that it cannot possibly be enforced as intended when the bill was passed.

Only two of the anthracite roads are affected by the decision, and these are the Delaware & Hudson and the Delaware, Lackawanna & Western, both of which own the mines. [illegible] necessary for these companies to transfer the mines to a subsidiary company, of which they may own all of the stock, or sell the coal at the mines instead of transporting it to tidewater before the sale is made. The roads will no longer be allowed to contract for the sale of the independent operators, but their subsidiary coal companies may do so, and as they own all or at least a controlling interest of the stock of these companies, the distinction is merely a question of bookkeeping. The coal combination may continue to operate on practically the same basis as before, continue to regulate the price of anthracite, charging what the trade will bear, and monopolize as they have for a number of years, the anthracite industry. The only change that the decision effects is to compel such railroad companies as would otherwise [illegible] to go through the form of organizing nominally separate coal companies or proceeding to sell the coal prior to shipment from the mines.

Marine Gas Power

Those who have grown accustomed to thinking of the gas engine and producer as a rather cumbrous and widely spread type of power equipment in comparison with steam apparatus were doubtless surprised at the comparison drawn by Mr. Straub between gas and steam equipment for a lake freight boat, which we published last week.* Of course, it was to be expected that a considerable saving could be effected in the space occupied by fuel for a given "radius of action," because of the higher economy of the gas plant; but it is rather surprising to learn that the engine room proper can be made smaller for a [illegible]-horsepower gas engine than for a steam engine of similar output and general shape. The greatest difference in space, however, is in the generating section of the plant, the boiler room, including coal bunkers, having [illegible] square feet of floor area against [illegible] square feet for the producer room, including coal bunkers. The reason, which contributes most to this difference, is the location of the respective firing spaces; the producer is charged from an overhead floor which adds nothing to the length of the producer room, whereas the boiler stokehold is on the same level with the boilers. The coal bunkers of the steam vessel also add to the length of the space occupied by the power equipment, while those of the gas vessel do not, being elevated.

In detail and altogether, the comparison was a most interesting one and we await with some impatience and much eagerness the actual installation of a gas plant such as Mr. Straub describes. If we might venture a suggestion, it would be that the [illegible] for the proposed gas engine.

Power Plant Machinery and Appliances

Original Descriptions of Power Devices
No Manufacturers' Cuts or Write-ups Used

MUST BE NEW OR INTERESTING

A Patent Boiler Furnace

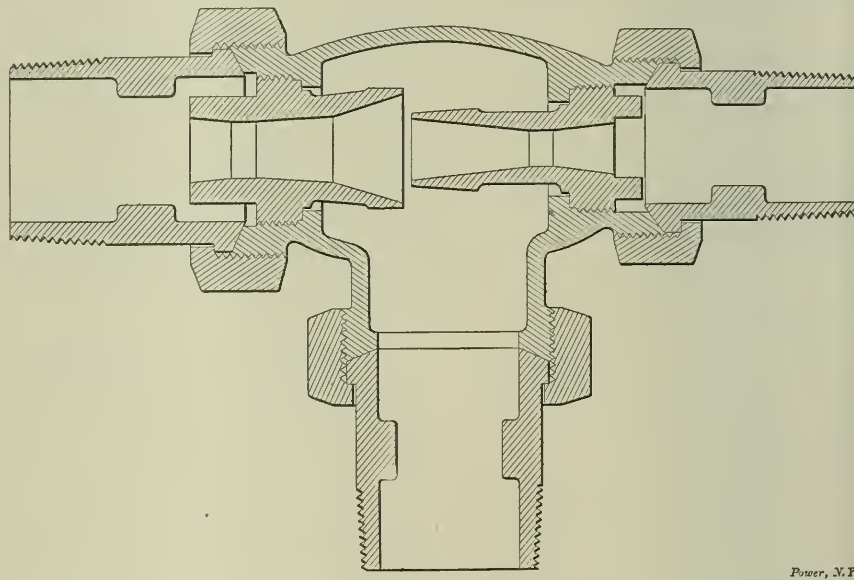
The accompanying illustration shows a patent furnace invented by A. W. Fredrickson, Hardy, Cal. It is in reality a steam boiler and furnace with a water-heating and purifying attachment, the object being to provide an attachment whereby the water may be heated and the sediment contained therein deposited before the water is delivered to the boiler proper in a continuous supply. The device consists of a double steel shell having an intervening space at the top, sides and front, as shown in Figs. 1 and 2. The grate is located in the double-wall section and fuel may be introduced either through the opening *A* or through the ordinary furnace door at the front.

The feed water is introduced in the water legs, where it is subjected to the heat of the inner walls, whereupon the deposits will fall to the bottom of the water legs below the grates, thence it may be blown out through the blowoff passages. The water in this chamber surrounding the firebox will be gradually heated to a temperature substantially equal to that in the boiler proper.

The furnace and heating chamber are separate from the boiler, with the exception of the pipes leading from the upper rear end of the heating chamber, and all the water delivered thereto is expected to be substantially purified and heated to such a temperature that the ebullition will be continued within the boiler in the usual manner.

An Improved Ejector

The Lunkenheimer Company, of Cincinnati, manufactures the ejector illustrated herewith. The claims for superiority made for it are based chiefly upon the tube construction. It is stated to be unsurpassed—on the scores of economy and efficiency—for raising water from deep wells, mines or pits, emptying and filling tanks, or for raising and transferring hot or cold liquids generally, and it is further claimed that it will raise water a greater hight and at higher temperature than heretofore attained. The tubes only are subjected to wear and can be renewed at slight expense. To operate, it is only necessary to turn the steam on fully and after the flow of water is established the steam may be throttled almost wholly.



NEW DESIGN OF EJECTOR

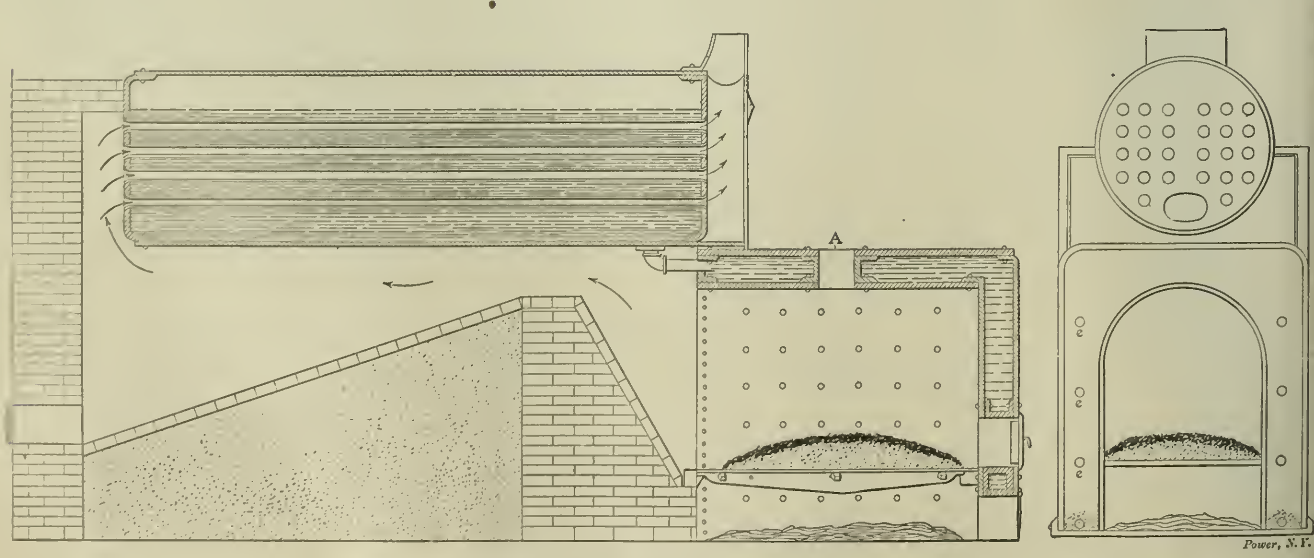


FIG. 1 FREDRICKSON'S PATENT BOILER FURNACE FIG. 2

The New Steam Stack Heater

In the power house there are the smokestack and the steam stack or exhaust pipe. If the boilers operate with an efficiency of 70 per cent., 30 per cent. of the heat units supplied to the furnace (less the small amount lost by radiation) go out of the smokestack. If the engine operates with an efficiency of 10 per cent., 90 per cent. of the heat units in the steam, or 63 per cent. of the heat units supplied in the fuel, go up the exhaust stack or into the river with the overflow from the condenser.

If any use can be found for steam at the temperature of the exhaust, much of the heat which would be rejected by the steam stack or exhaust pipe could be retained and usefully applied, and such opportunities offer in heating feed water, warming buildings and various manufacturing processes. A pound of exhaust steam is just as good for heating or drying purposes as a pound of live steam of the same temperature, and a pound of exhaust steam at atmospheric pressure contains 96 per cent. as much available heat as a pound of steam at 100 pounds pressure. Exhaust steam, as it comes from the engine, contains in addition to the entrained water which it has brought from the boiler and the condensation during its passage, the condensation due to the conversion of heat into work, and is further contaminated by the oil used for lubricating the cylinder. In order, therefore, to apply exhaust steam economically to heating and drying purposes the following points should be observed:

Steam should be thoroughly purified of oil before passing to the heating and drying coils, so that the latter may not become fouled with oil, and so that the condensed returns may be available for boiler feed purposes.

Some receiver or hotwell must be provided for the reception of the returns.

There must be a means of automatically admitting the cold water required to make up for losses by leakage, escape through the back-pressure valve, etc.

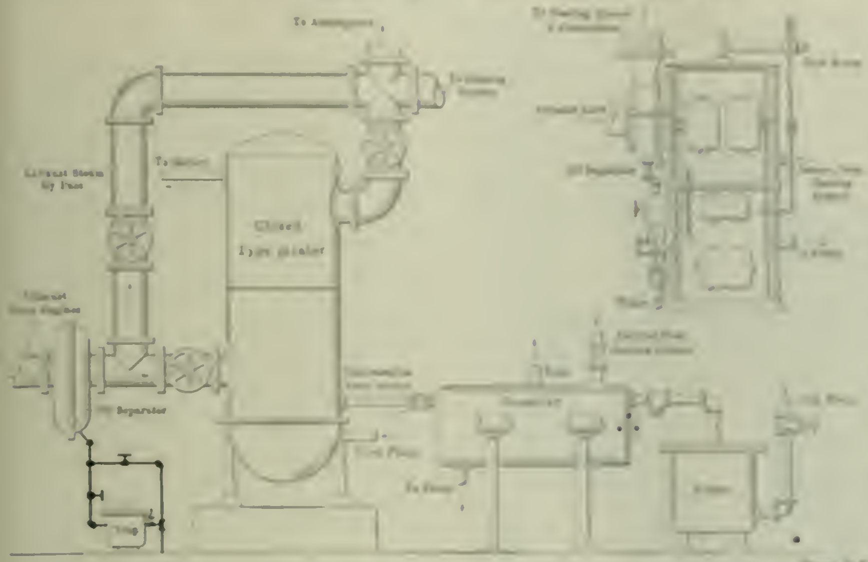

FIG. 1. SHOWING ORDINARY ARRANGEMENT OF A FEED-WATER HEATER [illegible] SEPARATOR AND FILTER [illegible]

It is generally advisable to filter the feed water, and the [illegible] from the feed-water heater and from the heating system must be arranged for. [illegible] is illustrated in Fig. 1.

[illegible]

The new "Steam Stack Open Heater" offered by the [illegible]

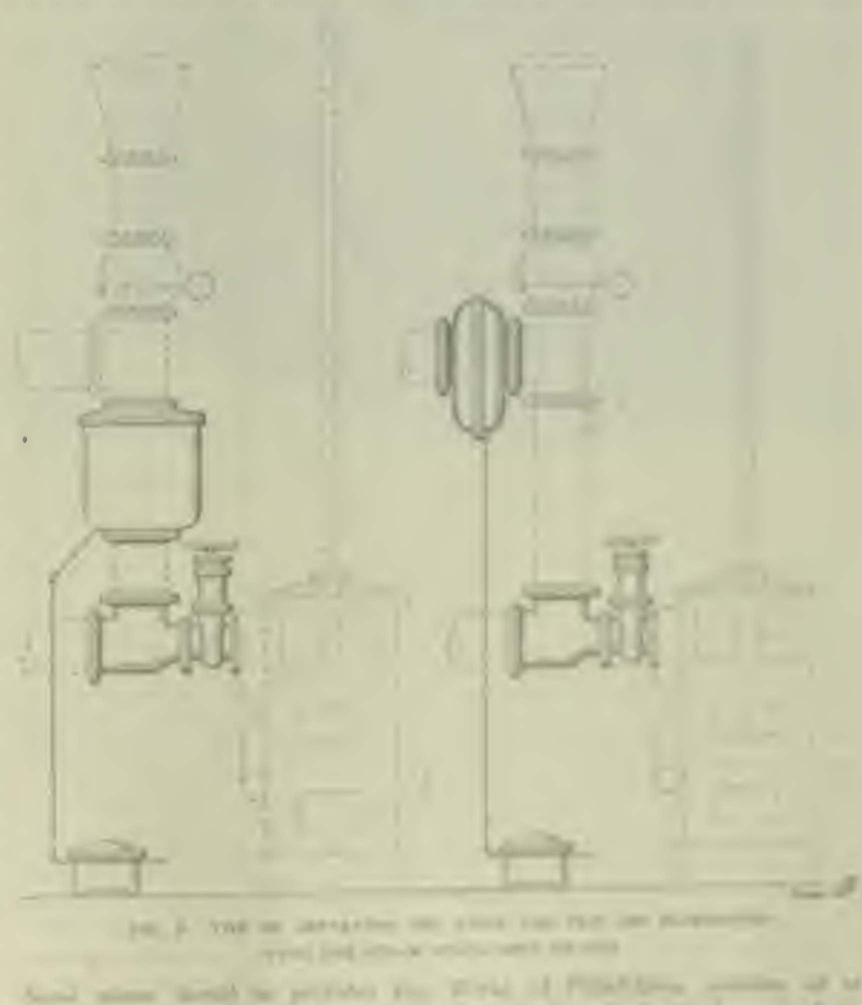

FIG. 2. [illegible]

Good means should be provided for heating the make-up and cold feed water before they are pumped to the boiler.

[illegible] of Philadelphia, combines all [illegible] functions in the single piece of apparatus shown diagrammatically at the right of Fig. 1 and in the views [illegible]

An interior view of this heater is shown in Fig. 3. The exhaust steam is piped to the heater in the usual manner, striking the baffle plate which forms the back wall of the oil separator which removes the oil contained in the exhaust steam. The steam then passes around the ends of the baffle plate and enters the heater where, mingling with the cold-water supply and gravity returns, heats them to its own temperature. The remainder of the steam is then passed on to the heating system thoroughly purified of oil. All oil is carried to the drip tank through a drip pipe. This tank is fitted with a float which operates a valve when the water in the tank reaches a certain hight, when the contents are discharged to the sewer.

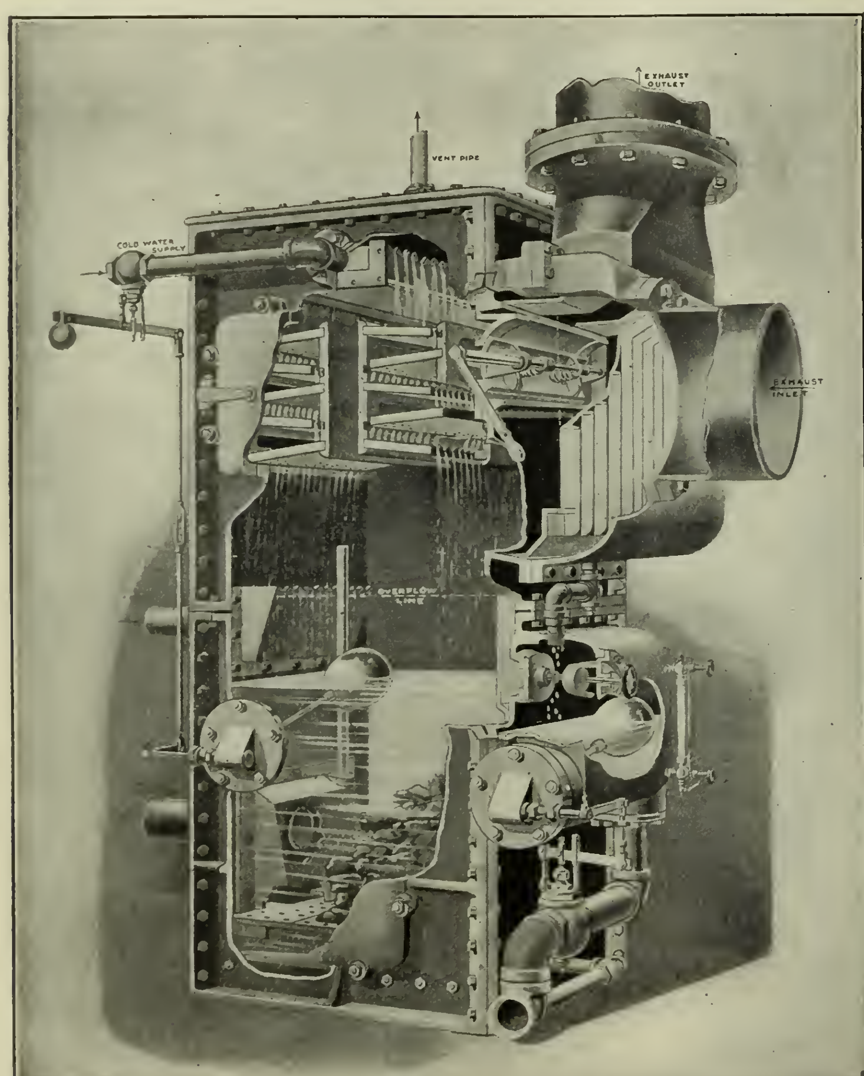

FIG. 3. SECTIONAL VIEW OF THE HARRISON SAFETY BOILER WORKS STEAM STACK OPEN HEATER

After being heated the clean water is drawn from the bottom of the heater, after passing down through the filtering material placed in the bottom of the tank. The water, after passing through perforated plates on which the filtering material rests, passes into a suction box and then on to the feed pump.

There are two features worthy of especial mention in connection with the construction of this heater. By noting the sectional view, Fig. 3, it will be seen that the heater can be entirely shut off from the steam by merely closing the semi-rotary type valve. The valve is shown closed, and the path of the steam is through the oil separator, past the oil-baffle walls and, finding no inlet to the heater proper, it escapes through the exhaust outlet to the heating system. It will be seen that cutting out the heater from service does not prevent the steam from being cleared of oil, as the oil separator is always in service.

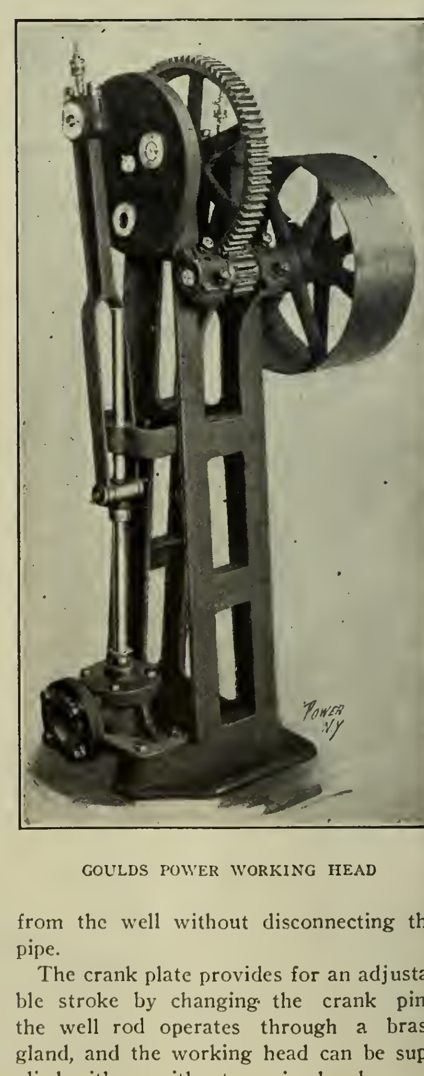
When the steam is passing to the heating system only the small disk valve shown in the oil-drip tank is closed, otherwise steam and oil would back up through the overflow into the heater. When the heater is in service, this valve is open and the overflow and scum from the reservoir, if any, escape into the drip tank and are delivered to the sewer. The float shown in the receiver regulates the water supply so that it remains practically uniform.

Various modifications can be made in the construction of this heater, as in case head room is restricted the steam stack can be connected to the side, rather than the top, or two steam outlets may be used instead of one.

Goulds Power Working Head

With a view of supplying a demand for a compact power working head for operating single-acting cylinders in wells from 50 to 175 feet deep, the Goulds Manufacturing Company, of Seneca Falls, N. Y., recently placed on the market a new type, which is constructed in a substantial manner, owing to the entire frame being cast in one piece.

The gear and crank plate are securely pressed and keyed on the main shaft. The gear and pinion are of charcoal-iron machine-cut from the solid, and the main and pinion shaft run in large babbitted bearings. The well cover is located in the base. It is so arranged that by taking out the bolts which secure it to the frame and disconnecting the well rod, the entire working head can be moved back from the well without disconnecting the pipe.



GOULDS POWER WORKING HEAD

The crank plate provides for an adjustable stroke by changing the crank pin; the well rod operates through a brass gland, and the working head can be supplied with or without an air chamber.

American Society of Mechanical Engineers

Details of the Spring Meeting at Washington; Proposed Amendments to the Constitution; Proceedings of the Gas Power Section

The spring meeting of the American Society of Mechanical Engineers was held at Washington during the week commencing May 3. The sessions were held in the ballroom of the New Willard, where on Tuesday evening the society was formally welcomed to the city by Hon. Henry B. Macfarland, president of the Board of District Commissioners, the response being made by Jesse M. Smith, president of the society. Professional sessions were held on Wednesday, Thursday and Friday forenoons. On Wednesday afternoon the society witnessed a special exhibition drill by troops at Fort Myer, and in the evening, A. P. Davis, chief engineer of the Reclamation Service, presented an illustrated lecture on "Home Making in the Arid Regions."

On Thursday afternoon the members and guests were received by President Taft in the East Room of the White House. On Thursday evening, Rear-Admiral George W. Melville, retired, addressed the society upon "The Engineer in the Navy," criticizing the attitude of the line toward engineering and condemning recent actions of the department in a manner which the morning papers termed "startling," but which seemed to have the sympathy and approval of his hearers. Walter M. McFarland, of Pittsburg, presented, on behalf of a number of his friends, a portrait of the admiral to the historical series of paintings in the National Museum. The portrait was accepted by Dr. C. D. Walcott, representing the Nation.

On Friday afternoon a visit was paid to Mount Vernon. A contemplated balloon ascension and an aeroplane exhibition at Fort Myer were precluded by a thunder squall.

Numerous invitations were received from local institutions of interest, the hospitality of several local clubs was extended to the members and socially the meeting, which was very well attended, was very pleasantly successful.

WEDNESDAY

The first professional session was held on Wednesday forenoon. The membership committee reported 148 names which had been passed upon by the council and they were formally added to the list of members.

Proposed Amendments to the Constitution

Announcements of intended amendments to the constitution affecting the qualifications of associate and junior members were read in anticipation of action to be taken upon them at the annual meeting. That upon associate members reads that:

"An associate shall be thirty years of age or over, and must be so connected with some branch of engineering or science or art or industry that the council will consider him qualified to cooperate with engineers for the advancement of professional knowledge. He need not be an engineer."

To the section relating to junior members it is proposed to add: "A person who is over thirty years of age cannot enter the society as a junior." A further amendment provided for the Public Relations Committee, as proposed by Morris L. Cooke at the last meeting.

O. C. Woolson addressed the society in favor of building a bulkhead around the sunken battleship "Maine," filling it in and erecting a suitable monument upon it.

Papers on Handling Materials

The first two papers dealt with handling materials. "A Unique Belt Conveyer," by Ellis C. Soper, was a description of the installation and operation of a belt conveyer, a quarter of a mile long, requiring less power to operate loaded than empty because the material is conveyed down hill. The only requisite labor to keep it in operation is that of a boy to do the oiling, adjust the rolls, etc.

E. G. Bennett called attention to a 36-inch movable conveyer over 1000 feet long on Riker's Island and other large installations.

In a discussion which ensued upon the life of belting, a member said that in his work a rubber belt lasted 7 or 8 years.

"Automatic Feeders for Handling Material in Bulk," by C. Kemble Baldwin, of Chicago, describes eleven types of automatic feeder in use today, favoring the shaking feeder because of its simplicity and flexibility.

"A New Transmission Dynamometer"

by Prof. William H. Kenerson, described a transmission dynamometer which will be described in a later issue.

There are three factors controlling its sensitiveness, the area of the diaphragm, the ratio of the controlling levers and the diameter of the flanges, so that practically any desired degree of sensitiveness may be had. So, however sensitive it is made, its construction is such that no complication as a measuring instrument would involve an interruption to the operation of the shaft driven through it. The only derangement which suggests itself is the cracking of the balls in the bearing, and the pressure upon them is so slight as to render this hardly possible.

THURSDAY

Gas Power Section

Thursday's session was filled entirely by the Gas Power Section of the society. After reports from the literature, plant operation and membership committees, an interesting report was presented by C. L. Straub on the progress in marine gas producer work abroad. The report indicated that while more has been done in Europe than in America in the application of producer-gas power for marine service, nothing approaching a standardized equipment has yet been developed. The Capitaine producer for gasifying small sizes of anthracite is practically the only one that has thus far shown encouraging results. The largest engine yet undertaken is an eight-cylinder single-acting machine now being built by Vickers Sons & Maxim. No bituminous producer capable of giving absolutely continuous service over long periods under marine conditions has yet been developed.

"Marine Producer Gas Power"

was the title of the first paper of the session. This was read by Mr. Straub at the conclusion of the report just referred to, and printed in very full abstract on page 8[illegible] of the May 11 number.

In the course of the discussion of Mr. Straub's paper, which was quite extended and interesting, E. T. Adams stated that gas engines for land service were now built about 25 per cent lighter in weight per horsepower than they were three or four years ago, because of the improvements in design due to the larger experience gained; therefore the very favorable figures given in the paper need occasion no surprise nor skepticism. Mr. Adams also stated that a plant of large gas engines, with producers and auxiliaries, could be housed in the same size of building that would be required for a steam-turbine plant of equal output with its boilers and auxiliaries, notwithstanding the fact that the turbine is the smallest of all types of prime movers.

Mr. Ober's paper on the "Operation of a Small Producer-Gas Power Plant" was read in abstract by Henry E. Longwell.

Mr. Obert being absent. This paper is printed on page 873 of this issue. The paper did not evoke the discussion which its character merited.

High Compression and Weak Mixtures

"A Method of Improving the Efficiency of Gas Engines," by Thomas E. Butterfield, was the next paper presented. The method consists in using high compression and diluting the combustible mixture with inert gases, such as the exhaust gases of the engine itself. Of course, the mixture is usually diluted to some extent by the products of combustion remaining in the clearance space after each explosion, but the present suggestion is to dilute still farther and to advance the time of ignition in order to compensate for the slowness of combustion produced by the dilution.

Discussing this paper, W. O. Barnes stated that premature ignition due to high compression was not as serious as it was commonly considered. In most cases this sort of preignition indicated faulty design of the combustion chamber, and the vigorous pounding that was sometimes produced by premature ignition was due to the fact that the affected parts were not sufficiently large to take care of the extra stresses caused by the unusual rise of pressure during the compression stroke.

Offset Cylinders

The final paper of the session was one by Prof. T. M. Phetteplace, entitled "Offsetting the Cylinders of Single-Acting Engines." The paper was an exhaustive mathematical analysis of the effects obtained by setting the crank shaft to one side of the line corresponding to the plane of the cylinder centers. The author's conclusion was to the effect that improvements obtained by offsetting are negligible as far as the thermal cyclic efficiency, mechanical arrangement, turning effort and lubrication are concerned; the real advantages are a reduction of the frictional losses due to the pressure of the piston on the walls of the cylinder, resulting in a slight increase in mechanical efficiency and less wear of the piston, piston rings, and cylinder, and consequently longer life; and a reduction of the maximum value of the side pressure of the piston on the walls of the cylinder, allowing the use of shorter connecting rods, shorter pistons, and shorter cylinders, resulting in a shorter and lighter engine and in lower inertia forces due to the reciprocating parts. The most important advantage would be the considerable saving in weight produced by the shortening of parts.

The disadvantage of offsetting lies in the fact that the reductions in average side pressure and maximum side pressure grow less as the speed and inertia force increase, so that for a speed of 1400 to 1500 revolutions per minute, there is either no reduction at all or an increase.

The author's summary of the principal physical results of offsetting was as follows:

Offsetting increases slightly the length of stroke and the crank angle passed over during the stroke toward the crank shaft.

The maximum value for the side pressure of the piston on the cylinder walls decreases as the offset increases up to a value of one-half the crank radius for any ratio of L/R. (L = Length of connecting rod; R = crank radius.)

The work lost in friction due to the side pressure of the piston on the cylinder walls decreases as the offset increases up to a value of 75 per cent. of the crank radius.

Both the maximum value of the side pressure and the work lost in friction increase as the value of the ratio L/R decreases.

Offsetting decreases the height and weight of the engine and increases the life of the cylinder and piston.

The advantages of offsetting as regards the maximum side pressure and work lost may be zero or negative for high inertia forces resulting from speeds of 1500 revolutions per minute or more.

In the course of the ensuing discussion, John H. Norris said that his company (building the Nash engine) had tried offsetting the cylinders over 20 years ago and found that in actual practice no real advantage was obtained by it.

FRIDAY

Papers Presented

The Friday morning session was devoted to the following papers: "Small Steam Turbines," by George A. Orrok (published in the May 11 number, page 850); "Tests on Compressed Air Pumping Systems," by Edmund M. Ivens; "Specific Volume of Saturated Steam," by Prof. C. H. Peabody (published in this issue, page 879); "Some Properties of Steam," by Prof. R. C. H. Heck (published in this issue, page 876); "A New Departure in Flexible Staybolts," by H. V. Wille (abstracted in the February 9 number, page 280).

In addition there was a continuation of the discussion, begun at the February meeting, of "Safety Valves," published in the March 16 number, page 520.

Discussions

In the discussion of Mr. Orrok's paper on "Small Steam Turbines," it was the opinion of Charles B. Rearick that high economy in the small turbine units in many instances is of minor importance. Reliability of service is most important. In nearly all large power plants the exhaust steam is all utilized in feeding water heaters and 80 per cent. of the heat is returned to the boilers. There is only one class of service in which high economy is absolutely necessary, and that is when the unit becomes the prime mover or the main unit for a plant. In this case the turbine is usually all right, for the speed can then be chosen for the best economy.

Charles A. Howard showed by comparing Mr. Dean's paper of a year ago with Mr. Orrok's curves, that the overall efficiencies of the turbine and engine in small sizes after the latter has been in use for some time, are but very little different, with perhaps a little in favor of the engine.

Prof. R. C. Carpenter expressed an opinion that the field of the small steam turbine is somewhat narrow as compared with that of the high-speed steam engine, and that the advantages of the small steam turbine must be due to other reasons than simply that of economy. Figures from the test of a small turbine running noncondensing showed that 350 degrees of superheat had about the same effect as 18 inches of vacuum, and the water rate of a machine given in the paper as approximating 50 pounds per brake horsepower went down to 22 pounds. The small steam turbine has special advantages for many kinds of work and for those kinds of work it was the speaker's opinion that the small steam turbine would ultimately supersede the small piston engine.

R. H. Rice, of West Lynn, Mass., commented on the fact that all of the turbines described are of the impulse, or action type. It was his opinion that the reaction turbine is not suitable on account of the complication and expense of the bucket system for small turbine work, and this leads to the conclusion that the great flexibility of the impulse type will render it the ultimate type of the future, superseding entirely the reaction machines for all classes of service. To the latter statement Professor Carpenter objected, stating that there is no question about the advantages of the impulse turbine for small work, but the reaction turbine for large powers will not drop out where a high vacuum can be obtained.

W. E. Snyder, of Allegheny, Penn., thought that all the emphasis should not be laid on the steam economy. Another point which should receive careful attention is the lower cost of maintenance, particularly where the turbines are used for boiler feed and replace the direct-acting boiler-feed pump generally used. In large plants where all of the large units are condensing, the steam from the auxiliaries is needed to heat the feed water, and a few per cent., more or less in steam consumption, of these auxiliaries, does not materially change the conditions of the total economy of the plant because most of the heat is recovered in the feed water.

Safety Valves

In the "Safety Valves" discussion, A. B. Carhart said that the limit of diameter size of valves for stationary boilers should be 5 inches, and for locomotives, 3½ inches; common practice is in accord with this. Units giving 1 square inch discharge area are the largest allowable for locomotives. Total discharge capacity of 2 square inches for locomotives having 35 square feet grate area, and 3 square inches for the largest ones having 50 square feet grate area, has been demonstrated to be amply sufficient. This should be divided into three units: (a) muffled valve with close adjustment, (b) reserve valve regulated for reasonably greater discharge, and (c) an emergency valve as the real protection against explosion, the other two simply to limit the working pressure under ordinary conditions.

Valves in use are [illegible] limited in regulation. The strain upon the boiler is dangerous when the opening is too large and sudden, and water [illegible] the relief through the safety valve and endangers the cylinders. A smaller valve with high lift is not the equivalent of a valve of larger seat diameter and less lift showing the same discharge area, for the smaller valve gives less percentage of steam discharge, there is greater danger of sticking in opening, more trouble from pounding at the seat and leaking, and the outlet area becomes too large in proportion to the inlet, causing chattering and giving ineffective relief to the boiler. The lift should not exceed 0.08 inch for locomotive valves and 0.10 inch for stationary valves used at lower pressures; prudence and economy would reduce rather than increase this limit.

Every valve has a wide range of adjustment; the lift can often be varied from 0.04 to 0.10 inch by anyone at will, and to still greater limits by exchange of springs in the same valve, to be had for the asking. Limited lift is a matter of preference or judgment, not of necessity, in valves as commonly made. All internal work for large lift of the disk that must be extracted from the escaping steam reduces the velocity and efficiency of the relief and requires an undue throttling of the outlet, strangling the discharge instead of relieving the boiler.

Philip G. Darling said that recent articles place the maximum lifts of safety-valve lifts variously at [illegible] and 0.11 inch for the same size of valve. The great number of these recommended lifts complicate the situation and naturally raises the question as to just what the basis in setting such maximum limits is and whether there are any inherent features or principles of design calling for general restriction in such values. Mr. Darling cited some instances in foreign practice showing that in England [illegible] valve regulations have been discovered limiting spring compression [illegible] inch on valve lifts [illegible] and it was his opinion that [illegible] limits actually restrict the progress of design in this country in spite of a general [illegible] among manufacturers

against advancement in the [illegible] of [illegible] purchase.

In safety valving a boiler, [illegible] of the [illegible] relieving capacity, and if [illegible] with a [illegible] valve, there is a positive [illegible] not only in original cost, but in [illegible] action of [illegible] small valves than large ones.

If it were a [illegible] to the [illegible] different valves which the engineering [illegible] should demand and legislate for, but rather the question of [illegible] Capacities as [illegible] not [illegible] however [illegible] but from the actual [illegible] to the valves themselves. A purchaser, or one specifying safety valves, should be given this capacity information by the different valve makers and he may intelligently select the proper size and type of valve, and the basis upon which this capacity is obtained should be demonstrated as reliable.

A logical policy is for the valve makers to continue to advocate each his own lifts and capacities in the different sizes of valves, but on the other hand for all to get together in agreeing to some sort of a test, to guarantee what the actual relieving capacities of these valves are, stamping them upon the valve as is already being done by one maker. This will give a rational basis for use in the application of safety valves to boilers.

Graft Charges in Chicago

Charges of graft among members of the board of examining engineers for the City of Chicago have been in circulation for some time, but no definite action was taken until recently, when States Attorney Wayman took the matter up, with the result that on Saturday, May 1, the Cook county grand jury returned an indictment charging [illegible], secretary of the board of examining engineers, and John Jenkins, journeyman engineer and member of the board, with obtaining money by false pretenses in the furnishing of an engineer's license to Joseph [illegible].

Louis [illegible], an engineer on the board, who is alleged to have been the "go-between" for the board members, has not [illegible]. The method of operation is said to have been through the [illegible] of advertisements in newspapers published in foreign languages in Chicago, saying that the advertiser could make the [illegible] of license easy. It is alleged that [illegible] answered one of the advertisements and [illegible] told him he would have to pay [illegible] part of which would go to the board. It is further alleged that [illegible] gave him the money and obtained his license.

Other charges have been [illegible] but no other cases [illegible] have been [illegible]

[illegible] Frank E. [illegible] [illegible] of the board of examining engineers [illegible] [illegible] "I [illegible] one of three members of the board. The other members [illegible] I have [illegible] [illegible] the [illegible] of the ordinary [illegible] [illegible] public records and I [illegible] [illegible] I have [illegible] [illegible]"

Following the [illegible], Mayor Busse [illegible] the resignation of the [illegible] and [illegible] that the board would be completely reorganized on different lines, bringing it more closely in touch with the city administration than has been the case in the past, so that its [illegible] could be subject to proper surveillance. Although Mr. [illegible] was not included in the charges, he had voluntarily tendered his resignation as president of the board.

Repairs to Turbines of U. S. S. "Salem"

As stated in the May 11 number, the United States scout cruiser "Salem" was sent to the builder, the Fore River Shipbuilding Company, for an examination of the main propelling turbines, which are of the Curtis marine type. During the [illegible] the starboard turbine was considerably slower than the port, with the same steam supply, thus indicating that some internal derangement had occurred, although there was no difficulty in its operation.

When opened up it was discovered that some foreign body had become caught in the [illegible] space between the nozzles and first row of buckets. It had then [illegible] the edges of the buckets so as [illegible] to prevent any steam passing through them and had broken short [illegible] of the [illegible] The foreign body which caused this had not been found at this writing, but a [illegible] which was found in the first stage, lying on the bottom of the casing, and [illegible] caught in the [illegible] parts.

Examination of the port turbine disclosed a [illegible] body [illegible] which was not a part of the turbine, lying in the first stage [illegible] the [illegible] in the second stage. The damage [illegible] slight.

The [illegible] of both machines were [illegible] to have [illegible] so as to [illegible] the [illegible] against the [illegible] [illegible] with the [illegible] in the first and second stages [illegible] the [illegible] guide blades were worn on the edges; but no blade stripping occurred. As in these stages the guide blades cover only a small part of the circumference, practically all the wear occurred on them and very little on the moving buckets.

All blading was found to be entirely free from any erosion due to the action of the steam, and the surfaces were as smooth as when first installed.

This shows that turbines can withstand considerable abuse and still remain in operative condition; as even in this condition the vessel made 24½ knots for 24 hours and for the first 8 hours made 25 knots, while the contract speed required was 24 knots for 4 hours. Also, the operation of the turbine was all that could be desired, and except for the drop in revolutions, it would not have been known that any internal damage had occurred.

The damage is being repaired, and is expected to be finished in 30 days from the vessel's arrival at the yard. The accompanying photograph shows the damaged buckets on the first row of the fifth stage. The three bucket rows of the fifth stage are marked 1, 2 and 3, the damaged row being No. 1.

The company officials state that they make no charge of vandalism regarding this damage, as it was quite possible for stray bolts or nuts accidentally to drop into the turbine during installation.

THE DAMAGED BUCKETS OF THE U. S. S. "SALEM"

The resistance to failure by shear and diagonal tension and the effectiveness of metallic-web reinforcement are discussed in Bulletin No. 29, "Tests of Reinforced Concrete Beams: Resistance to Web Stresses," by Arthur N. Talbot, just issued by the Engineering Experiment Station of the University of Illinois. This bulletin of 85 pages gives the results of tests made in the laboratory of applied mechanics of the university.

Copies may be obtained gratis upon application to the director, Engineering Experiment Station, Urbana, Ill.

The fifth annual convention of the Southwestern Electrical and Gas Association will be held in Dallas, Tex., May 20, 21 and 22 next.

Meetings of State Associations, N. A. S. E.

Iowa, Cedar Rapids, May 20, 21, 22.
Kentucky, Henderson, June 4 and 5.
Pennsylvania, Erie, June 4 and 5.
New Jersey, Hoboken, June 5.
New York, Syracuse, June 11 and 12.
California, San Francisco, June 14 to 19.
Connecticut, Waterbury, June 25 and 26.
Massachusetts, Springfield, July 9 and 10.
Michigan, Bay City, July 15, 16, 17.
Ohio, Columbus, September 13.

Pennsylvania N. A. S. E. Convention

The tenth annual convention of the Pennsylvania State Association, N. A. S. E., will be held at Erie, Penn., June 4 and 5 next. Erie being the engine- and boiler-manufacturing city of the State, it is expected that this convention will be the largest, in point of attendance, ever held by the Pennsylvania N. A. S. E.

Annual Convention of the A. O. S. E.

The annual convention of the American Order of Steam Engineers will take place at Reading, Penn., during the week commencing June 7. Headquarters will be at Penn hotel.

Annual Convention of the Universal Craftsmen

The annual convention of the Universal Craftsmen, Council of Engineers, will be held at Washington, D. C., August 3, 4, 5 and 6. Headquarters will be at the National hotel.

The Fidelity and Casualty Company reported 19 boiler explosions in this country, including two engine boilers, between March 15 and April 14, inclusive; there were also a number of minor boiler accidents. From March 19 to April 7, inclusive, three flywheels were reported burst.

On Saturday evening, May 22, Illinois Association No. 3, N. A. S. E., of Waukegan, Ill., will hold an open meeting at which the following will speak: L. M. Eckstrand, on "Coal;" J. W. Swearingen, on "Pumps;" J. W. Townsend, on "Some of the Mishaps of the Past."

Announcement is made that the annual convention of the American Street and Interurban Railway Association and its affiliated associations will be held at Denver, Colo., October 18, 19, 20, 21 and 22, 1909.

Inquiries

Questions are not answered unless they are of general interest and are accompanied by the name and address of the inquirer.

Cause of Bent Fire Tubes

In a fire-tube boiler some of the tubes are curved so that they are nearer together in the middle than at the ends. What bent them?

H. S.

At some time the bent tubes have been hotter on one side than on the other, and the stress caused by the unequal expansion resulted in a permanent deformation or bend.

Cause of Leakage with Cold Water in Tank

Why do the girth seams of a horizontal water tank leak when the tank is half full of cold water but do not leak when the water is hot? The tank is used as a hotwell with exhaust steam admitted above the water.

G. H.

Difference in temperature between the upper and lower parts causes strains which open the seams enough to allow a slight leakage.

Producer Gases

Please explain the differences between water gas, producer gas and coal gas.

G. J. R.

Any gas made from coal is coal gas, but the name is commonly applied to the lighter gases driven off from coal by the application of moderate heat. Water gas consists chiefly of carbon monoxide and hydrogen formed by passing steam through a bed of incandescent coke. Any gas made in a gas producer is producer gas, but the name is commonly restricted to the gas made by passing air and steam through a bed of incandescent fuel and a bed of fuel not yet brought to incandescence.

"Mud" in a Water Column

Our water column used to get choked with mud. How is the circulation produced that carries the mud into the column connections?

C. H.

What you designate as mud is probably iron oxide made by the union of oxygen and iron. Corrosion of the iron in this case would produce a spongy mass of nodules which would in a very short time entirely fill the pipe leading to the bottom of the combination and stop the pipe, not because of any peculiar kind of circulation which carried mud into the pipe, but the lack of enough circulation, by blowing or otherwise, to carry the mud away.

Storage Battery Requirements

What size of storage battery is required to give a normal discharge rate of 20 amperes at 110 volts, and how is the size determined?

C. C. C.

Each cell must have 24 square inches of surface area on the positive plates for each ampere of discharge rate. For 20 amperes, therefore, the positive plates of each cell must have 480 square inches of surface. Each cell gives from 1.8 to 2.5 volts, according to its condition; at the beginning of the discharge 50 cells would give 110 volts, but toward the end the battery would drop to about 90 volts. It would be advisable to put in 60 cells in order to keep the potential up to 110 volts.

Different Pressures for Boilers Connected to Same Steam Line

I have two boilers connected to the same steam line. One is horizontal and the other is vertical, but otherwise they are the same, in thickness of shell, in diameter and in riveted joints. Why is it that the inspector allows five pounds more pressure on the vertical boiler than on the horizontal one?

A. O. L.

It is not just clear how more steam pressure can be carried on one boiler than on the other as long as both are connected to the same steam main. If the shells are equal in strength the lower steam pressure should be allowed on the vertical boiler, owing to the extra pressure of water in the vertical boiler due to its hight.

Why the Manhole Joint Leaks

In a 11x15-inch manhole a new gasket is required every time the plate is removed, and when the pressure falls below 20 pounds the joint always leaks. What is the cause?

A. B.

The face of the plate does not fit the face of the ring. When the gasket is new it is somewhat elastic and the joint is tight under the rising pressure. At working pressure the pressure on the back of the plate exceeds the stress of the bolts and the plate is held in place by the pressure on its back. As the pressure is reduced the plate, which has been warped by the pressure to fit the ring, tends to resume its natural shape and as it does so it opens a crack for the escape of steam.

Book Reviews

THE ENGINEERING INDEX ANNUAL FOR 1908. Compiled from the engineering index published monthly in *The Engineering Magazine* during 1908. Published by The Engineering Magazine, London and New York. Cloth, [illegible] pages, [illegible] inches.

Although the 1908 volume is not materially larger than the 1907 Annual it indexes [illegible] more articles [illegible] [illegible] [illegible] volume than in its predecessor. [illegible] and planning [illegible] has been used, also in standardizing the classification—particularly in following a uniform system for placing articles of doubtful classification, and in using cross references so freely that [illegible] to the goal.

This is the seventh volume of the Index since the work was first undertaken, and the third since it assumed the "Annual" form, and it makes available a continuous index to the engineering and technical literature of the past 25 years. The list of periodicals included comprises [illegible], representing [illegible] nations and [illegible] languages.

MILLWRIGHTING. By [illegible] F. Hobart. Hill Publishing Company, New York. Cloth; [illegible] pages, [illegible] inches; illustrated. Price, $[illegible].

The old-fashioned millwright has become lost between the mill architect or mechanical engineer and the contractor and erecting man, and yet there must be somebody to [illegible] the work [illegible] [illegible] the designing engineer, to [illegible] [illegible] [illegible] [illegible].

[illegible]

Resolutions on the Death of Ira Watts

The Combined Association, N. A. S. E., of Manhattan and the Bronx has adopted the following resolutions:

"In every association there are a few men who, by reason of their sterling qualities and unselfish devotion, stand out prominently among its membership, and whose counsel and efforts can least be spared to the common cause. Such a man was our late friend and companion, Ira Watts, the news of whose death in far away Spokane, Washington, comes as a blow to us, his fellow engineers and associates.

"An accomplished engineer, a faithful officer, an untiring worker, an exemplary citizen and an ever-ready helpmate, he was an ornament to his profession, a pillar of strength to the association, and an example worthy of emulation to his fellow men.

"The General Committee of the National Association of Stationary Engineers of Manhattan and Bronx, New York, in regular meeting assembled, desirous of giving public expression to their sense of bereavement at his loss, and of recording their appreciation of his high qualities, do hereby

"Resolve that in the death of our beloved brother, Ira Watts, the engineers of America and especially the General Committee of the National Association of Stationary Engineers of Manhattan and Bronx, have lost one of their most useful, esteemed and representative members, one whose place in our counsels and in the hearts of his fellow men it will indeed be hard to fill; and be it also

"Resolved, that we extend to those even more near and dear to him the sympathy of fellow mourners and of sharers in the deep affliction which his untimely calling away has imposed upon ourselves as well as them, and be it further

"Resolved, that these resolutions be spread in full upon the minutes, and that a copy thereof be forwarded to the family of our deceased brother."

Business Items

The Tatnall Engineering Company, of Philadelphia, announces that it has severed its connection with the Wetzel Mechanical Stoker Company.

Muralt & Co., engineers, have opened a branch office in the Temple Court building, Bay and Richmond streets, Toronto, Ont., with J. Eugh as manager.

The repair shop of the Crocker-Wheeler Company, Ampere, N. J., has been placed in charge of Edmund Land, who, for five years, held an executive position with the Wheeler Condenser and Engineering Company.

B. Elshoff, for 12 years assistant superintendent of the Allis-Chalmers-Bullock Company, of Cincinnati, and for the past two years superintendent of the electrical department of the Allis-Chalmers Company, of Milwaukee, recently severed his connection with the last-named company. Mr. Elshoff may eventually accept a position with an eastern firm, but for the present will remain in Milwaukee.

The Keystone Lubricating Company, of Philadelphia, claims that the best and most economical method of lubricating the guide rails of freight and passenger elevators is to use a refined high-grade petroleum-oil grease applied by a simple compression-cup lubricating device carried by the car. Keystone grease is stated to be in use for this work in a large number of the principal office, warehouse and factory buildings in the country.

The increasing demand for Bird-Archer boiler compounds in the Orient has necessitated the opening of the following new offices by the Bird-Archer Company, of New York: Honolulu, J. P. Lynch, 42 Young building; Manila, Lambert Springer Company, 99 Plaza, Santa Cruz; Yokohama, T. M. Laflin, Exchange market; Hong Kong, Shanghai and Singapore, United Asbestos Oriental Agency, Ltd. All of these agents have competent steam engineers to direct boiler owners in the proper use of the compounds.

Walter B. Snow, publicity engineer, 170 Summer street, Boston, Mass., announces the association with his staff of Carl S. Dow, engineering department, Harvard University, late publicity manager, B. F. Sturtevant Company, and formerly in charge of instruction and textbook departments, American School of Correspondence. Mr. Dow brings to the organization a diversified experience, which will add materially to the value of the service rendered in all lines of technical publicity.

The Public Service Corporation, of New Jersey, has recently purchased from the Hewes & Phillips Iron Works, Newark, N. J., eight special engines, 16½ inches in diameter by 24-inch stroke, to run 175 revolutions per minute. They will be direct-connected through flexible couplings to blowing apparatus. They are to be used in distributing illuminating gas under pressure to the outlying districts of Newark and Jersey City. The engines will be arranged with a special pressure control, the governors working to fractions of ounces. These engines are of the heavy-duty tangye type.

The American Blower Company, of Detroit, Mich., has adopted a method of following up every engine it ships by means of a blank report which it forwards to the purchaser, accompanied by a form letter, and followed by a "follow-up" letter in case a prompt response is not forthcoming. The report or information blank asks the customer for information concerning the size of engine, for what it is used, when installed, the revolutions per minute, steam pressure, if oil has been added and how often, the quantity of oil added each time, and how often and where adjustments have been made. By this means the company "keeps tabs" regarding every engine it sends out.

In a pamphlet, entitled "Automatic Draft Control for Steam Boiler Furnaces," the Green Fuel Economizer Company, of Matteawan, N. Y., describes an appliance recently brought out for so regulating the draft of steam boilers that the pressure within the firebox shall be at all times neutral. To accomplish this, just enough pressure is supplied under the grates to force the air through the fuel, while enough draft is applied in the smoke flue to draw the gases of combustion through the boiler. This system of draft is thought to have an important bearing in connection with the researches which have recently been made by the engineers of the United States Geological Survey with the object of increasing greatly the rate of steam production per square foot of heating surface in steam boilers.

New Equipment

The Chickaska (Okla.) Light, Heat and Power Company will erect a new power house.

The Standard Chemical and Oil Company, Troy, Ala., will rebuild its electric-light plant recently burned.

The Merchants Heat and Light Company, Indianapolis, Ind., has secured a site for a new plant, to cost $300,000.

The Boston Confectionery Company, Cambridge, Mass., will install a 200-horsepower gas engine in plant, also other equipment.

The Greenwich Cold Storage Company, New York, has been incorporated with $25,000 capital by H. R. Carberry, I. C. Mosher, P. J. McKeen, etc.

The Fitzgerald (Ga.) & Ocilla Electric Railway & Power Co. is making arrangements for the construction of a power plant on Lake Beatrice.

The Lytle Creek Power Company, San Bernardino, Cal., has decided to spend $300,000 in extending system. Duplicate plant will be installed.

The North Carolina Sanatorium for Treatment of Tuberculosis, Greensboro, N. C., will build power plant to furnish heat, power, water and light.

The Scotia Worsted Company, Woonsocket, R. I., is making preparations to construct a new power house. New engine and boilers will be installed.

The Springfield (Mass.) Street Railway Company is making plans for improvements to cost about $80,000, which will include new electrical equipment, etc.

The Thousand Island Electric Light and Power Company, Clayton, N. Y., is thinking of substituting a gas-producer plant for the present steam plant.

12,500-H. P. Turbines of the "North Dakota"

Description of the Curtis Marine Type Turbines Built for the First American "Dreadnought," Which Requires a Total of 25,000 H. P.

The United States battleship "North Dakota," now building at the Fore River Shipbuilding Company's works at Quincy, Mass., and the first of the American "dreadnoughts," is 510 feet long, 85 feet beam, draws 27 feet and has a displacement of 20,000 tons. She has a full speed of 21 knots, requiring an aggregate of 25,000 horsepower which is supplied by two Curtis marine reversible turbines driving twin screws. The turbines are designed to run with [illegible] pounds gage pressure, [illegible] degrees of superheat and [illegible] inches of vacuum.

The velocity acquired by a jet of steam expanding through this range in one bound would be some [illegible] feet per second, so excessive that it would not be possible to build a turbine the blades of which could run at anywhere near one-half the speed of the jet, the condition of maximum efficiency. By dividing the expansion into a number of stages, the lesser velocity which the steam has acquired from the lower range of expansion can be taken out in each stage before it is allowed to expand to the next, and the speed of the jets be brought down within practical limits by using such a number of stages, as in the Rateau, that the temperature fall through each range, and thus the energy and velocity generated, will be small, or by using a fewer number of stages and making the jet act successively upon several rows of blades in each stage, which is the characteristic of the Curtis. In Fig. 3, for example, the steam is entering the first stage from the steam chest at the top through the two valves which are open, and, expanding in the two left-hand nozzles, acts upon the first row of moving blades, which are, however, running at [illegible] one-half of the jet velocity that they do not take its energy all out of it and bring it to rest. It therefore passes between the stationary blades and is reversed so that it acts upon the middle row of moving blades in the direction of their movement, where its velocity is still further reduced, and by the time the operation has been repeated the third time the steam leaves the discharge edges of the moving blades at the first stage pressure, but with its velocity practically all gone. It then acquires new velocity by expanding through the second set of nozzles to the second stage, where the operation of absorbing the velocity in successive moving and stationary blades is repeated. Notice that in the diagrams the passages for the steam are made wider as it gets away from the nozzle. This is not because the steam is expanding, for no expansion takes place in the compartment in which the wheel revolves.

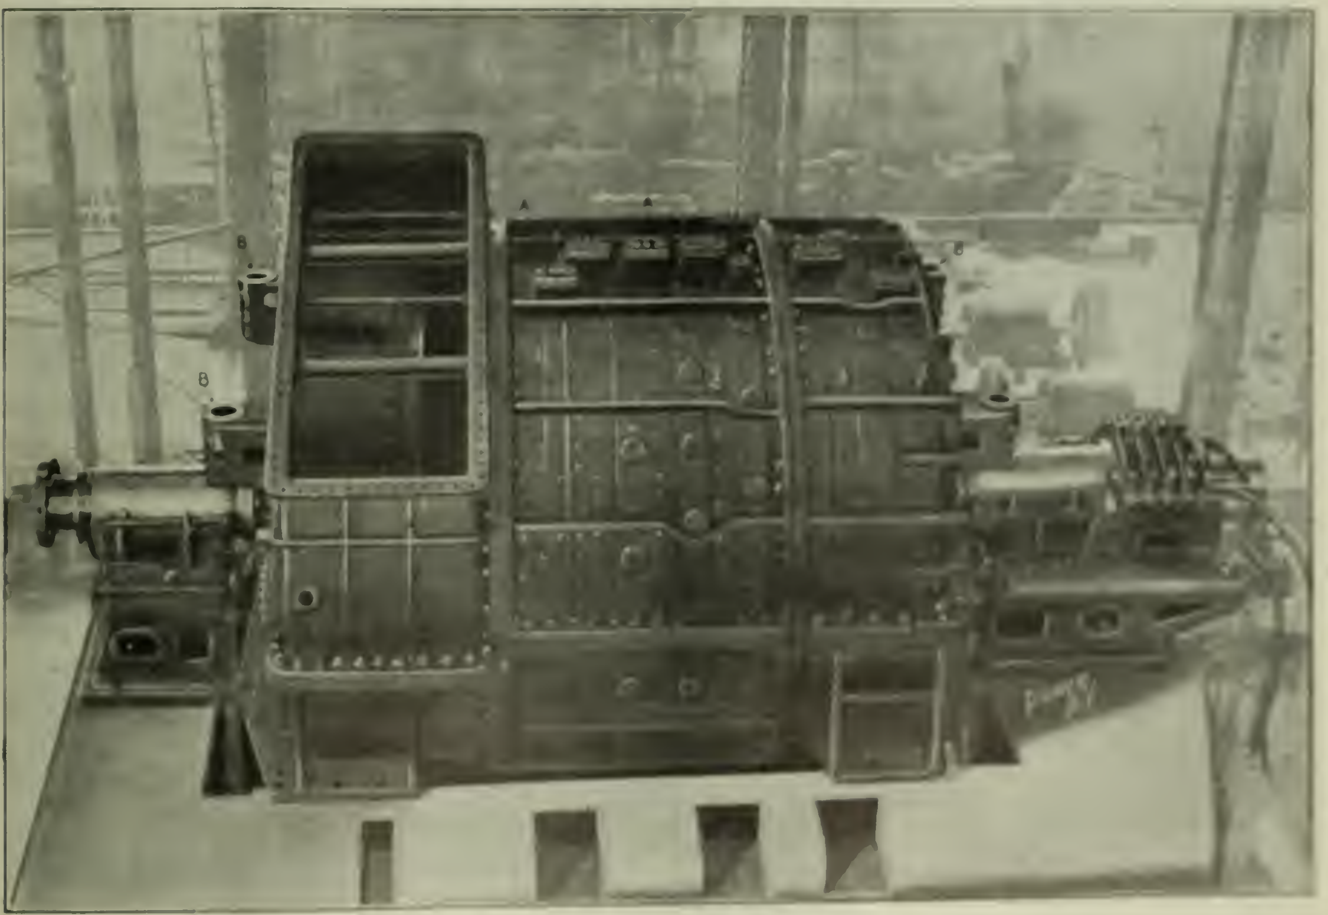


FIG. 1. [illegible]

but because the velocity of the flow is decreasing continuously, and larger passages are required to pass the same volume at the lower velocity.

An important advantage of this method is that steam is not admitted to the shell and working parts of the turbine until its pressure and temperature have been reduced by expansion in the first set of nozzles. Only the steam chest upon the front of the turbine case (or the rear when reversing) is subjected to the initial pressure and temperature.

In the turbines of the "North Dakota" the expansion range is divided into nine stages, as shown in Fig. 2. Between the "ahead" steam chest on the front of the turbine and the compartment containing the first wheel there are 20 nozzles, of which 18 are controlled by sliding valves, each operated by a key upon the squared head of the protruding stem, as shown at *A*, the motion being communicated to the valve through bevel gears and a screw thread, as the drawing shows. No valves are used to control the nozzles between the stages, experience having proved it an unnecessary refinement. For continuous running, enough of the first-stage nozzles are left open to give the required speed and the throttle is left wide open, giving initial pressure in the steam chest, which is of cast steel to give the required strength without excessive weight. Manœuvering is done with the throttle. In order to avoid excessive pressure in the shell, the nozzles of the first set are so proportioned as to reduce the initial pressure of 265 pounds to 75 pounds absolute (60 gage), and the resulting velocity is such that four sets of running blades with three sets of intermediate reversing blades are required in the first stage, while three rows of running blades and two of stationary blades suffice for the remaining stages. The distribution of pressures in normal continuous running is as follows:

	Gage.	Absolute.
Steam chest	265	280
First stage	60	75
Second stage	35	50
Third stage	15	30
Fourth stage	5	20
Fifth stage	— 4	11
Sixth stage	— 9	6
Seventh stage	—11.4	3.3
Eighth stage	—12.9	1.8
Ninth stage	—13.7	1

The first nozzle is convergent-divergent on account of the greater expansion, while for the remaining nozzles a parallel passage with a convergent approach suffices for the lower expansion ratios. The area through the nozzles is increased progressively by increasing both the number and cross-section to accommodate the greater volume of the expanded steam. The 20 nozzles of the first stage occupy only about 42 degrees of the circumference. The passages leading to the nozzles of the third stage are shown at the top of the circular casting which is standing upright at the left in Fig. 3 and which

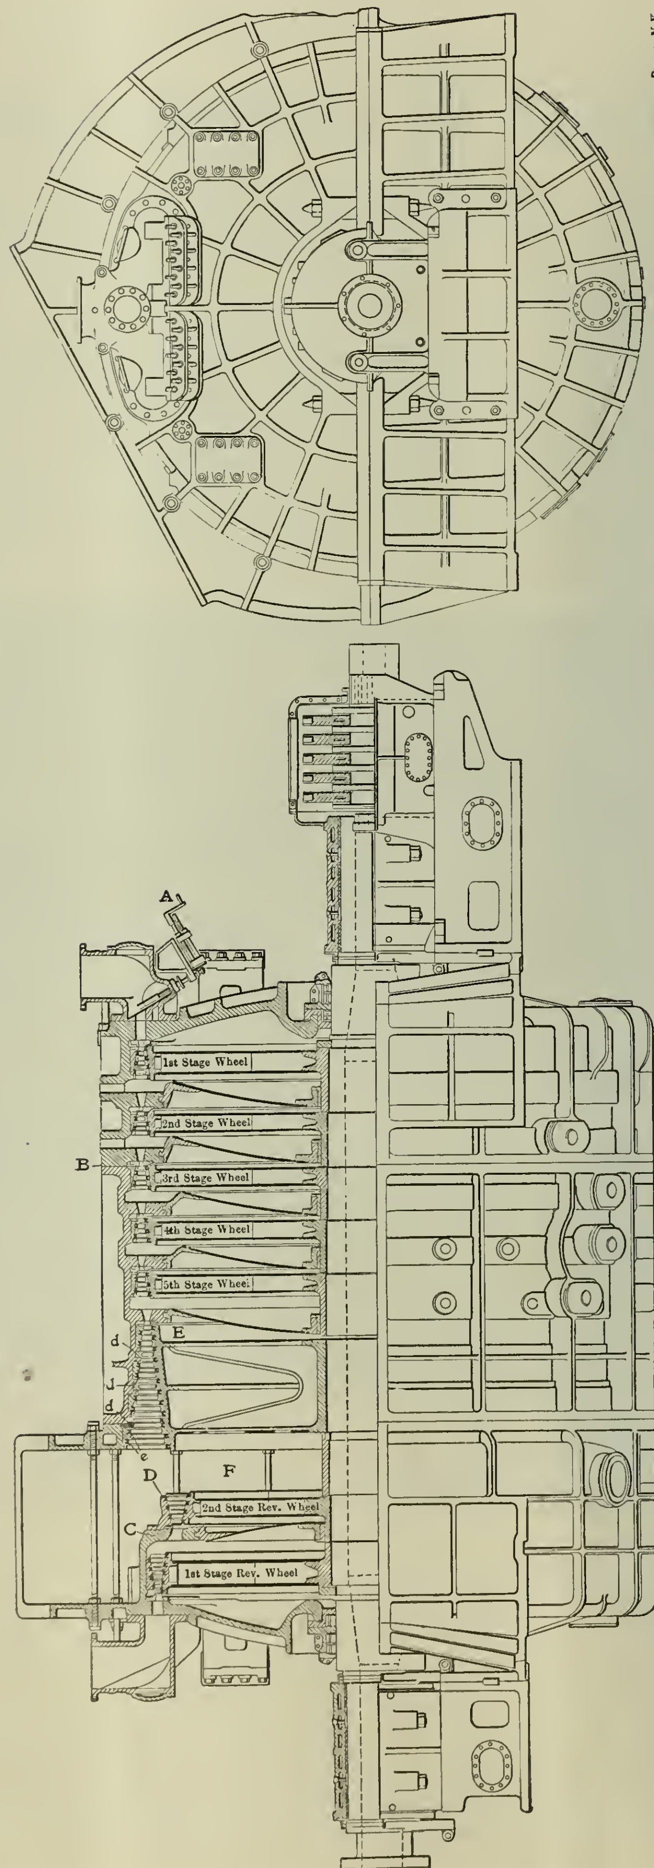

FIG. 2. SECTIONAL AND END VIEWS OF THE CURTIS TURBINE FOR THE "NORTH DAKOTA"

FIG. 3. PARTS OF TURBINE IN SHOP

FIG. 4. EXHAUST END OF CASING

is shown in section at B in Fig. 2, the head section containing the first three stages being of cast [illegible] with the joint at B. [illegible] and the sixth stage in the [illegible] around the entire [illegible]. The exhaust end of the casing which occupies the center of Fig. 3 and is shown on a larger scale in Fig. 4 has a [illegible] ring [illegible] the [illegible], this being the ring shown at C in Fig. 2. The ring of [illegible] part of which is standing on the casing, is that which is shown at D, Fig. 2. [illegible] to have [illegible] blades only on [illegible] of the [illegible], [illegible] one each of the [illegible] which [illegible]. The [illegible] blades, which are [illegible] into the [illegible] shown in Fig. [illegible] are of [illegible] and are shown in Figs. 8 and 9 in the [illegible] machines which are used for [illegible] them on.

The wheels are made up of disks of boiler plate, which are turned and [illegible] as shown in Fig. 10 which shows the [illegible] of the wheel after one side has been covered with the boiler plate. Some of the completed wheels are shown in the foreground and elsewhere in Fig. 3. The increased area required for the passage of the steam through the wheel at the diminishing velocity is obtained by lengthening the successive blades, as will be apparent from the segment of the casing, shown in Fig. 9, containing the three rows of stationary reversing blades for the second reverse stage.

For reversing, two wheels are used, running, when not active, in the vacuum at the discharge end of the turbine to avoid windage. Efficiency being here of little moment on account of short and infrequent use, only nine rows of running blades are used, five upon the first and four upon the second wheel.

The inlet pipe is 13½ inches in internal diameter, while the exhaust outlet is 4 feet in width by 9 feet in length, having thus more than 40 times the area of the inlet.

The blades for the first five stages are carried upon wheels running in compartments divided by steam-tight diaphragms, while the last four stages are grouped upon a single drum, the difference in pressure upon the front and back of which, i.e., at E and F, Fig. 2, is used to balance the thrust of the propeller. The separation of the stages upon the drum is effected by bringing the nozzle rings *ddd*, Fig. 2, sufficiently close to the drum to prevent leakage. The low-pressure difference existing between these stages, which will be seen by referring to the foregoing table of the pressure distribution, and the small amount of steam which will pass through a given opening at the very much diminished density of these lower stages, make this matter of separation comparatively easy.

The blades are made from extruded stock, furnished to the works by the Coe Brass Company, in bars of the required crescent-shaped section and of various sizes. The bars are cut to the required length and finished with a projection upon each end, as in Fig. 10. The blades are set into channel bars worked out of the solid

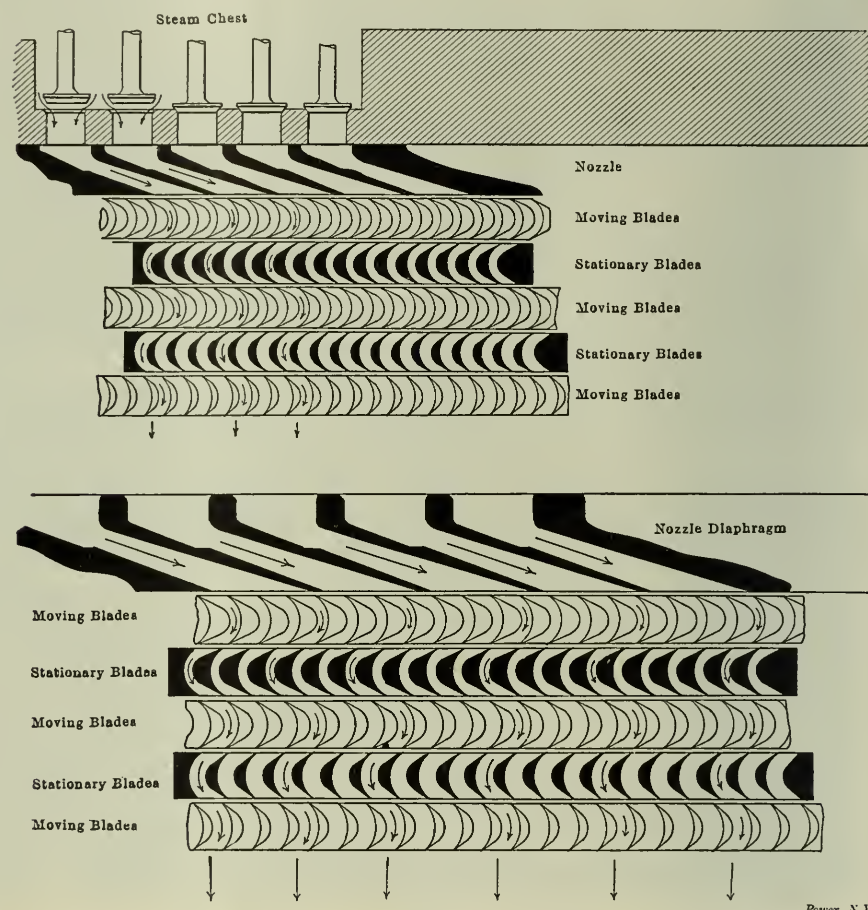

FIG. 5. DIAGRAM OF NOZZLES AND BUCKETS IN CURTIS STEAM TURBINE

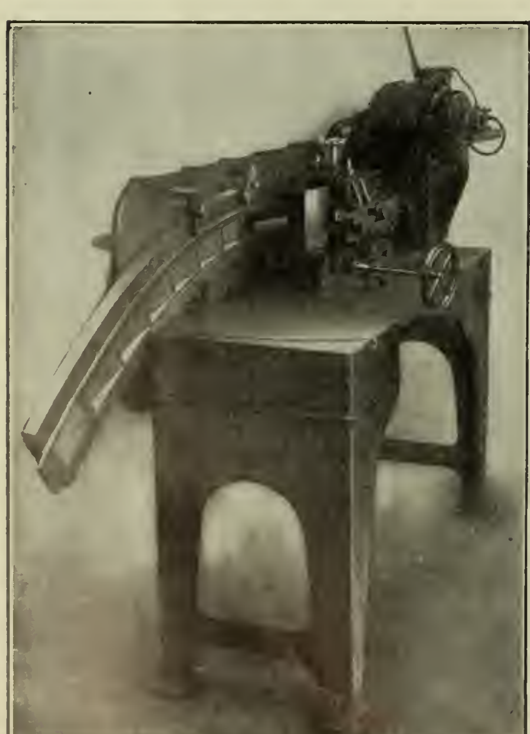

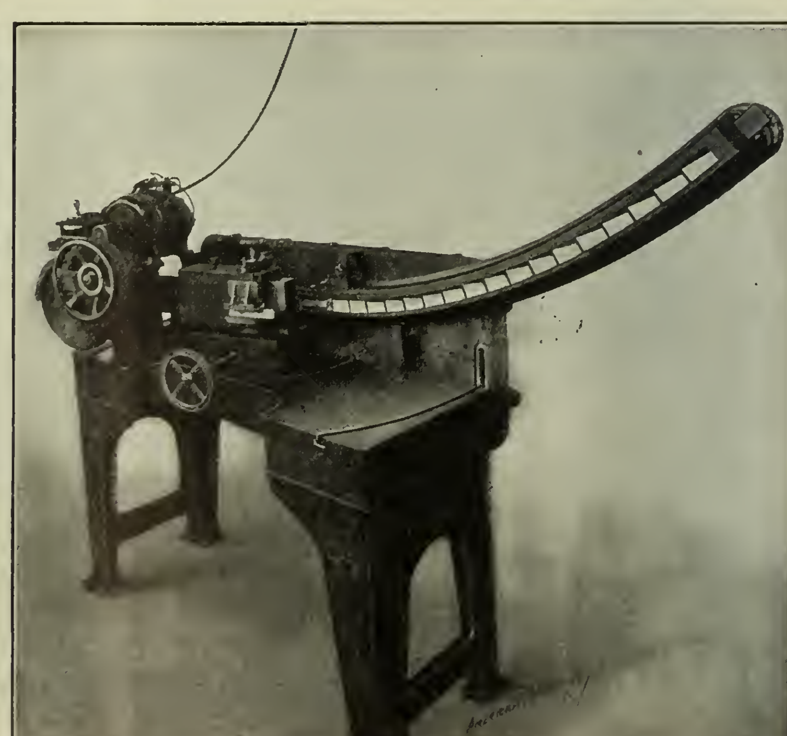

FIG. 6 TURBINE NOZZLE-PLANING MACHINE FIG. 7

grooved for their reception, and secured by calking the material of the drum into grooves cut into their sides as shown in Fig. 11. The shroud, which consists of a plain strip of steel punched to receive the projections on the upper ends of the blade, is then riveted on as shown in Fig.

FIG. 10

by special milling machines, with regularly spaced holes into which the projections on the lower ends of the blades are set and riveted over as shown in Fig. 11. The fins of these channel bars are then slotted crosswise, as shown in Fig. 12, in the same way that a carpenter saws a molding which he wishes to bend, and the sections of blading are then cut to the radius of the drum, which is

15, where the first row is shown with the shrouding yet to be put on. The parts detached and assembled are shown in Fig. 12. Fig. 13 shows the rotor completely bladed and in position in the lower half of the casing. The first stage, with four rows of moving buckets, is at the right, then the four stages with three rows of blades each, then the drum with the 12 rows of the last four stages, and beyond these, at the extreme left, the reversing

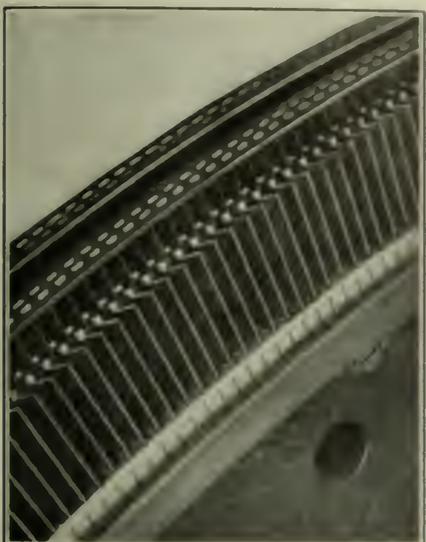

FIG. 15. SECTION OF WHEEL RIM AND BLADES

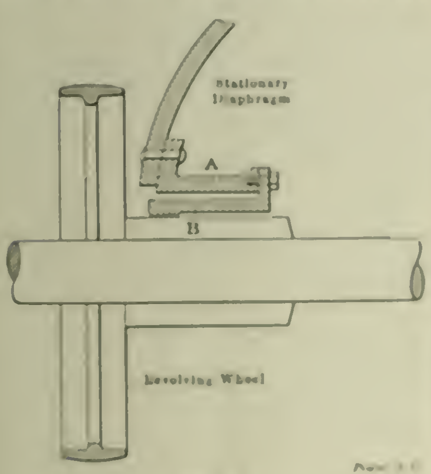

FIG. 16

elements. The inward projections of the casing between the wheels, which show plainly in this view, are grooved to receive the diaphragms as shown in Fig. 5.

The diaphragms are made of boiler steel varying from three-quarters of an inch in thickness at the first stage to three-eighths at the division between the fifth stage and the drum. These are riveted onto cast-steel rings mortised into the projections of the casing, as just mentioned, at their outer edges and to cast-steel rings surrounding the shaft and carrying the packing rings at their inner edges. The details of the packing rings are shown in Fig. 16. To the cast-steel block *A* bolted to the inner edge of the [illegible] diaphragm is bolted a bronze casting *B* carrying upon one end the rings of the labyrinth packing. Sufficient clearance is allowed between *A* and *B* to permit *B* to expand freely should the free end become heated from the contact of the rings. This construction has proved a complete remedy for interstage packing troubles.

Fig. 14 is a view of the rotor from the low-pressure end, the short blades of the [illegible] and those of the final row 10 inches in length. There are altogether about [illegible] moving buckets in the eleven stages, the rotor weight complete about [illegible] and the complete turbine without auxiliaries weight about [illegible] tons.

The concentric rings at the extreme right in Fig. 13 are those of the thrust bearing. Since the pressure is the same throughout the compartment of any one stage, there is no tendency of the rotor

FIG. 17. UPPER HALF OF EXHAUST END OF CASING

FIG. 18. LOWER HALF OF EXHAUST END OF CASING

high-pressure end of the revolving element being immediately in front, the long blades of the final wheel of the second section in the middle and the short blades of the initial stage at the far end. The wheels of the first five stages are [illegible] to the general line of [illegible] (see Fig. 20) and at the rated speed of [illegible] revolutions per minute have a velocity on the pitch line of [illegible] feet per second. The blades of the first row are [illegible] built into the base of the blades and [illegible] are incapable of keeping the [illegible]. As [illegible], they [illegible] from [illegible] of an inch in a [illegible] depending upon the proximity of the [illegible] blade holders, as shown in Fig. 1. The longitudinal clearance, the distance between the stationary and moving blades, must be kept within limits to prevent the dissipation of the energy of the jets in eddy currents, and at a wheel revolving submerged in a body of water and actuated by a water jet entering beneath the surface would have to be placed close to the entering jet to get the full benefit of its velocity before it was dissipated in stirring the other water. For this reason, the axial clearance is kept down to 1/10 of an inch on the first wheel and to ¼ of an inch on the last. The thrust block serves to maintain these clearances, and is properly placed at the high-pressure end where they are the smallest, allowing whatever movement may occur by differences of temperature or mechanical effects to take place in the wider spaces at the more distant blades.

Drain pipes connect each stage with the next so that the condensed steam in any stage will pass to the next one of lower pressure and there give up a part of its heat to useful work. The exhaust chamber drains to the condenser and the discharge is assisted by a small steam-operated ejector.

Where the shaft passes out through the ends of the casing, it is provided with carbon stuffing boxes which prevent steam leaking out at the head end or air leaking in at the back end where a vacuum exists. The rear stuffing boxes are supplied with boiler steam in the spaces between the carbon packing to prevent air leaking in and lowering the vacuum, and are drained to the fourth-stage compartment.

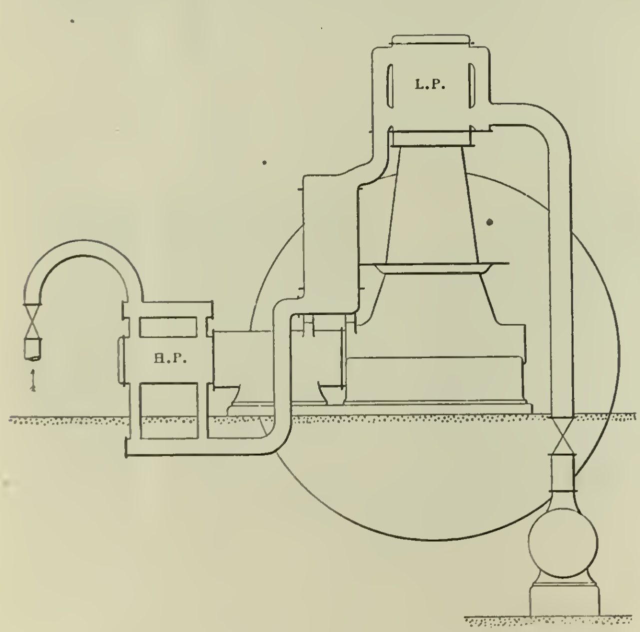
Fig. 17 is a view of the upper half of the exhaust end of the casing, showing in front the two rows of stationary blading *ee* in Fig. 2 and farther back the stationary blading for the reverse elements. The long straight flange on top is that of the discharge passage for the exhaust steam. Fig. 18 shows the lower half of the same section of the casing. Fig. 1 shows the starboard turbine assembled. The capped projections at *AA* are openings or peepholes into the several compartments. Through the sockets *BB* extend vertical rods or stanchions to guide the upper case when it is lifted from the lower.

Should the High or Low Pressure Cylinder be the Vertical in an Angle Compound?

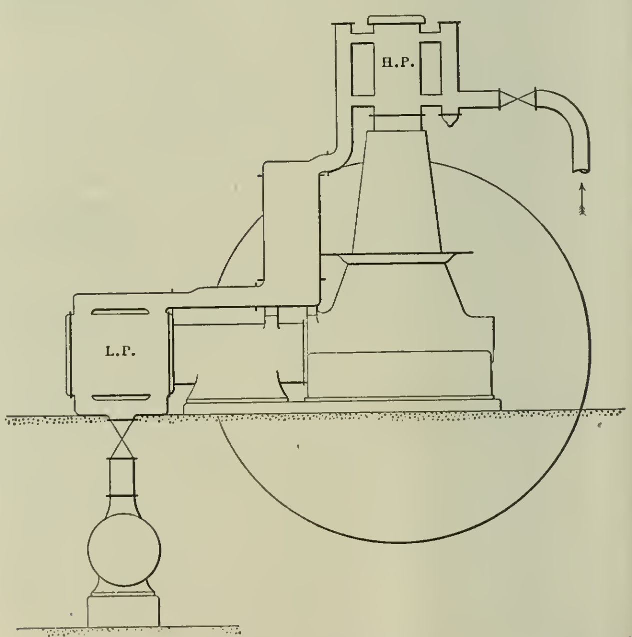
The Greenwich station of the London County Council Tramway has four angle-compound reciprocating engines of the Manhattan type, with the exception that instead of running the low-pressure cylinder vertically, as is done at the Manhattan station, and generally in America, the low-pressure cylinder is placed horizontally at the floor level, and the high-pressure cylinder run vertically in the elevated position. The leading thought in the American practice is to take the weight of the heavy low-pressure piston off of the cylinder. The engines, which were built by John Musgrave & Sons, Ltd., are mentioned by John Hall Rider in a paper upon the "Electrical System of the London County Council Tramways," recently presented before the Institution of Electrical Engineers, as of particular interest from the fact that they are the first of this angle-compound type to be installed in the United Kingdom.

The weight of the low-pressure piston is partially carried by a tail rod, and Mr. Rider gives the accompanying diagrams to show that the course of the steam and water, and, therefore, the drainage, is progressively downward in the case of the English engine, and upward, with the opportunity for forming pockets, in the case of the American engine. There is an advantage for the American engine besides the favorable position of the low-pressure piston, which these sketches do not show, and that is, that if the condenser is placed on the level of the low-pressure cylinder sufficient hight will be available to drop the water out of it through a barometric tube. The performance of these engines, which are coupled to 3500-kilowatt generators, is as follows:

	Full Load.	Half Load.
Duration of test	6 hours	3 hours
Average steam pressure at stop valves	180 lb.	181 lb.
Average steam temperature at stop valves	460° F.	446° F.
Average revolutions per minute	94.46	94.81
Mean total indicated horsepower	5,315	2,622.9
Mean total kilowatts	3,494	1,780
Total water from all sources	353,909 lb.	89,049 lb.
Average weight of water per hour	58,984 lb.	29,683 lb.
Water per indicated horsepower per hour	11.098 lb.	11.31 lb.
Water per kilowatt per hour	16.88 lb.	16.67 lb.
Vacuum	26.74 in.	26.8 in.



IMPERFECT DRAINAGE SYSTEM OF AMERICAN ENGINE



Power, N.Y.

NATURAL DRAINAGE OF RECIPROCATING ENGINE

The 5000-kilowatt Parsons turbines are guaranteed by Willans & Robinson, Ltd., their builder, to run on 15 pounds per kilowatt-hour, with steam at 180 pounds pressure, superheated to 550 degrees Fahrenheit and a 95 per cent. vacuum. No bonus is offered for better results than this, but a penalty will be incurred if the results are worse. The British Westinghouse Company is to furnish two Rateau turbines of the same capacity.

Large Gas Engines for Electric Stations*

Relative Merits of Internal- and External-Combustion Engines; Comparison of the Costs of Generating Power under Conditions Assumed

BY L. ANDREWS AND R. PORTER

Hitherto the use of large gas engines has been chiefly confined to iron and steel works, where they are run on blast-furnace and other waste gases for driving blowing engines and generating electric power, which is used for rolling mills, etc., in the works, the surplus power being sold at a very low rate for municipal lighting and tramway loads, and for industrial works in the neighborhood.

In Germany the manufacture of large gas engines is an established industry on a large scale. Even in 1900 out of 49 smelting works 41 had either installed gas engines or had placed orders for them, the engines actually installed at that time aggregating over 295,000 horsepower. While there have been a few blast-furnace gas-engine installations working in this country for some years, the engines used have been mainly limited to capacities of from 300 to 500 brake horsepower.

The use of large gas engines for driving electric generators is a subject that is also receiving considerable attention in the United States. A few months ago the National Electric Light Association appointed a special committee to report on the use of large gas engines for driving electric generators, and the report was presented to the association at its convention held in Chicago last May. [This report was abstracted in POWER AND THE ENGINEER for June 9, 1908.—EDITOR.]

While the authors believe that there is an important field for the use of large gas engines for driving electric generators, they do not consider that there is at present justification for the suggestion that has been made that the internal-combustion engine will, in the early future, be used to the exclusion of the external-combustion engine.

The situation, as far as present knowledge goes, may be briefly summarized as follows:

The internal-combustion engine is very much more economical than any external-combustion engine yet known.

The capital cost of a gas engine and producer installation is greater than that of a steam turbine and boiler installation of equivalent maximum capacity.

There is no material difference in the reliability nor in the cost of labor, stores and repairs of the respective systems.

In cases, therefore, where the cost of fuel is low, and the load factor is low, it will generally be a mistake to use gas engines.

On the other hand, where the load factor is high or the cost of fuel is high, there can be no doubt that gas engines will prove to be by far the cheapest prime movers to employ for driving electric generators.

The majority of cases to be dealt with will doubtless fall between these two extremes, and engineers responsible for the design of future power houses will have many points to consider before definitely deciding whether the prime movers for the electric generators shall be steam- or gas-driven, or a combination of the two. As the conditions which go to determine whether gas engines should or should not be used are in most cases so widely

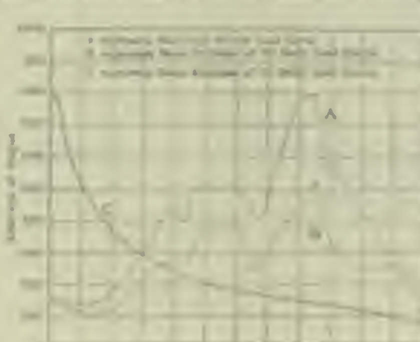


FIG. 1

different from the conditions under which experience has, up to the present, been obtained, it is extremely difficult for engineers to utilize the available knowledge upon the subject to the best advantage. We have, therefore, endeavored to collect facts from a large number of different sources, and to apply the information obtained to one or two hypothetical electric-supply stations as nearly comparable as possible with some of the existing supply stations in different parts of the country. For comparative purposes we have endeavored to show what would be the respective total cost of generating power by steam turbines and by gas-driven generators under the assumed conditions specified.

For the first scheme to be considered we have assumed that the maximum continuous load to be dealt with shall be 8000 kilowatts.

That the nominal and standby capacity of the plant shall be such as to carry the maximum load of 8000 kilowatts for at least two hours, should any portion of the plant break down at the time when one unit is already laid off for overhaul.

That the power generated is utilized for public and private lighting, and that for a tramway and general industrial motor load the load factor is 25 per cent. and the efficiency of distribution

$$\left(\frac{\text{energy sold to users}}{\text{energy generated}} \right)$$

equals 80 per cent., and that the usual daily load curve is approximately of the shape shown in Fig. 1.

That the cost of good bituminous slack, having a calorific value of 13,000 B.t.u. per pound, is 10 shillings per ton delivered at the generating station.

CHOICE OF SITE

The points to be considered in selecting a site for a gas-driven station are practically the same as for a steam-driven station, viz.: (a) A plentiful supply of water for cooling purposes. (b) Transport of fuel. (c) Suitability of site relatively to position of center of distributing area, as affecting cost of feeders. (d) Liability of nuisance to adjoining property. (e) Cheapness of land. (f) Cost of constructing foundations for plant, buildings and chimneys.

In choosing a site for a steam-turbine station it is often good policy to sacrifice other advantages in order to get a site with a plentiful supply of cold water for condensing purposes. This advantage has usually, however, to be heavily paid for. As the latitude in the choice of a site is very limited, the cost of land will probably be very much greater. The cost of foundations will also generally be greater, added to which the right of using the water will generally have to be paid for; and, finally, it is more than probable that the site available will not be a good one from the point of view which American engineers term "the electrical center of gravity"—that is to say, the cost of feeders will probably be much greater than if a more central position were selected. It is consequently often very much cheaper, on the whole, to install cooling towers for condensing purposes. Inasmuch as it is impossible to estimate the cost of obtaining a site with a plentiful water supply, as this will vary largely in every case, we have based our comparisons upon the assumption that cooling towers will be

*Abstract of a paper read before the Manchester Section of the Institution of Electrical Engineers of Great Britain.

used in conjunction with a public water supply.

We assume that a convenient piece of land has been secured, bounded on one side by a railway track and on the other side by a roadway, the width of the land being 325 feet, and the length being ample to allow for all probable future extensions. A convenient layout for the steam plant will be that shown in Figs. 2 and 3. Figs. 4 and 5 show a corresponding layout for the gas plant. (We have shown natural-draft cooling of the usual dimensions in Figs. 2 and 4, but since these plans were made we have been advised by the Midland Engineering Company that its Zylberlast cooling towers occupy only two-thirds of the space shown for the same capacity. If, therefore, these towers were used, the space occupied by the cooling towers for both steam and gas plants would be reduced by this extent.) Either layout provides ample yard-space room for cables, stores, etc., without encroaching on the ground available for future extensions.

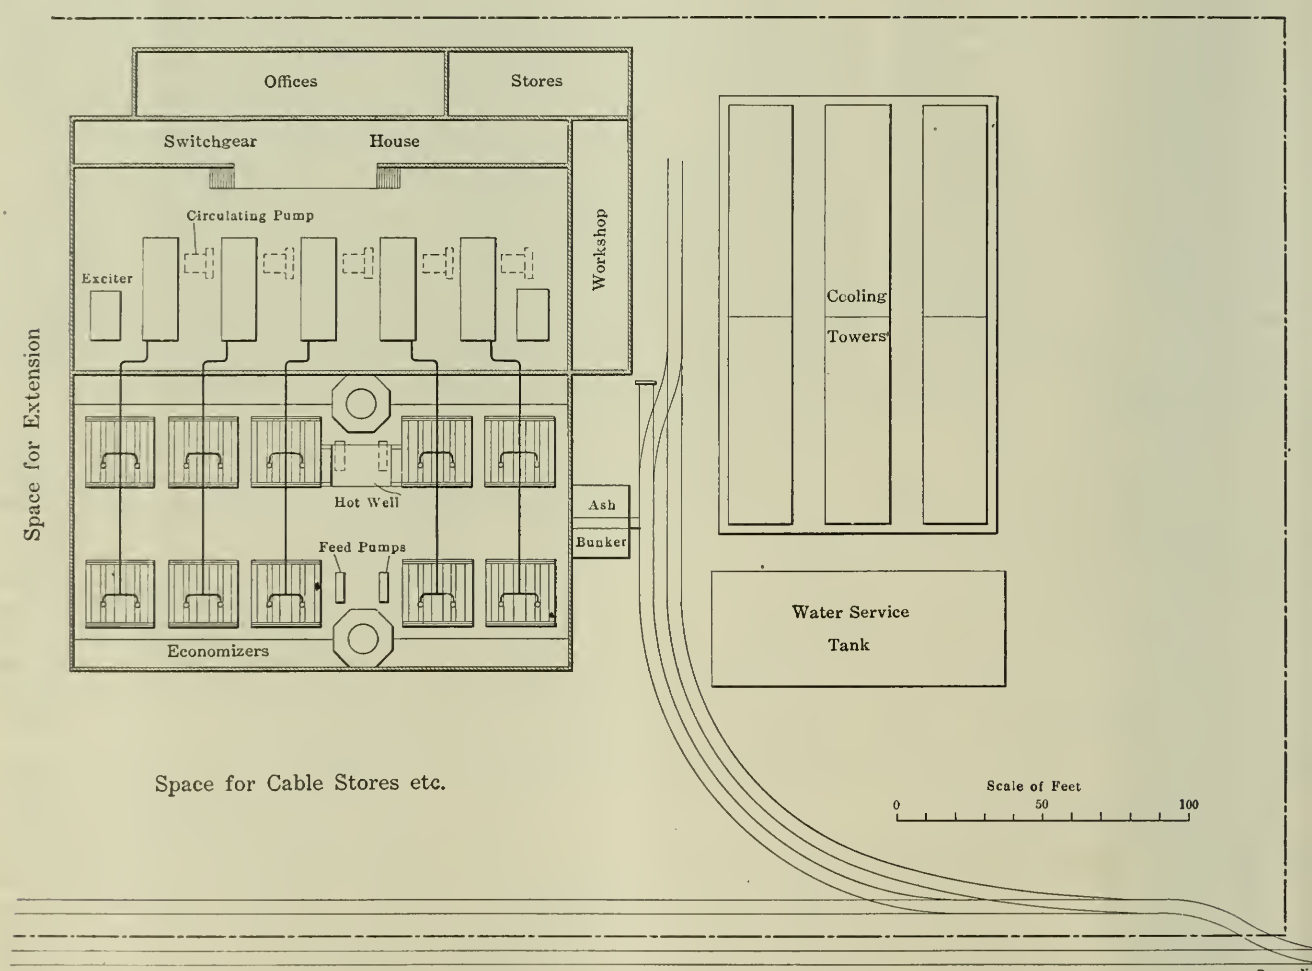

FIG. 2. PLAN OF 10,000-KILOWATT STEAM PLANT

Type of Generating Plant

For the steam plant we have assumed steam turbines of the horizontal type direct-coupled to three-phase generators and each turbine exhausting into a separate contraflow surface condenser placed directly below the turbines; that the cooling water would be obtained from a town supply and circulated by electrically driven centrifugal pumps through natural-draft cooling towers, a separate pump being installed for each unit.

For the gas plant we have assumed engines of the slow-speed double-acting tandem type, working on the four-stroke cycle and direct-coupled to three-phase generators; the flywheel to overhang. The cooling water for the engines, as in the case of the steam plant, would be obtained from a town supply and circulated by means of small piston pumps driven from the engine shafts, the water being cooled in natural-draft cooling towers.

Capacity of Generator Units

Experience has shown that large units in steam plants are considerably more economical, both in first cost and running cost, than smaller units, and as they can at present be obtained in much larger sizes than gas engines, they have, in some cases, a considerable advantage in this respect. For a maximum output of 8000 kilowatts, it appears that the most economical arrangement would be five units, each having a normal capacity of 2000 kilowatts, with an overload capacity for two hours of 33⅓ per cent. In the event of two units being laid off simultaneously, the remaining three would then be capable of supplying the maximum demand for a period of two hours as specified.

The output of gas-engine units is, at present, limited to about 1500 brake horsepower per cylinder, this being the largest size that has yet been made. The arguments against the use of very large steam units for the hypothetical case under consideration also apply to gas units. In fact, for the gas scheme it does not appear to be advisable to use even such large units as 2000 kilowatts because the overload capacity of gas engines is only 10 or 12 per cent., and consequently three 2000-kilowatt plants would be able to deal only with a maximum demand of from 6600 to 6700 kilowatts; six units of this capacity would, therefore, be required to deal with the specified maximum demand and provision for standby. A more economical installation would be seven units each having a normal capacity of 1450 kilowatts and a maximum capacity of 1600 kilowatts. With such an installation if two generators were laid off simultaneously the remaining generators would be able to deal with the full maximum demand of 8000 kilowatts for two hours, as specified.

In Fig. 6 are presented curves showing the approximate capital cost of engines and generators erected complete with pipework, foundations and flywheels necessary for the above-specified cyclic regularity for both single and twin tandem engines of outputs varying from 500 to 5000 brake horsepower. A curve is also plotted showing the corresponding capital charges for an equivalent output generated by a number of 500-horsepower units in parallel. These curves show that the capital cost of a twin tandem unit is appreciably higher than a single tandem unit of the same output. The cost of fuel, oil and repairs will be slightly higher for the twin tandem combination, though not appreciably so. The cost of driver's wages for the twin tandem will be practically double that of the single tandem set, as experience has shown that one engine driver is required for each line of engines, whatever the output of the engine. These remarks apply to cases where the total maximum demand is insufficient to justify the use of larger units than can be obtained in single tandem sets, as in the assumed case. From the foregoing, it appears that for the conditions under discussion a single tandem engine is the best type.

Boilers for Steam Plant

We have assumed that boilers of the water-tube type would be used for the steam plant, fitted with self-contained superheaters and automatic stokers, and that these boilers would be grouped into units corresponding to the output of the turbo-generators, the normal capacity of each battery of boilers being equal to that of the normal output of its turbo-generator. In calculating the boiler capacity we have assumed that the steam consumption of the turbines under working conditions including the steam for feed pumps and exciters, would be 20 pounds per kilowatt-hour generated. We have, therefore, provided for four 10,000-pound boilers for each 2000-kilowatt turbine. In order to keep the boiler house about the same length as the engine room we have provided two rows of ten boilers, grouped in five batteries of four boilers. An economizer is provided for each boiler.

Producers

From inquiries made in Germany and the United States, it would appear that large producers for gasifying bituminous coal have not been entirely satisfactory in either of these countries. This is, perhaps, partly accounted for by the fact that the class of coal available in both these countries contains a far greater percentage of ash and is much more liable to clinker than the bituminous coal available here. Whatever the cause may be, the fact remains that there are numbers of bituminous producer installations in this country working satisfactorily in conjunction with large gas engines. One firm of English producer makers alone has in service plants supplying gas to large engines having an aggregate output of over 50,000 brake horsepower. From information obtained from users it appears that these producers are giving entire satisfaction. Difficulties were experienced in the early days in the removal of tar, dust and other impurities, but the efficient cleaning appliances now included in every properly constructed producer plant appear to have either eliminated these difficulties or reduced them to such an extent that the percentage of impurities carried into the engine with the gas has no deleterious effect.

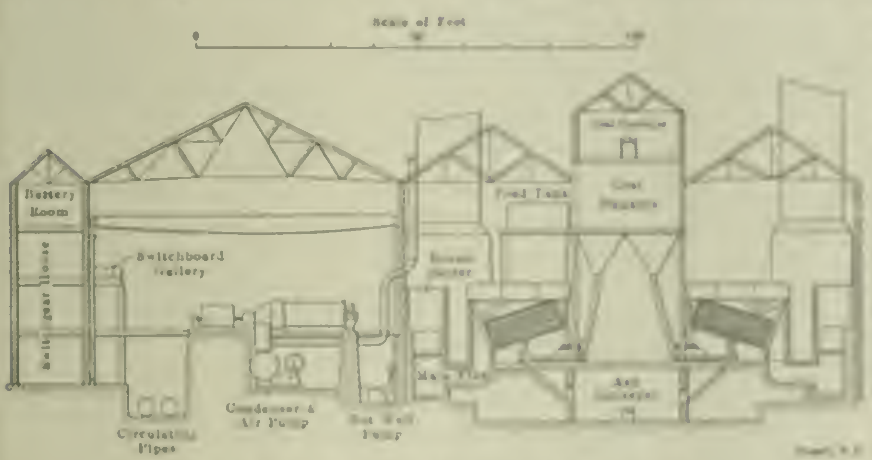

FIG. 3. ELEVATION OF 10,000-KILOWATT STEAM PLANT

Difficulties arising from variations in the quality of the gas caused by charging or clinkering the producers practically disappear when a number of producers are connected together to feed into a common main or common [illegible] the gases from the various producers are mixed together, and the effect of any variation in the quality of the gas from individual producers is thereby neutralized. To derive the full benefit of this feature the producer plant should not be divided into units corresponding to the generator units, as has been recommended for steam boilers.

Ammonia Recovery

A very important point to be considered in designing a gas-engine station is that of providing for the recovery of sulphate of ammonia. There are numbers of recovery plants that have been working for some years, where the sale of the by-product has almost equalled the cost of the fuel used. Results obtained have been so entirely satisfactory that one is at first sight tempted to think it would pay to provide for sulphate of ammonia recovery in every instance. There are, however, many expenses incidental to the recovery of sulphate of ammonia in addition to the fuel.

The following points must be taken into consideration as affecting the use of ammonia-recovery plants: (1) The first cost of the recovery plant, particularly for small sizes, is very much greater than the first cost of nonrecovery plant. (2) Considerable extra labor is involved in operating the plant. (3) The purchase of sulphuric acid, of which approximately [illegible] ton is required for every ton of sulphate of ammonia turned out, is quite a heavy item. (4) The yield of heat units per ton of coal is slightly less if sulphate of ammonia is recovered than the yield from nonrecovery plants. (5) The extra cost of repairs and the cost of handling and packing the by-product absorbed some of the profits obtained by the recovery process.

Experience up to the present appears to indicate that it is not worth while to attempt to recover sulphate of ammonia unless the total output of the plant is greater than 3000 horsepower, and then only at an exceedingly good load factor. For a maximum output of 8000 kilowatts it would probably pay to install an ammonia-recovery plant, even for so poor a load factor as in this case. An even more profitable arrangement, however, would be to provide for ammonia recovery on one portion of the plant, which could be kept working at a very high load factor almost continuously, and to use nonrecovery equipment for dealing with the peak load and remaining portion of the total output. For the particular conditions now under discussion the Power Gas Corporation, to which we are indebted for this suggestion, recommends the use of eight producers, of which only [illegible] would be arranged for ammonia recovery.

Coal Handling and Storage

For both the steam and gas plants we have assumed that coal bunkers will be provided capable of carrying a fortnight's consumption of fuel under maximum load conditions. In the case of the steam plant we have assumed that the coal bunkers would be placed over the firing floor of the boilers. These bunkers would have a capacity of 1500 tons. In the case of the gas plant the coal would be stored in bunkers placed on the ground at the back of, and parallel with, the producers. It would be unloaded by hand from the railway trucks on the elevated siding at the back of the bunkers, from which it would gravitate into the coal-conveyer buckets and be hoisted by these into the hoppers over the producers. These hoppers would be of sufficient capacity to carry 24 hours' supply under mean load conditions. The ashes raked out from below the producers would also be lifted by the same conveyer into the ash hopper provided for the purpose. A sectional elevation of one of the producers with the coal- and ash-handling arrangements used is shown in Fig. 7.

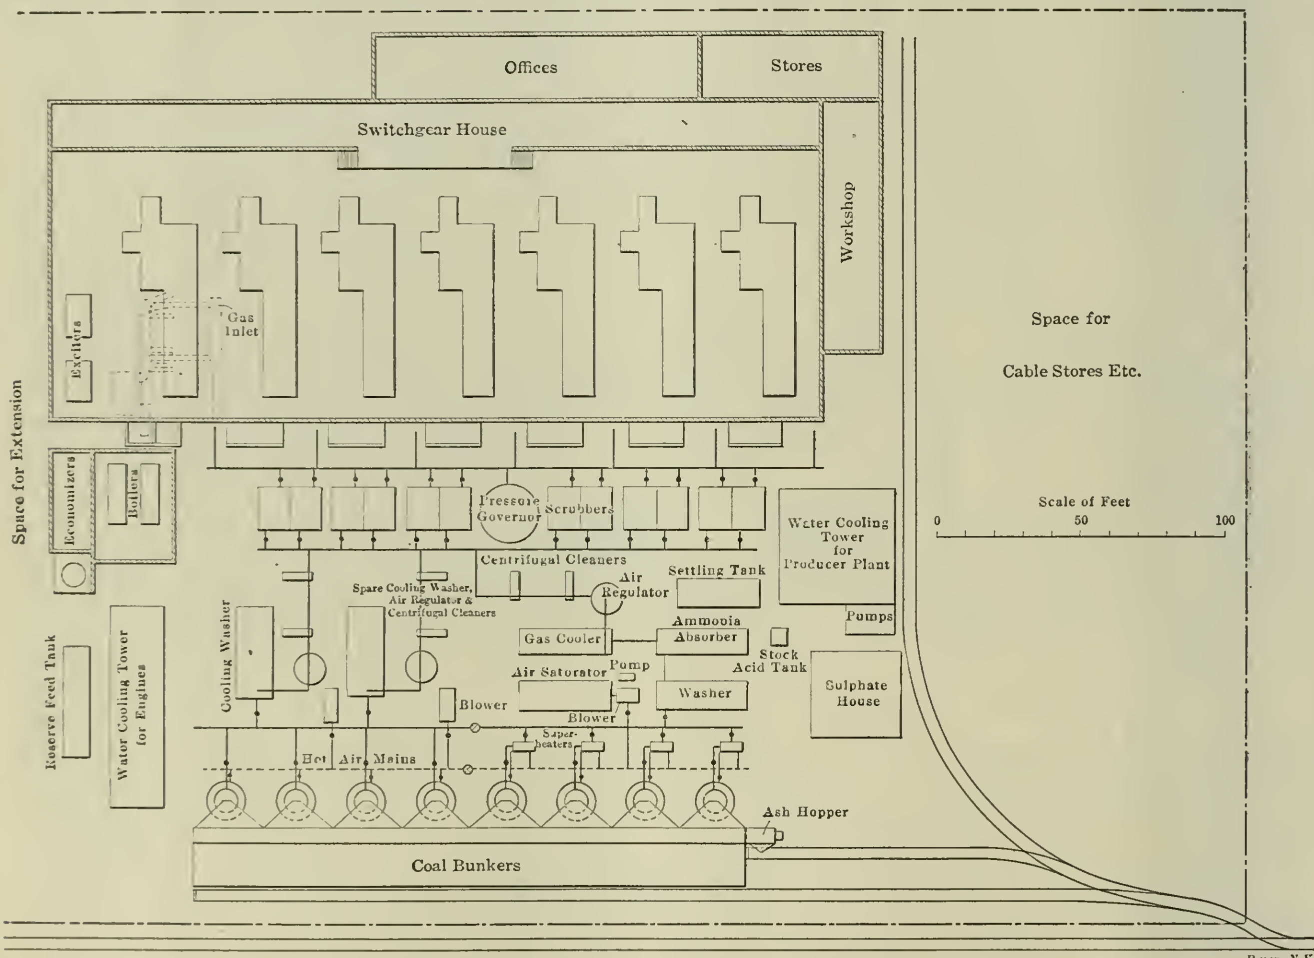

FIG. 4. PLAN OF 10,000-KILOWATT GAS PLANT

Building and Foundations

The cost of the engine room and engine foundations for the gas-driven plant is, of course, considerably greater than that of the steam plant, but no building is required for the producers (beyond small boiler and sulphate houses) and the cost of the foundations for the producers is very small compared with the cost of boiler foundations, flues, chimneys, etc. The total cost of buildings amounts to considerably less, therefore, for the gas station than for the steam station. We have based our estimate of the cost of buildings for the gas-driven plant upon tenders actually received. The price covers a substantial steel-frame building with brick walls, lined internally with a glazed brick dado 6 feet high and with tiled engine-room floor. We have included suitable store, workshop and office accommodation in each case.

Exciting Plant, Switch Gear, Etc.

We have assumed that for both the steam plant and the gas plant the field circuits of the generators would be excited from busbars fed by two steam-driven exciters, each capable of generating the whole of the exciting current required on full load. The exciters would be supplemented by a battery capable of maintaining the full field current required for a period of 24 hours.

In the case of the gas plant the steam for the exciters would be furnished by one of the small coal- or tar-fired boilers installed for this purpose. The exhaust steam from the exciter engines would be used in the producers, any additional steam required by the latter being raised by boilers heated by the exhaust gases from the main engines.

The switch gear would be of the remote-control type, the oil-break switches being placed in a switch room running the length of the engine room.

The capital cost of the switch gear for the gas plant will be somewhat higher than for the steam plant, as two additional generator panels and connections will be required.

Capital Outlay

The total capital cost of the respective steam and gas plants for the specified maximum load of 8000 kilowatts will, we estimate, be as stated in Table 1.

TABLE 1. COST OF GENERATING STATIONS.

STEAM PLANT.

5 2000-kilowatt turbo-generators, erected complete	£39,500
5 surface condensers with air and circulating pumps	9,875
Circulating pipes	1,200
Cooling towers erected complete	6,900
20 water-tube boilers erected complete with mechanical stokers, economizers, superheaters, feed pumps, water-service tank and feed tank, water-softening plant and all pipe work	31,300
Buildings with engine and boiler foundations, 2 chimneys and flues	33,600
Overhead traveling crane	1,000
Steel structural work, coal bunkers, coal and ash conveying plant	8,900
Exciters, battery, switch gear and connections to generator	7,250
	£139,525

Or £13.952 per kilowatt installed.

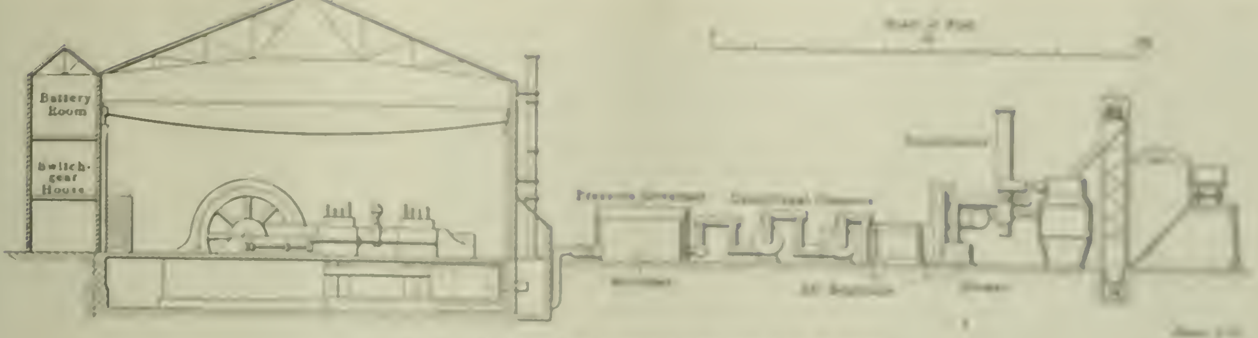

FIG. 5. ELEVATION OF [illegible]-KILOWATT GAS PLANT

Gas Plant

7 1450-kilowatt gas engines, generators, air compressors, gas, water, air and exhaust pipes and all auxiliaries erected complete	£ [illegible]
4 ammonia-recovery producers, erected complete with superheaters, blowers, cooling and washing towers, centrifugal cleaners, scrubbers, ammonia absorber and all pipe work	18,400
Duplicate blower, washer and centrifugal cleaners	3,780
4 non-recovery producers with necessary scrubbers, etc.	10,340
Steam-raising plant, economizers, feed pumps, etc.	4,850
Water-cooling towers, pumps and water softener	1,[illegible]
Buildings and foundations, etc.	24,271
Overhead traveling crane	1,250
Steel structural work, coal bunkers, coal and ash conveying plant	6,1[illegible]
Exciters, battery, switch gear and connections to generators	7,750
	£176,871

Or £17.087 per kilowatt installed.

Running Cost

The fuel consumption of a gas plant, as of a steam plant, is dependent upon at least four important factors: The actual output; the no-load losses, which include friction, windage and electrical losses incurred in running the generator on open circuit, together with all power required for exciters, pumps, and other auxiliaries; the standby losses of boilers or producers, and the ratio of the actual ascertained fuel consumption under day by day working conditions to the theoretical consumption based upon the test results, which we will term the "discrepancy factor."

The steam- and fuel-consumption curves shown in Fig. 8 have been plotted from a number of published tests of steam turbines and gas engines of different sizes. The ordinates above the zero line represent the steam and fuel utilized for the actual generation of electric power and those below indicate the fuel required per hour to run the generators at full voltage on open circuit. The former are approximately proportional to the units generated and are practically independent of the hours the plant is run, whereas the latter are approximately directly proportional to the hours the plant is run and are not appreciably affected by the units generated. It will be noted that the slope of the "consumption per unit generated" curves of steam turbines gradually decreases as the output of the plant is increased, whereas the corresponding curve of gas-driven generators is constant for all outputs. Various tests on gas engines of outputs ranging from [illegible] to [illegible] brake horsepower show that the actual consumption of fuel per unit generated exclusive of no-load losses is approximately 1 pound per kilowatt-hour for any output from no load to full load.

The [illegible]-kilowatt steam turbine curve is plotted from the recently published tests of a [illegible]-kilowatt turbo-generator at Manchester. The total steam consumption at full load was [illegible] pounds, or [illegible] pounds per kilowatt-hour generated exclusive of steam for exciter and auxiliaries. The characteristic of the steam-consumption curve at lighter loads appears to indicate that the no-load consumption of the plant would be approximately [illegible] pounds of steam per hour. We have, therefore, plotted the no-load consumption of [illegible] pounds below the zero line, and the balance of [illegible] above the zero line, which gives a steam consumption per actual kilowatt-hour generated of 13.4 pounds. To the no-load ordinates below the zero line we have added the estimated steam consumption of exciters, air and circulating pumps, feed pumps and all other auxiliaries, which are taken at [illegible] per cent. of the total full-load steam consumption, and from this second curve we are able to ascertain the no-load losses of any size of plant. The corresponding curve showing the no-load losses of gas engines with all auxiliaries is also plotted below the zero line.

The standby loss, through radiation of heat from boilers and steam pipes, and by leakage of cold air through the brickwork of boilers, is a very heavy item in all steam-driven electric-generating

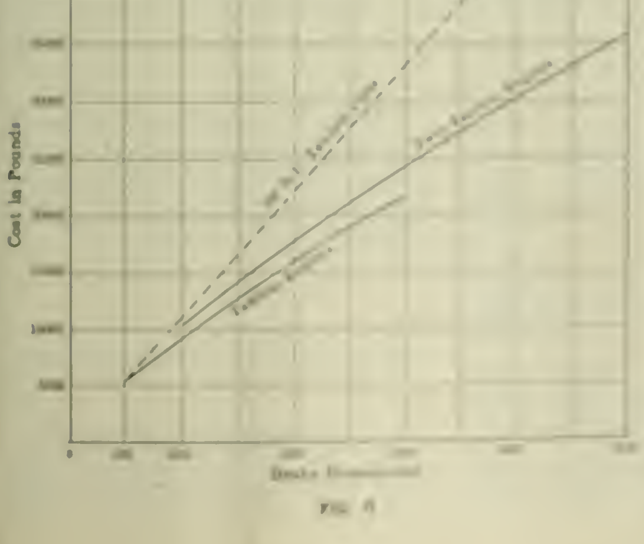

FIG. 6

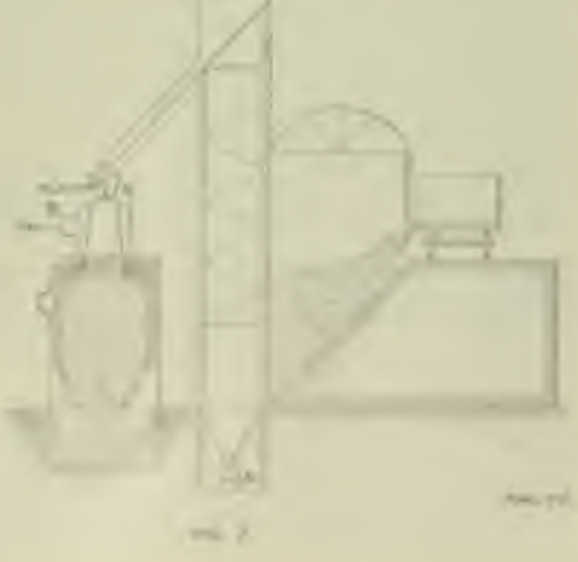

FIG. 7

stations, as the conditions of load are generally such that the majority of the boilers are banked for many hours every day. Collings Bishop, of Newport, found that two boilers, each rated for an evaporation of 10,000 pounds per hour, require 224 pounds of coal per hour for banking = 11.2 pounds of coal per hour per 1000 pounds of steam. As four such boilers are required for each 2000-kilowatt unit in connection with the steam-turbine station on which we have based our calculations, the coal for banking these boilers will be at least 448 pounds per hour per plant unit.

The fuel required for banking producers is only a small fraction of that required for banking boilers. The standby losses of the producers for the scheme under consideration are guaranteed not to exceed 50 pounds per hour per producer.

Discrepancy Factor

It is difficult if not impossible to keep this factor within reasonable limits, by reason of variations in the quality of the fuel supplied; fuel utilized in heating up cold boilers; the gradual fouling of boiler tubes, condenser tubes, etc., between cleaning periods; errors of judgment as to the correct time for running up and shutting down plant units, and other seemingly small details. For both the steam plant and the gas plant we have added 25 per cent. to the ascertained fuel consumption under test conditions to cover this factor.

For a maximum demand of 8000 kilowatts a load factor of 24 per cent. and a distribution efficiency of 80 per cent., the kilowatt-hours generated per annum will be 21,000,000. From Fig. 8, the steam consumption of a 2000-kilowatt turbo-alternator per kilowatt-hour is 15.5 pounds, or, assuming an evaporation of 8 to 1, 1.94 pounds of coal. The chart also shows that the no-load consumption for a plant of this size amounts to 900 pounds per hour.

Fig. 9 indicates the average hours the respective plant units would be required each day to deal with the assumed load curve. The minimum total engine hours would be 35 hours per day, or 12,800 hours per annum, and the banked boiler hours would be 45 hours per day, or 16,800 hours per annum. The total annual coal consumption for the steam turbines will therefore be as follows:

	Tons.
21,000,000 kilowatt-hours at 1.94 pounds	18,170
12,800 engine hours at 900 pounds	5,140
16,800 banked boiler hours at 448 pounds	3,330
	26,640
Discrepancy factor (1.25)	1.25
Total	33,300

= 3.55 pounds per kilowatt-hour generated.
Overall thermodynamic efficiency = 7.4 per cent.

For the gas station, Fig. 8 shows that the no-load consumption of a 1500-kilowatt gas plant amount to 800 pounds of coal per hour, and the useful output consumption to 1 pound per kilowatt-hour generated. Fig. 10 shows the minimum average engine hours per day for the gas plant and the average hours per day the producers would be banked. It appears from this that the total engine hours would be 17,450 hours per annum, and banked producer hours would be 35,000 hours per annum. The total coal consumption for the gas plant will therefore be as follows:

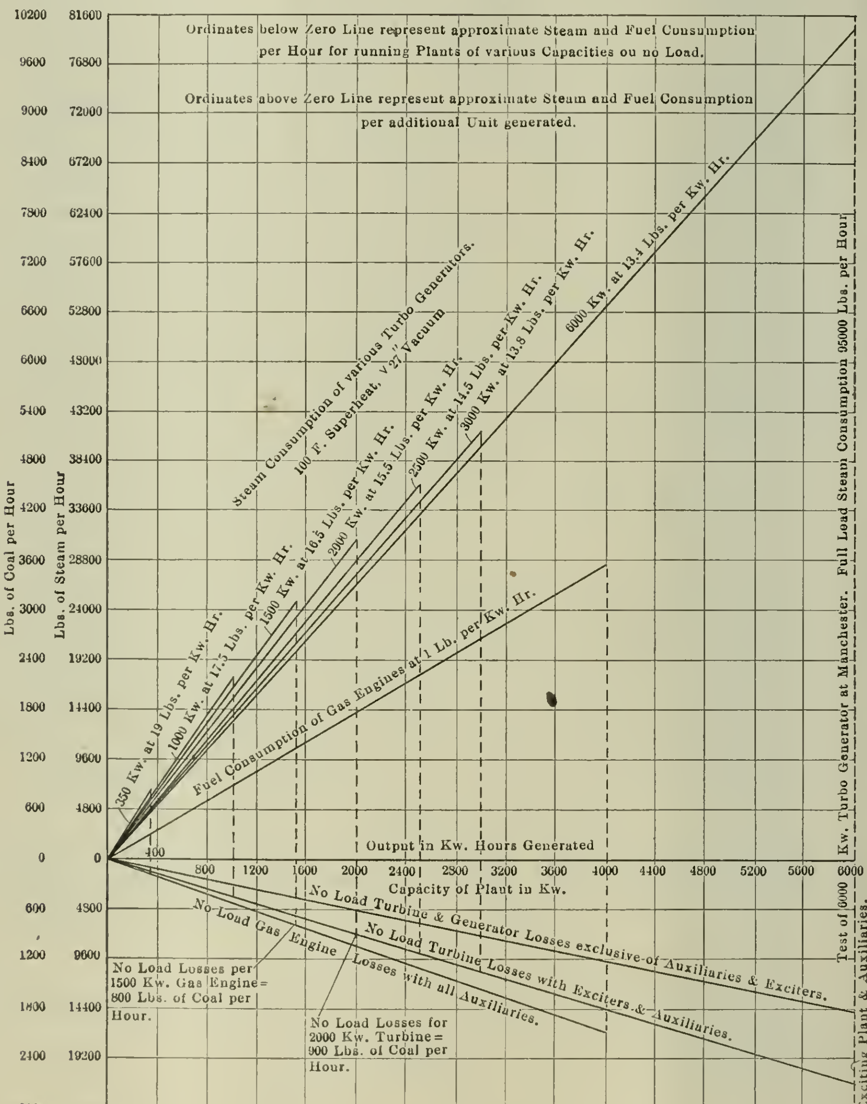

FIG. 8

	Tons.
21,000,000 kilowatt-hours at 1 pound of coal	9,360
17,450 engine hours at 800 pounds	6,230
35,000 banked producer hours at 50 pounds	782
	16,372
Discrepancy factor (1.25)	1.25
Total	20,465

= 2.18 pounds per kilowatt-hour generated.
Overall thermodynamic efficiency = 12 per cent.*

*Since these estimates were prepared, we have obtained actual fuel consumption results, taken over a considerable period, at a number of modern steam and gas installations, which show an actual average thermal efficiency for the steam stations of 6.7 per cent., or 10 per cent. less than our estimate based on theoretical conclusions; whereas the actual gas installations show a mean efficiency of 13.9 per cent., or 10 per cent. greater than our estimate (see table 3).

It is estimated that approximately 71 per cent. or 14,580 tons of the total coal consumption would be gasified in the ammonia producers and would yield at least 586 tons of sulphate of ammonia. Estimating the value of this at £11 per ton, which is considerably less than its present market value, the sale of this by-product would yield £6446 per annum. One ton of sulphuric acid, costing 30s. per ton, is required for each ton of sulphate of ammonia, and the cost of bags for packing the ammonia is estimated at 1s. 6d. per ton. The cost of acid and bags will therefore be £922, reducing the total amount to be credited on account of sale of sulphate of ammonia to £5524.

Oil, Waste and Stores

The cost of oil for the steam-turbine plant is estimated at 0.003d. per kilowatt-hour generated. This figure, which, it is thought, is considerably below the average oil consumption in steam-turbine generating stations, is based upon a figure given in the paper by Parsons, Stoney and Martin on "Steam Turbines." The oil consumption for large gas-driven generators is stated, by different authorities, to be from 0.2 to 0.37 gallon per 1000 horsepower-hours, the average cost of the oil used being 1s. 6d. per gallon. Taking the higher figure, the oil consumption per plant unit will be 0.74 gallon per hour, costing £970 per annum. The cost of the oil for the auxiliaries is estimated at £200 per annum. Total £1170 per annum.

The cost of waste and engine-room stores is estimated at 0.002d. per kilowatt-hour generated for both the steam plant and for the gas plant, thus bringing the total cost of oil, waste and stores to £438 for the steam plant, or 0.005d. per unit, and to £1345 for the gas plant, or 0.0154d. per unit.*

Water

Each steam unit requires 288,000 gallons of condensing water per hour, of which it is estimated 3 per cent. will be evaporated from the cooling towers. The water evaporation will therefore be 8640 gallons per hour × 12,800 engine hours = 110,500 thousand gallons per annum; at 6d. per thousand gallons, this will cost £2760 per annum.

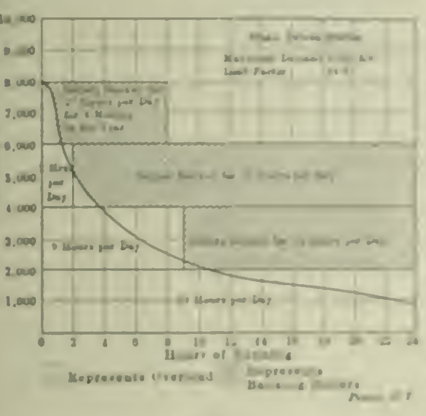

FIG. 13

The cooling water required for the gas engines would be about 12 gallons per kilowatt-hour of output; each 1500-kilowatt plant will therefore require 18,000 gallons per hour. Again assuming an evaporation of 3 per cent., the water evaporated from the engine cooling towers will be 540 gallons per engine hour × 17,450 engine hours = 9420 thousand gallons per annum. The water consumption for the producers is estimated at [illegible] gallons per day = 14,700 thousand gallons per annum. The total water for the gas plant will therefore be [illegible] thousand gallons at 6d. per 1000 = £[illegible].

Labor

The labor charges are estimated as follows:

Steam Plant

	£	s.	d.
2 operating engineers at £5 per week	[illegible]	[illegible]	[illegible]
2 switchboard attendants at 40s. per week	[illegible]	[illegible]	[illegible]
4 assistant engineers at [illegible] per week	[illegible]	[illegible]	[illegible]
4 oilers and cleaners at 25s. per week	[illegible]	[illegible]	[illegible]
2 firemen at [illegible] per week	[illegible]	[illegible]	[illegible]
8 "boiler" house and auxiliary plant staffs (including labor for cleaning boilers) at 30s. per week	[illegible]	[illegible]	[illegible]
4 men for unloading coal and removing ashes at 28s. per week	[illegible]	[illegible]	[illegible]
Total labor charges per annum			£[illegible]

Gas Plant

	£	s.	d.
2 operating engineers at £5 per week	[illegible]	[illegible]	[illegible]
2 switchboard attendants at 40s. per week	[illegible]	[illegible]	[illegible]
8 assistant engineers at 35s. per week	[illegible]	[illegible]	[illegible]
[illegible] assistant engineers at 30s. per week	[illegible]	[illegible]	[illegible]
[illegible] oilers and cleaners at 25s. per week	[illegible]	[illegible]	[illegible]
[illegible] producer hands at 35s. per week	[illegible]	[illegible]	[illegible]
8 producer hands at 28s. per week	[illegible]	[illegible]	[illegible]
7 ammonia recovery hands at 30s. per week	[illegible]	[illegible]	[illegible]
[illegible] men for unloading coal and [illegible]			
[illegible] at [illegible] per week	[illegible]	[illegible]	[illegible]
	[illegible]	[illegible]	[illegible]

Total labor charges per annum, £[illegible]

Maintenance and Repairs

This is the most difficult item to estimate with any degree of accuracy for either the steam or gas plant. With steam turbines the principal risk appears to be that of the blades stripping. With large gas engines the most serious risk is that of the fracture of the piston or of the cylinder liners. Troubles of this nature, while somewhat frequent in some of the earlier gas engines, owing to makers not having had experience to enable them to design these parts as to reduce the expansion and contraction under wide ranges of temperature to a minimum, are, however, fast disappearing.

As far as the actual wear and tear of the moving parts is concerned, this will probably be smaller in a gas engine than in a steam turbine. Practically the whole of the weight of the pistons and piston rods is carried on guides external to the engine cylinder; the wear upon the cylinder liners, therefore, is only that due to the pressure of the piston rings against the liners. It was thought at one time that the wear on the exhaust valves would be considerable, and in the early design of engines it was considered necessary to water-cool these valves to prevent overheating of the valve faces. Ehrhardt & Sehmer came to the conclusion some two years ago that the water-cooling of exhaust valves was an unnecessary complication, and they have now entirely abandoned this practice for all sizes of engines. Numbers of examples are recorded of large engines in continental generating stations that have been running for 12 or 18 months without being opened up.

The repairs for generators would certainly be lower for a gas-driven plant than for a steam-turbine-driven plant.

One of the principal items in the maintenance of a steam station is that of the repairs of steam pipes, whereas the maintenance of pipe work in connection with a gas engine will obviously be extremely small. The principal liability of repairs to pipe work appears to arise from the risk of the exhaust pipes being attacked by sulphuric acid if the water is allowed to mix with the exhaust gases and combine with the small percentage of sulphur in them.

The cost of producer repairs appears to be a very small item, and will undoubtedly be only a fraction of the cost of repairs to high-pressure steam boilers. The Power Gas Corporation estimates that the total cost of repairs to the entire producer plant, including the ammonia-recovery appliances as shown in Fig. 2, would not exceed, on the average, £[illegible] per annum over a period of a number of years.

We are of opinion that the total cost of repairs for the 10,000-kilowatt gas-driven station, including all machinery, apparatus and buildings, would not exceed £[illegible] per annum. We have estimated the repairs and maintenance of

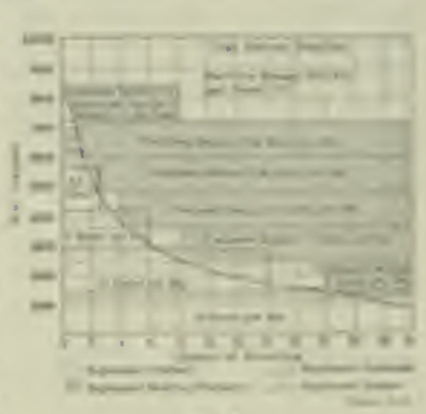

FIG. 14

the steam plant at the same rate as the gas plant, though we believe that this is a lower figure than has yet been secured in any steam station over a period of several years.

Amortization, Depreciation and Interest

As the use of large gas engines is so comparatively new in this country, some engineers may be inclined to think that the designs will be so altered during the next few years as to render it necessary to set aside a large amount to provide against obsolescence. Those, however, who have visited some of the large gas-engine installations on the Continent will have been impressed by the great similarity in general design between all the engines that have been erected during the past three or four years. The very first gas installation at the [illegible] Iron and Steel Works, for example, includes engines running with the same [illegible] from [illegible] to [illegible]. These engines [illegible] to be [illegible] and [illegible] have been [illegible] under [illegible] conditions than the [illegible]

*The cost of oil, waste and stores for the gas-engine plant at the [illegible] works of John Cockrill & Co. is stated to be [illegible] per kilowatt-hour generated, the output of the plant being 24,000,000 kilowatt-hours per annum.

gines appear to be running in every way as satisfactorily as those of more recent date.

The correct amount to allow for interest and depreciation on electric-generating machinery is a somewhat debatable point. It is usual in preparing estimates for industrial plants to allow 10 per cent., but Mr. Snell, in his paper on "Cost of Electrical Power for Industrial Purposes," justifies the figure of 6¼ per cent. As this point has a very important bearing on the comparison of steam- and gas-engine cost, we have in each case shown the comparative cost, including these charges at 10 per cent. and alternatively at 6¼ per cent. The total running costs of generating 21,000,000 kilowatt-hours under the above conditions will, we estimate, be respectively as follows:

	Gas.	Steam.
Total cost of coal at 12s. per ton	£12,280	£19,968
Less sale of sulphate of ammonia	5,524	
Net cost of coal	£ 6,756	£19,968
Oil, waste and stores	1,345	438
Water	555	2,550
Labor	3,180	2,590
Repairs	4,000	4,000
Interest and depreciation at 10 per cent. on capital	17,687	13,952
Total cost	£33,523	£43,668
Total cost per unit	0.383d.	0.498d.
Total cost, allowing 6¼ per cent. for interest and depreciation.	£26,900	£38,428
Total cost per unit	0.306d.	0.438d.

The total cost (including 6¼ per cent. for interest and depreciation) of generating power by steam = 45 per cent. greater than the cost of generating power by gas.

Effect of Price of Coal and Load Factor

In the particular case considered, the conditions are more favorable to the use of gas engines than in many of the existing provincial municipal electric stations in this country. There are at present only 15 public electric central stations working at a load factor of over 24 per cent., though many more have load factors varying from 20 to 24 per cent. In many cases, too, a suitable coal can be obtained at less than 12s. per ton delivered at the works. We will, therefore, go to the opposite extreme, and consider the case of a generating station having the very poor load factor of 10 per cent., and able to obtain fuel at 8s. per ton. We will also assume that the maximum output is only 4000 kilowatts, and that the use of the sulphate of ammonia recovery plant for a portion of the producer plant, as

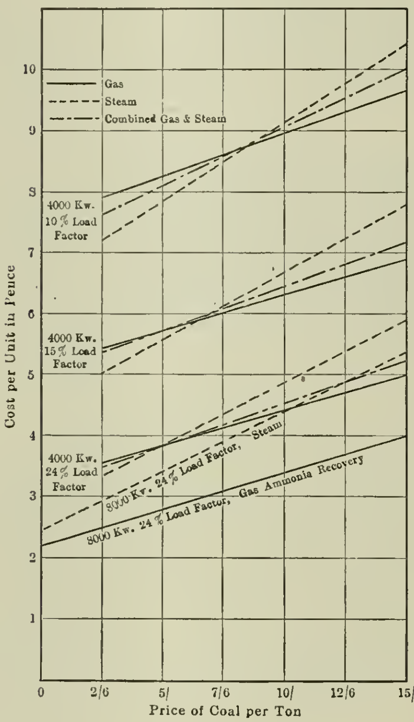

FIG. 11

in the scheme previously considered, is not justifiable. Under these conditions the saving in fuel effected by using gas

TABLE 2. OPERATING COST FOR A 4000-KILOWATT STATION.

Load Factor 10% Coal, 8s. per Ton.

	A. Steam.	B. Gas.	C. Combined.
Coal	£ 3,916	£ 2,073	£ 2,791
Oil and waste	95	297	248
Water	710	100	170
Labor	2,400	2,500	2,745
Repairs	1,250	1,250	1,250
Interest and depreciation at 10 per cent	7,452	9,578	8,639
	£15,823	£15,798	£15,843
Cost per kilowatt-hour generated	0.878d.	0.867d.	0.868d.
Total cost including interest and depreciation at 6¼ per cent	£13,037	£12,209	£12,608

engines is little more than sufficient to pay the 10 per cent. interest and depreciation charges on the higher capital outlay of the gas plant.

It has been suggested that for such conditions a combined gas and steam plant might be used, the gas plant being utilized

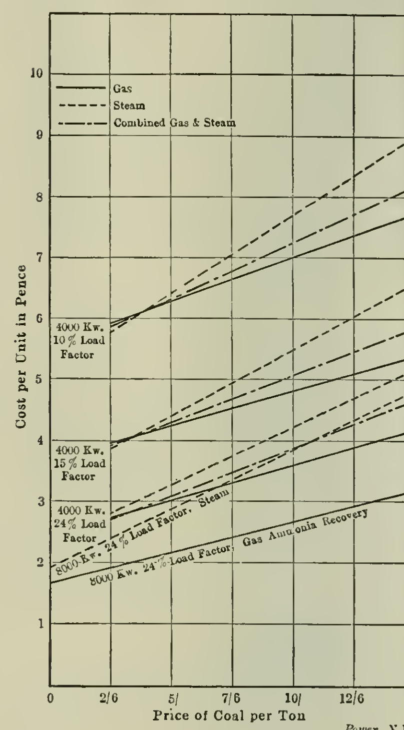

FIG. 12

for the long hour portion of the load curve and the steam plant with its lower capital charges for the peak load. Table 2 shows the estimated annual running costs with plants consisting respectively of, (A) five 1000-kilowatt steam turbo-generators; (B) seven 700-kilowatt gas engines and generators, and (C) four 1000-kilowatt steam turbo-generators and two 700-kilowatt gas engines.

The table shows that under the conditions stated and with a 10-per cent. charge for interest and depreciation, there is no choice between the different types of plant, as far as running cost is concerned, but with interest and sinking fund charges of 6¼ per cent. the combined station shows an overall economy of 3 per cent. over that of the steam plant, and the all-gas plant an improved econ-

TABLE 3. GAS PLANT EFFICIENCIES.

								Average overall efficiency of above eight replies =			13.95

omy of 6 per cent. over the all-steam plant.

The charts, Figs. 11 and 12, show similar comparisons with coal at various prices ranging from 2s. 6d. to 15s. per ton; the former is based on 10 per cent. allowance for interest and depreciation and the latter on 6¼ per cent.

It will be seen that under no condition is it worth while, when building a new station, to install a combination of steam and gas plant. With a nonrecovery plant and coal above a certain price, a gas plant is more economical, and below that price a steam plant alone is more economical than either a gas plant alone, or a combined steam and gas plant. This applies only to entirely new installations. There are many existing installations equipped with comparatively inefficient apparatus where a large economy would be effected by installing one or more gas engines to be used for the flat portion of the curve, the inefficient machinery being used only to carry the peak load and for emergencies.

It will also be seen that if the size of the installation or the load factor permits of a recovery gas plant being used that is more economical than a steam plant, however low the price of coal.

Table 3 gives the results of eight inquiries as to the actual operating efficiencies of gas plants. The kilowatt-hours generated are the total number supplied to the feeders. Current used for driving auxiliary apparatus in generating stations, lighting, etc., is not included under this heading. The load factor is calculated from

$$\frac{\textit{Kw.-hours supplied to feeders} \times 100}{\textit{maximum load on feeders} \times 8760}$$

The plant factor is calculated from

$$\frac{\textit{Kw.-hours supplied to feeders} \times 100}{\textit{plant hours run} \times \textit{capacity of plant}}$$

The fuel consumption is the total fuel used for all purposes. The calorific value of the fuel is the engineer's estimate of the mean calorific value based on periodic calorimeter tests.

The eighth regular prize competition of the Austrian Engineers' and Architects' Society has been announced. A solution is asked for the following question:

"How is it possible to avoid the injurious effects of the so-called higher harmonics of current and voltage waves which permanently or temporarily enter the alternating circuit; or how may their production be generally prevented?"

Three prizes are offered, the amounts being $600, $200 and $100. Persons who desire to obtain further particulars and to ascertain whether they are eligible to enter the competition, should address "Oesterrlicher Ingenieur und Architekten-Verein," Eschenbachgasse 9, Vienna, Austria.

Superheat and Wiredrawing

By F. L. Johnson

Upon returning from lunch the other day, I found my friend Sawyer sitting by the window poring over a work on "Water Power Engineering." As I seated myself after shaking hands and hanging up my hat, he said:

"It has always seemed to me that it was about an even thing between the cost of a steam and a water horsepower, when all of the factors of the problem are considered and properly treated. But reading this book has brought fresh to my memory two incidents that are in no way connected with water power, and I do not understand why they come to me now, for I have not thought of either of these for years. As I said, they can have no connection with water power, for they were examples of a gain that may be made in some instances by the use of steam superheated by wiredrawing.

"Several years ago I was visiting an engine room where I noticed two check valves, opening inwardly, attached to the indicator piping of the cylinder. Asking why they were there, the engineer closed the outer end of one, by putting his hand over it, and at once the exhaust valves began to rattle, showing that the cutoff was so short that expansion was carried so far below atmospheric pressure that during part of the stroke air and exhaust steam were drawn into the cylinder through the exhaust pipe lifting the valves from their seats, making a disagreeable rattle which the air let in through the check valve stopped by equalizing the pressure above and below the valve.

"While I was looking at the arrangement, the chief engineer from the new power plant, a comparative stranger and recent arrival in town, came in and introduced himself. He was shown the check valves and some indicator diagrams with and without the checks in operation. He smiled and said:

"'That is an ingenious way of stopping a disagreeable noise. You probably do not know that you are using a patented device, but as the patent expired a great many years ago, I do not think you will have to pay a royalty for its use.'

"Then, after a moment, he continued: 'I am a stranger to most of the engineers in town and I do not wish to be fresh, but I think I can help you in this case by making your engine run better without the check valves than it does with them, and by reducing your very small coal bill by nearly one-half.'

"These remarks were met somewhat doubtfully but with a spirit of willingness to learn of better methods, and the visitor was invited to go ahead. The engine was a 10x20, running at 75 revolutions per minute, and the steam pressure in the boiler was 80 pounds. It was a 72-inch by 18-foot boiler, with 33 square feet of grate surface, and a safety valve set to blow at 100 pounds. From 80 pounds the boiler pressure was raised to 85, by changing the weights on the damper regulator. Then the visitor went to the throttle and slowly closed it until the drawing-in of air at the check valve ceased and the drop of the [illegible] showed that cutoff was taking place in the vicinity of quarter stroke. Then he sat down and said:

"'Let us watch it awhile.'

"In a few minutes the engineer went to the belt-driven, [illegible] boiler-feed pump and changed the position of the bypass valve slightly. Asked what he was doing, he said that water was getting in the boiler and that he was cutting down the feed. He further stated that at the time the pressure was raised the water was slowly falling, and he expected to increase the feed instead of decreasing it.

"After sitting and chatting for awhile longer, the visitor said:

"'You have rather a hard combination here from which to get good results. Your grate surface is too large for the boiler, the boiler is too large for the engine and the engine is too large for the work to be done; but we can do considerably better than we are doing. If you have the [illegible] and some firebrick, I will come in next Sunday and we will fix up the boiler a little.'

"He was there the next Sunday, all right, and got right into the furnace and laid firebrick faster than two masons and better than I ever saw them laid before. He reduced the grate area from 33 feet to 24 by building a new firebox inside the old one. While washing up and changing his clothes, he said:

"'I will come down in the morning and see how the plant runs, for I am as much interested in it as you are.'

"After some general conversation and an exchange of cigars we went away.

"About three months afterward I went into that plant again, just to see how it was coming on. I asked the engineer if that man from the central station had saved him half the coal, as he promised.

"'Yes,' confound him [illegible]. 'In the old way I used to pile all my scraps into the furnace and get rid of them without any bother, but now, with the small grate that won't hold any coal, a lot of rubbish don't burn. He said he would cut the coal bill in half. He did better. I use about half the fuel I did before, but as I have just as many scraps to burn, I think I do not really use more than quarter of the coal that I did. That engineer at the central station knows how to run engines and boilers all right, and I am free to say that although I have been in the business twice as long as he has, he can give me cards and spades and then some and [illegible].'

Relighting the cigar that he had allowed to go out, Sawyer blew a few smoke rings and then said:

"I spoke of two instances of superheating by throttling, and although I wandered a little by telling of more than the throttling of the steam supply to an underloaded engine, I will stick to the text in the story that I am going to tell you now. Once I went from Duluth, Minn., to Ashland, Wis., on a tug. Besides myself there was another passenger, who wandered into the engine room and got into conversation with the engineer.

"After awhile the stranger asked the engineer to experiment a little for the sake of what could be learned by it. The lake was as smooth as glass, and the fireman had not changed the speed of the feed pump for an hour. The throttle was wide open and the engine was making 85 revolutions per minute. After counting the revolutions several times for a period of five minutes, to insure accuracy, the engineer was asked to close the throttle until he could plainly hear the steam rushing through it, which he did. Then the fireman was asked to note the water level and not to change the speed of the pump without notifying the engineer. After about fifteen minutes the speed of the engine was again counted and was found to be 86½ revolutions per minute, instead of 85, as before the throttle was partially closed.

"Soon the water was perceptibly higher in the boiler and shortly the fireman reported that he would have to slow the pump slightly. He also said, on being asked, that the boiler never fired easier nor steamed better. For several hours the experiment went on; in fact, until I turned in to sleep; and when I awoke we were at the dock, and I have seen neither the engineer nor his visitor since.

"But the facts are these: With a partially closed throttle there was an increase in the speed of the engine of more than one and three-quarters per cent., and a decrease in the amount of coal and water used. I do not know the man who suggested the experiment, nor do I know if anything ever came of it. But it has made me think a whole lot about wiredrawing and superheat, for in both of these cases the steam was superheated. When it entered the cylinder it had a temperature above that due to its pressure."

Then, looking at his watch, he said:

"I have stayed longer than I intended to and must move along. I will be in again in a couple of weeks," and he left me to think of superheat and wiredrawing.

If the work in the cylinder is done by heat, how is more heat utilized by checking the supply? I do not know and that is why I ponder over it.

Changing One Thermometer Reading To Another

By A. L. Hodges

As we are so unfortunate as to have two types of thermometer in common use, and as articles appear right along in engineering magazines, in which one or the other is used, sometimes both, it is absolutely necessary not only to know each individually, but to know their relations and common points. Of course, most of us are familiar with the formula to do this, but a formula is not as easy to remember as a simple diagram showing the relations. The writer has had a good deal of experience teaching engineers and has always found that the accompanying diagram enabled them to remember the relations better than anything else.

Besides the Centigrade and Fahrenheit thermometers, we have to do with the "absolute" thermometer, when dealing with a gas or with superheated steam. Any absolute temperature may be derived by simply adding 273 to the Centigrade temperature; but this has been included in the diagram.

To make the diagram, all one has to do is first to draw two vertical lines to represent the Centigrade and Fahrenheit thermometers, mark on the Centigrade line two points, 0 and 100, and mark opposite these, on the Fahrenheit line, 32 and 212, respectively. It is easy to remember that these are the freezing and boiling points of water on the respective thermometers. It will be seen that one degree on the Fahrenheit scale is equivalent to 5/9 of one on the Centigrade, because the same distance that indicates 100 on the Centigrade scale shows $212 - 32 = 180$ on the Fahrenheit. To change from one reading to the other, an addition or subtraction of 32 is necessary, as will be seen by reference to the diagram.

Suppose it is desired to change 50 degrees Centigrade to the corresponding reading on the Fahrenheit scale. As every degree Centigrade is equal to 5/9 degree Fahrenheit, it will be necessary to multiply 50 by 9/5 to get the number of Fahrenheit degrees above freezing point of water. But even this will not give the correct Fahrenheit reading unless 32 is added. This rule is expressed by the simple formula:

$$F = 9/5\ C + 32,$$

where F is the Fahrenheit reading and C the Centigrade.

From similar reasoning, then, in case it is desired to change from Fahrenheit to Centigrade, we must multiply by 5/9, but only after subtracting 32, because the Centigrade zero is at the freezing point of water. This is expressed by the following formula:

$$C = 5/9\ (F - 32),$$

where the symbols have the same significance as before.

As regards the "absolute" thermometer, it is graduated in degrees of exactly the same value as those of the Centigrade; so in changing the absolute to Centigrade, or *vice versa,* it is not necessary to multiply or divide by a fraction. If 50 degrees Centigrade is to be changed to absolute, simply add 273 degrees and the thing is done. If an absolute reading is to be changed to Centigrade, simply subtract 273 degrees and the correct result appears. Thus, 290 degrees absolute = 17 degrees Centigrade; also, 200 degrees absolute = − 73 degrees Centigrade, simply algebraic subtraction. So the formulas between the absolute and the Centigrade are very simple:

$$A = C + 273 \text{ and } C = A - 273.$$

If we try to change the absolute to Fahrenheit, or *vice versa,* without employing the intermediate Centigrade formula, the operation becomes slightly more complicated, but a glance at the diagram will make things clear. First, change −273 Centigrade degrees to Fahrenheit degrees by multiplying by 9/5. This gives the number of Fahrenheit degrees, below the freezing point of water, equivalent to zero, absolute. But to change this to the Fahrenheit reading it is necessary to subtract 32, which will give us − 459⅖. From this the logical formula results:

$$F = 9/5\ A - 459\tfrac{2}{5},$$

and the reverse formula, of course, is:

$$A = 5/9\ (F + 459\tfrac{2}{5}),$$

the symbols meaning the same as before, for the reading on the respective thermometers signifying the same degree of heat or cold.

Several peculiar things appear if certain relations are required. For instance, at what temperature do Centigrade and Fahrenheit read the same? Simply substitute Centigrade for Fahrenheit or Fahrenheit for Centigrade in (1) or (2) and it is found that at −40 (or 40 below zero) on either scale means the same degree of coldness. This is verified by the diagram. Similarly, several such points are shown on the diagram.

They are easy to memorize and come in handy occasionally. For example, when the temperature Fahrenheit is 320 degrees and it is desired to change it to Centigrade, the diagram enables one to know that the Centigrade reading to correspond is exactly ½, or 160 degrees. So, for approximate results anywhere within a few degrees of 320, simply divide by two. With the absolute scale there is one point that reads the same as the Fahrenheit, namely, 549¼; but, from the nature of things, no point on the absolute scale is the same as the Centigrade, for it is necessary to add 273 to the Centigrade, no matter what it is, to get the absolute.

What Zero Absolute Means

The zero absolute means just what it says: That a body is perfectly cold at that temperature, containing no heat whatever. Therefore, there can be no "minus" degrees absolute, or "below zero" absolute, even in theory. To realize fully the significance of an absolute scale the mind must have a clear mental picture as to what heat really is and exactly what happens to a body when that body gets hotter or colder.

Heat is defined as "molecular vibration." To grasp this, one must think of every body, no matter of what material composed, as being made up of very small particles, called molecules, that are in a state of constant vibration at all ordinary temperatures, jumping about in little cells of their own.

When the body becomes warmer, as we say, what happens to these molecules? It has been shown that they go faster in their vibrations, occasionally knocking one another away to make room for themselves. In the case of a solid, for instance iron, if heated, all the molecules at once seem to go faster and through longer distances. They knock one another about until room is made. This, of course, is transmitted outward to those on the surface of the body and they seek the line of least resistance and consequently extend their paths outward. What has happened to the body in the meantime? As everyone knows, it has grown larger or "expanded." Yet no matter has been added, for a hot body weighs no more than the same body cold.

Heat, then, means simply the amount of vibration of the molecules. When we cool a body it contracts, that is, the molecules go slower and through shorter distances. When the molecule has no motion whatever we have the absolute zero. It is needless to say that this condition of affairs has not so far been reached experimentally by inhabitants on this earth, and will probably never be reached, for the vibration of a molecule is presumably of such nature that it can never become quite still, although approaching that condition as a limit.

This absolute scale is of peculiar interest in the case of a gas. It has been found experimentally that all gases when cooled 1 degree Centigrade contract almost exactly 1/273 of their volumes at zero Centigrade. So if we could cool a gas to —273 degrees Centigrade, or absolute zero, it would have practically no volume. This is in perfect accord with the theory of gases being composed of little molecules very, very far apart in relation to their sizes, so far apart that they seldom hit one another in their vibrations. So it stands to reason that if they had no vibration and were packed closely together, their volume would be very small indeed. Even if absolute zero could be reached it would be of no value in proving the small volume of a gas because all gases liquefy or solidify long before absolute zero is reached. The last to liquefy is helium, which a German professor claims to have frozen at —271 degrees Centigrade or 2 degrees absolute. This has not been verified, however.

DIAGRAM FOR CONVERSION FROM ONE THERMOMETER TO ANOTHER

Sewalls Falls Plant Near Concord, N. H.

2000-Kilowatt Water Power Plant Containing the First Installation of Vertical Multirunner Direct-connected Open-flume Turbine

BY S. RICE

Up to the time of the installation of this type of turbine, the vertical single-runner turbine, with gearing to jack shaft direct-connected or belted to generators, had been developed and extensively installed, with a view to meeting conditions prevailing for low-head developments in which limited space and extreme variations of water level are controlling factors. These particular turbines are said to have given, however, the first commercial demonstration of a method hydraulically efficient and desirable from a construction and operating standpoint.

The Sewalls Falls plant of the Concord Electric Company is located on the Merrimac river, 4½ miles above the city of Concord, N. H. The Merrimac river at this point drains an area of about 2350 square miles and has a normal flow of about 2500 second-feet and an average fall of about 16 feet. The total development aggregates 2000 kilowatts.

In the winter of 1904-05 the company decided to add 1000 kilowatts to the capacity of the original plant, then consisting of five 200-kilowatt generators belted to twin turbines in plate-steel casings, in order to supply power to the street-railway system projected by the Boston & Maine Railway in the neighborhood of Concord, and to various other consumers of electric power. The design had to provide for flood variation of some 19 feet. Due to the excessive tailrace excavation required, it was impracticable to locate the addition at the northern end of the old power plant. Placing the installation at the southern end made it necessary that the building be as compact as possible, on account of forebay extensions and in order to reduce foundations and to simplify the protection from the thrust of the river.

Fig. 2 shows the design adopted, which includes two 900-horsepower vertical triplex open-flume turbines direct-connected to two 500-kilowatt vertical generators, with a speed of 100 revolutions per minute, excitation being furnished by a motor-driven exciter generator. How well the plan adopted fulfils the conditions may be observed from Figs. 1, 2 and 3, where it will be seen that the generator floor is above flood mark and that the power house is approximately one-third the length of the old one, being at the same time equal in capacity.

Turbines

There are two turbines, as heretofore stated, designed for operation under a normal head of 16 feet. These machines, as shown in Fig. 5, each consist of a twin center-discharge turbine mounted above a single turbine by means of substantial column construction. The turbine gates are of the swivel type operated through regulating shafts and connections. The advantages of swivel gates over cylinder gates for this type of turbine are:

First—That swivel gates give increased efficiency at partial gate opening and equally good efficiency at full gate opening, while the efficiency with cylinder gates is low, due to the fact that excessive hydraulic disturbances, eddies, etc., occur at partial gate openings.

Second—With the use of the swivel type, the increase or decrease in power, resulting from opening or closing the gates, occurs uniformly throughout the stroke from wide open to closing position, which characteristic is necessary for uniformly sensitive regulation from no load to full load. With the cylinder type, a considerable closing of the gates from wide-open position is necessary before any reduction in power is effected. Moreover, at very small gate opening (required for friction load) the friction eddies in the water, while passing through the gates, is so great that no power whatever is developed in the wheel. This inevitably results in impaired regulation at full- and friction-load gate openings.

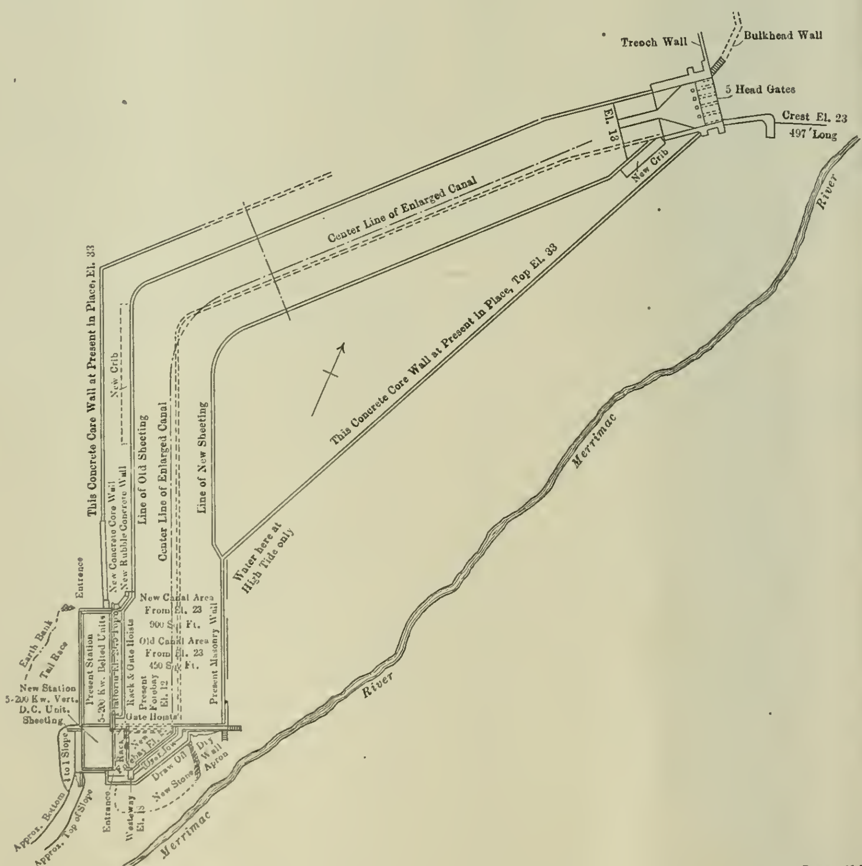

FIG. 1. GENERAL PLAN OF DEVELOPMENT

The bronze runners, shown in Fig. 7, are designed to develop 900 brake horsepower at a 16-foot head and 615 brake horsepower at a 12-foot head, with a constant speed of 100 revolutions per minute. The characteristics of these runners enable normal speed to be maintained under a reduction of normal head, with but slight loss in efficiency, thus making

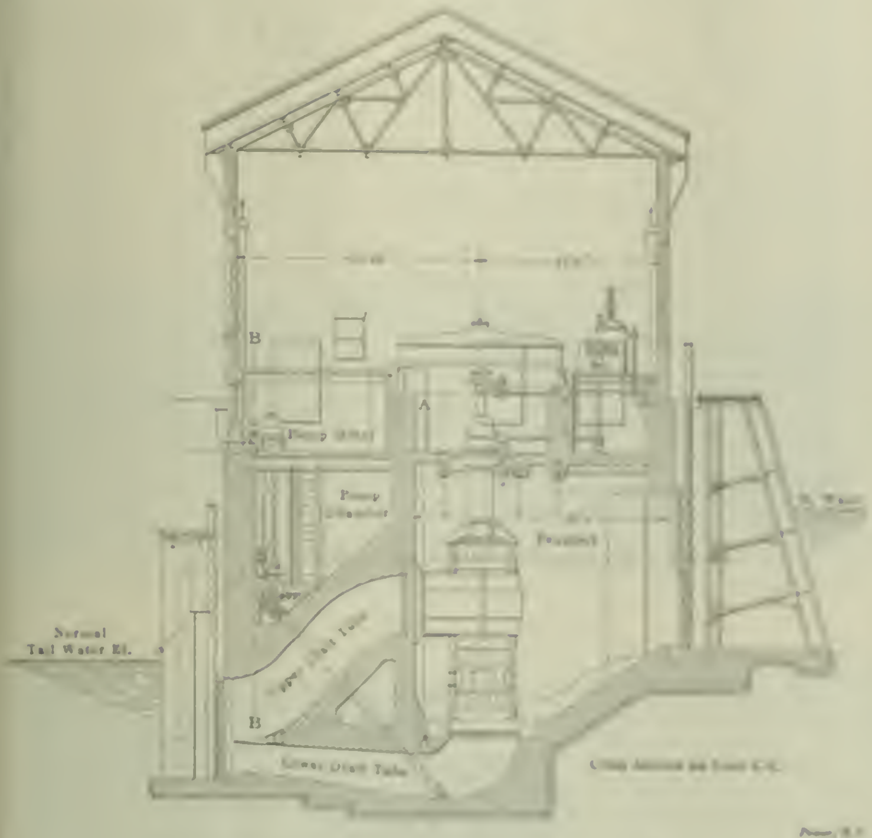

FIG. 2. TRANSVERSE SECTION OF NEW STATION

draulic disturbances. The object in this, as with all draft tubes, was to so construct them as to abstract a maximum practicable amount of its kinetic energy from the water before discharging it into the tailrace. How little attention has been given to the proper design of draft tubes in this country will be readily seen by referring to illustrations in the current hydraulic turbine catalogs showing the short, straight draft tubes and settings which they recommend. A striking example of the losses incurred with such draft tubes is shown in a recent case where 25 per cent. actual increase in plant capacity was obtained by replacing a straight, short wrought-iron draft tube of the catalog type mentioned above with one properly designed and constructed of concrete.

Thrust Bearings

The thrust bearings furnished are of the standard Allis-Chalmers oil-bath self-contained type. A view of the outside casing and base ring is shown in Fig. 5. The bearing is built to run wholly in a bath of oil and has demonstrated, during years of continuous commercial operation, that it requires minimum operating attention. A further advantage of this thrust bearing is its economy in the use of oil. In a plant containing eight 875-horsepower vertical turbines, which was recently described in this paper, an av-

them particularly adaptable to variable head developments.

Tests made after installation have established the fact that remarkable uniformity in efficiency is maintained through a wide range of gate opening, a feature of great importance from the standpoint of economy of water.

Governors

For regulating the speed of the turbines the governors used are of the oil-pressure type, as described on pages 455-459 of the September 15, 1908, number of POWER AND THE ENGINEER. In this installation they are arranged so as to be entirely self contained, the rotary oil pump, tanks, regulating cylinder and governor mechanism proper being mounted on a single base. The governor head and pump are driven from the main shaft by means of bevel gears, and the regulating piston is connected to the regulating shafts by means of a simple link arrangement, avoiding, as is the builder's regular practice, the use of gearing and the lost motion inherent in such arrangements.

Draft Tubes

As shown in Fig. 2, the concrete draft tubes were designed to lead the water to the tailrace from the center discharge casing and lower runner with uniformly decreasing velocity and minimum hy-

FIG. 3. LONGITUDINAL SECTION OF NEW STATION

tual saving of over $6000 a year in oil was effected by replacing the pressure thrust bearings, originally installed, by oil-bath bearings of this type.

Three metal guide bearings were supplied with each turbine. They are supported by the center discharge casing and fed with oil from above.

Electrical Apparatus

There are two 500-kilowatt three-phase 60-cycle 2600-volt vertical direct-connected revolving-field generators of the type shown by Fig. 8. These machines revolve at a speed of 100 revolutions per minute, and the features of especial interest are the stator and rotor. The stator is bolted to the cast-iron supporting ring which is carried upon concrete foundation beams worked into the lower floor, as shown in Fig. 2, and has bolted to its top the spider which supports the guide bearing. The rotor is of the "umbrella" type, constructed of cast steel and especially designed to withstand the stress due to its great diameter and posi-

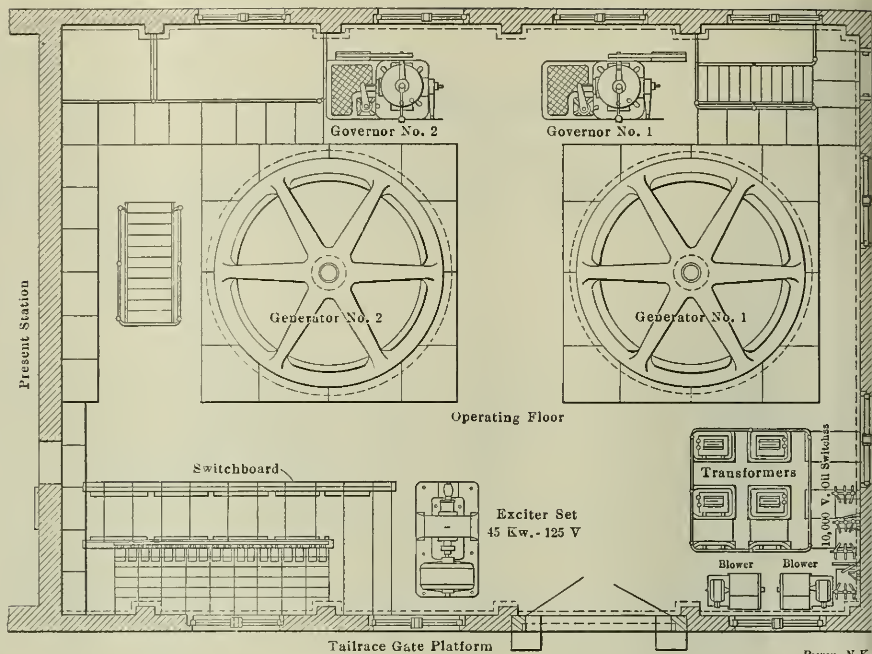

FIG. 4. PLAN OF OPERATING FLOOR

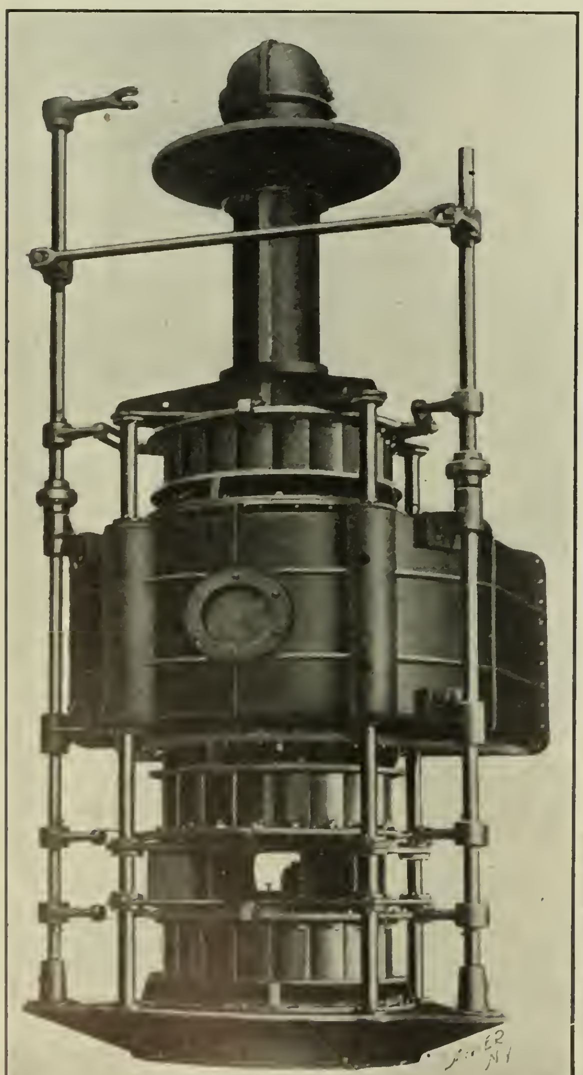

FIG. 5. 900-HORSEPOWER ALLIS-CHALMERS VERTICAL TRIPLEX TURBINE

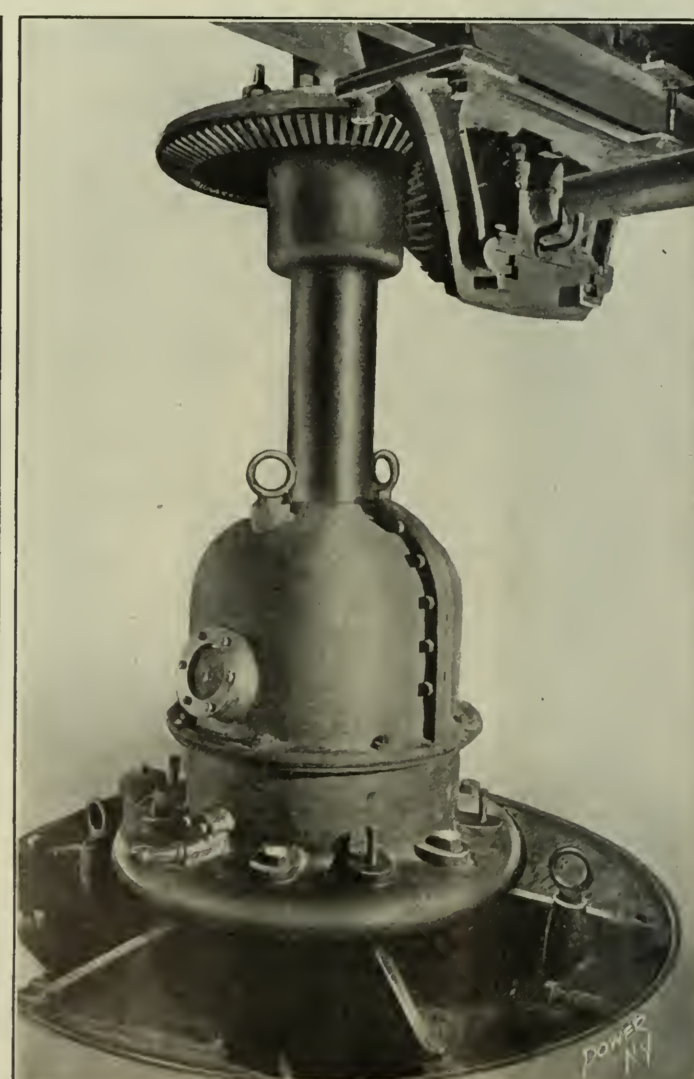

FIG. 6. THRUST BEARING OF TURBINE

tion with reference to its field coils. It is mounted on a short shaft, the collector rings being arranged immediately above the coupling to which the turbine shaft is connected.

Excitation is furnished by one 45-kilowatt 125-volt compound-wound generator, direct connected on the same cast-iron baseplate to a 75 horsepower 60-cycle three-phase induction motor wound for 2000 volts, and a speed of 680 revolutions per minute. This type of exciter was chosen in preference to a waterwheel unit on account of the necessity of economizing space as much as possible.

The switchboard is of blue Vermont marble, 21 feet 4 inches long and divided into eleven panels. The generator, exciter and exciter motor have each a separate panel with a blank panel for a future line. A portion of the switchboard is shown in Fig. 8.

The 10,000-volt air-blast step-up transformers are placed on the lower floor. These transformers are provided with ducts below and connections to the air shaft communicating with the blowers. A damper is provided for shutting off air from each set of transformers.

General Construction and Development

There are several points in connection with the general construction involved in this development which are of engineering interest, and will be noted in the general drawing, Fig. 1, and power-house arrangement, Figs. 2, 3 and 4.

Power House—The design and dimensions may be seen by referring to Fig. 4. Reinforced and rubble concrete is used for the substructure and the superstructure is of brick, with a slate roof supported by steel trusses. A hand-power crane is provided, the crane girder being carried on steel columns. On the upper or operating floor are located the generators, governor, switchboard, motor generator and blowers for the transformers. In the construction of the floor provision is made for easy access to the space around the generators, to the bulkheads in the lower floor and to transformers. Removable slate slabs resting on leveling strips are used for this purpose and the part of the floor is made level with the remainder, which is of concrete with smooth interior finish.

On the lower, or thrust-bearing floor, are located the thrust bearings, transformers and a 5-inch motor-driven centrifugal pump for unwatering the turbine pits. The generators are supported on circular concrete bases carried on floor arches, and platform with steps is provided for reaching the generator collector rings and brushes. The draft tubes

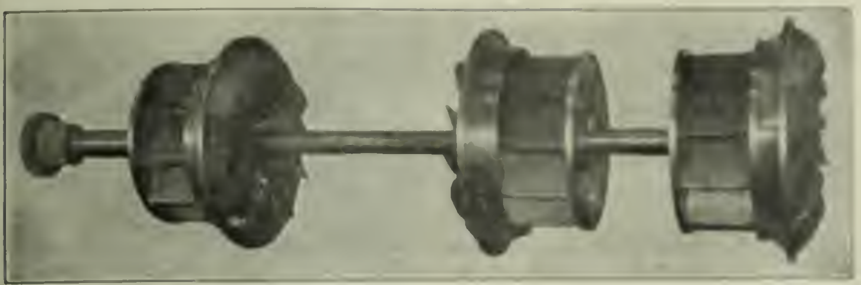

FIG. 7. 55-INCH RUNNERS OF VERTICAL [illegible] TURBINE

[illegible] of reinforced concrete designed as previously described, and the maximum velocity at their outlets is brought down to nearly that of the tailrace. In addition to head gates and tailrace gates, stop log slots are provided.

Dam—The dam is a cribwork structure [illegible] feet long, with planked apron protected by iron plates. The abutments, wing walls and canal head-gate works are of rubble masonry. The elevation of these works is from [illegible] to [illegible] feet above the crest of the dam.

Canals—The original canal, about [illegible] feet in length, was [illegible] feet deep and [illegible] feet wide at the top with a cross-section area of [illegible] square feet. At the time of the installation of the two units, the canal was widened to give double the cross-section. Fig. 1 shows the widened canal as left there. It will be noticed that the inner curve was made with considerably greater radius than that of the original canal, the inner side of which is shown in dotted lines. This was done because it was found that the angle in the old canal was sharp enough to cause considerable erosion at the curve.

The sheeting of the newly excavated side of the canal toward the river consisted of tongue-and-groove hard-pine planks, [illegible] inches thick, placed in a trench and driven to hard pan. The sheeting on the old bank of the canal was repaired as necessary and at the upper corner of the station on the canal a concrete wall was built, making the joint secure. It was estimated that the loss in head in the canal and entrance, and down to the mouth of the tailrace, would not exceed [illegible] feet under normal conditions. The canal head gates are built of selected Georgia hard pine with racks, guides, tracks and hoisting apparatus, and are arranged so that they may be hoisted by hand or by geared motors.

Forebay—For a length of [illegible] feet, the top of the forebay wall has an elevation of [illegible] feet and serves as an overflow. In this wall is a [illegible] gate for drawing down the water in the canal. For ordinary passage of ice, driftwood and handling waste water a [illegible] wide by [illegible] overflow gate is provided. The bottom of the opening is [illegible] feet below the normal surface of the water in the canal and extends [illegible] to the top of the wall. This gate is arranged to lower entirely below the [illegible] and is operated in conjunction with the canal head gates to control the height of water in the canal.

Racks and [illegible]—The racks are built up on a [illegible] steel frame resting on a [illegible] masonry flooring and are braced back against the [illegible]. The gratings are of [illegible] bars spaced [illegible] inches in the clear and are made up in sections with the [illegible] placed back of the [illegible]

FIG. 8. ONE OF TWO [illegible] TRANSFORMERS

of the bars to allow the teeth of the rakes to pass without catching. The whole is made of sufficient strength to act as a dam, should anchor ice close up the openings and the water be drawn from behind.

The head gates are double, each 15 feet 6 inches by 7 feet 6 inches, built in two parts on account of their large size. Two-part gates were required, since solid gates would have necessitated placing the hoisting apparatus much higher and shutting off the light from the station windows.

Since the inception of its developments in 1892 the Sewalls Falls property has changed hands several times, and is now owned and operated by the Concord Electric Company of Concord, N. H., of which Allen Hollis is president and F. P. Royce, vice-president. George B. Lauder is superintendent and chief electrician, and L. D. Martin chief engineer. The consulting engineers are Hollis French and Allen Hubbard, of Boston, Mass., under whose supervision the installation above described was executed.

The Storage Battery

By A. Wohlgemuth

The storage battery, or, as it is also called, the accumulator or secondary battery, does not store electricity in the strict sense of the word; the electricity which it delivers is the result of chemical action caused originally by passing a current of electricity through the battery. This phenomenon was first observed by a French scientist, Planté, in 1860. M.

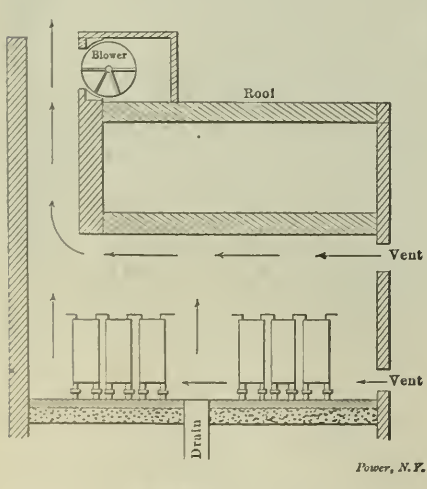

FIG. 1. ARRANGEMENT OF BATTERY CELLS AND PROVISION FOR VENTILATION

Planté passed current through a cell containing two lead plates immersed in a solution of sulphuric acid, and on discontinuing this charge connected the two plates to a current indicator. He noticed that a current of electricity was passing through the instrument, but in an opposite direction from the original current. Charging, discharging and recharging were continued for some time, the discharge becoming stronger the oftener and longer the charge was kept up. At the same time the surface of the plate was changing greatly. The plate to which the positive pole was connected took on a dark-brown color, and became brittle to the touch, while the other, a negative plate, assumed a light grayish hue, and felt soft and spongy. On discharge, the plates gradually assumed their original character. The plates of a modern battery formed in this manner are therefore called "Planté plates."

This forming process is a rather tedious operation, and was improved upon by another Frenchman, Faure, who conceived the idea of using ready-made active material pasted on the plates, instead of the material formed by repeated charging. The substances which can be used, and are used in the manufacture of Faure

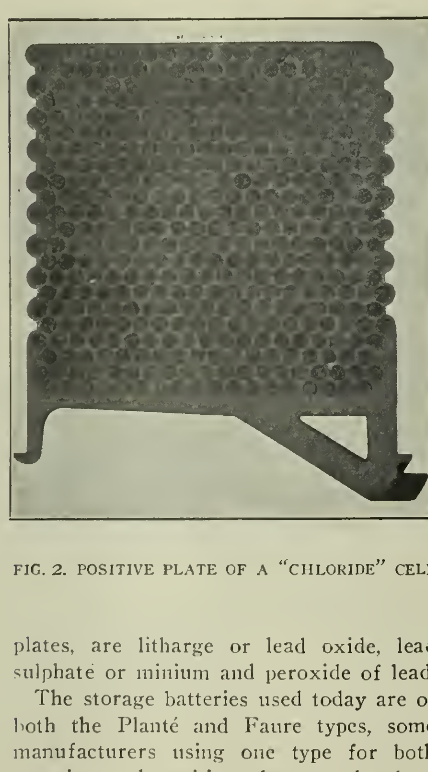

FIG. 2. POSITIVE PLATE OF A "CHLORIDE" CELL

plates, are litharge or lead oxide, lead sulphate or minium and peroxide of lead.

The storage batteries used today are of both the Planté and Faure types, some manufacturers using one type for both negative and positive plates, and others using the Planté type for one polarity and the Faure type for the other. Several diverse methods are employed to get the greatest amount of active material per given area and weight of plate; the kind of battery to be installed in any given case depends largely upon the use it will be put to.

In selecting a location for the battery room, facilities for proper ventilation, light and atmospheric conditions in the room ought to enter into consideration. The temperature should not be allowed to go much over 75 or 80 degrees Fahrenheit and not much lower than 50 degrees Fahrenheit. In modern battery rooms the floor is usually made of concrete protected by layers of tar paper and asphaltum, and finished with vitrified brick laid in asphaltum. Drains are provided and so arranged that collection of water is prevented; this is usually done by sloping the aisles between the tanks and providing cesspools to carry off the water. All drain pipes should be of lead and all metal supports should be covered with several layers of good lead paint, to pre-

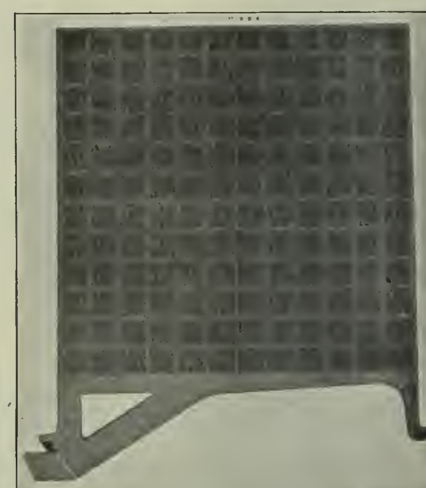

FIG. 3. NEGATIVE PLATE OF A "CHLORIDE" CELL

vent the acid from attacking and corroding the metal. The ventilation of the battery room is a very important matter. There are always gases present and when the battery is charging a large amount of gas and spray is given off, which, if not drawn off, is very injurious to all metal in the rooms. Exhaust fans are used almost exclusively to draw off these gases. (See Fig. 1.)

The tanks containing the plates are made of glass in small installations and of wood lined with lead in the larger plants. Lately, tanks made of earthenware have been installed with more or less success. The tanks are placed on glass or porcelain insulators, which are in turn supported by heavy wooden beams. In a great many instances the beams are done away with and the insulators are supported by mounds of sulphur, topped by a slab of vitrified brick. In all cases the bottom of the tank is from 6 to 8 inches above the floor, to allow free circulation of air and to prevent grounds.

When the tanks are in position heavy glass plates, 3/8 inch thick, two to each cell, are placed longitudinally in the tanks, which act as support for the plates. The latter are now placed in the tanks, negative and positive, alternately, and glass or hard-rubber tubes are put between each plate to act as separators. There is always one more negative than positive plate in each cell, in order to have both sides of the positive plate oppose the negative. The plates are now connected, the negatives of two cells to one strip of lead and the positives of two cells to one strip.

When all the plates are burned in, and all other necessary connections are made, then, and never before, the electrolyte is

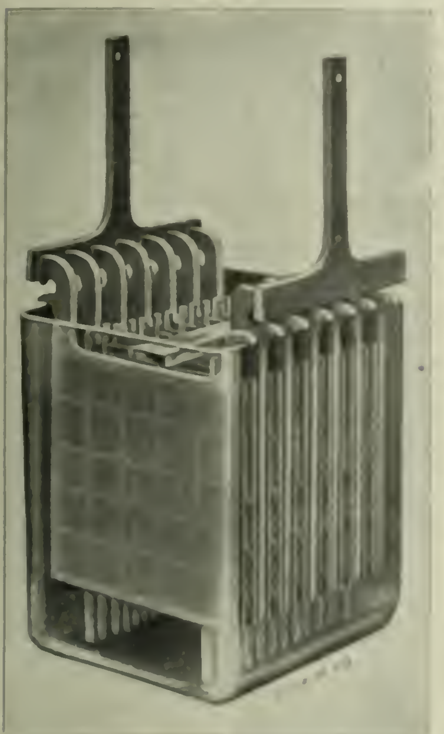

FIG. 4. [illegible] "CHLORIDE" CELL

poured in and the battery is ready for its first charge. This is usually of 24 or 30 hours' duration, and it is good practice to start this charge at a low rate, to prevent excessive heating due to the large internal resistance of the uncharged cell. As the voltage of the battery rises the charging current is increased until the maximum rate is reached. Toward the end of the charge, the current is again decreased, to prevent chemical action of too violent a nature. During the charge careful readings should be taken and great care exercised to get at the condition of the battery. The normal voltage of a fully charged cell in good condition is from 2.2 to 2.5 volts and the density or specific gravity of the electrolyte should be from 1.2 to 1.25.

Like every other apparatus, the storage battery if not treated properly will not do the best work it can. In commercial service the storage battery will develop a great many faults and if not watched intelligently will rapidly decrease in efficiency. There is one point which cannot be impressed upon users of the storage battery too often, and that is that a battery should never be allowed to stand "dead," that is, idle and disconnected from both charging and receiving circuits. As soon as the battery is allowed to lie idle for any length of time, especially in a discharged or semi-discharged condition, local action between the plates will increase enormously and a deleterious process called sulphating will begin. Sulphate of lead, a whitish, nonconducting and insoluble substance, forms on the plate and will soon reduce the efficiency to almost zero. One way to overcome the effect of partial sulphating is to charge the cell at a low rate for a long time—until the sulphate is reduced. If the sulphating has advanced very far, the only remedy is to draw off the acid, disconnect the plates and rinse them in pure water, using a brush to rid the plates of the sulphate. Then immerse them in water for 24 hours and rinse them again. Then reassemble the cell and charge at a low rate until the electrolyte shows signs of activity.

One other fault which gives the batteryman a lot of worry is the short-circuiting of the plates, which is caused either by buckling or by sediment in the bottom of the cell. Buckling of plates is

FIG. 5. POSITIVE PLATE OF [illegible] CELL

due to uneven expansion of the active material, causing the grid to bulge, until it touches the neighboring plate. It is usually the result of too heavy a rate of charging or discharging—more often the latter. Sediment is active material which has dropped off the plate and sunk to the bottom of the cell. If allowed to accumulate, it will finally reach the plates and thus short-circuit them.

The reversal of a cell is as a rule caused by an overdischarge, and by charging the cell at a low rate for a long period of time the cell can be brought back to its normal condition.

At the completion of a charge, the electrolyte of a healthy cell is in a great state of activity. It gasses, or throws off a lot of spray, and bubbles of hydrogen appear on the surface. If any of these signs are missing, the hydrometer will invariably indicate a low specific gravity, and if the attendant is positive that none of the faults already described is present in the cell, then it is advisable to add some fresh acid. To do this while the cell shows signs of other trouble, however, is wrong, as a low specific-gravity reading, in many instances, is an indication of trouble other than low density.

The charging and discharging of the battery must not be carried on in a haphazard manner, but must be done so as to conform strictly with the rated capacity of the battery. The charge or discharge capacity is rated in ampere-hours at an 8-hour rate, and for the majority of plates it is [illegible] ampere-hours per square foot of surface on both sides of the positive plates, and about [illegible] ampere-hours per pound of metal in both positive and negative plates. For example, if a battery is rated at 400 ampere-hours, it can be discharged at 50 amperes for eight hours. If discharged at a higher rate for 8 hours or for a longer time at the proper rate, reversals of cells, buckling of plates and other faults will be the result; and if this habit is persisted in the battery will deteriorate rapidly. A 400-ampere-hour rated battery, for example, rated at 8 hours, can be discharged, if conditions are favorable, at 100 amperes for about two hours, which is only 200 ampere-hours, but it would not stand such a discharge rate for three hours or even two and one-half hours if the performance were repeated often. Although in an emergency, such as breakdown, very heavy discharging is permissible, it must not be regularly practised or the plates will not last long.

If for any reason the use of the battery must be discontinued for any length of time,

FIG. 6. NEGATIVE PLATE OF [illegible] CELL

it is best to place it out of commission altogether in the following way: First give a complete charge and draw off the electrolyte. Fill the tanks with water and discharge the battery until the cells fall to about 1 volt each. Then draw off the water and the battery may remain in this condition until it is again wanted.

Air Compressor Valves

Fig. 1 shows a simple form of valve used in certain vertical air compressors. Some of these valves have no guide other than that afforded by the spring which tends to close them, and a valve of this type will not wear true on the seat. In Fig. 2 is shown another fault in the design of this type of seat; it has not sufficient metal backing. The constant closing of the valve causes the seat to lower, as shown. I have seen them driven down until they struck the piston head of the compressor. Fig. 5 would be a better construction for these seats. Here the proper amount of metal is allowed for the wear and lowering of the valve, and the piston head is recessed to allow proper clearance for the free working of the valve.

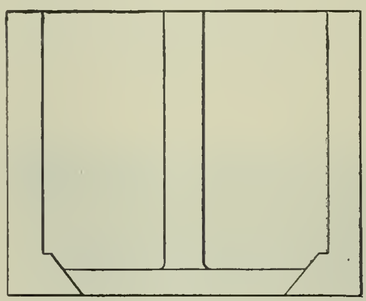

FIG. 1

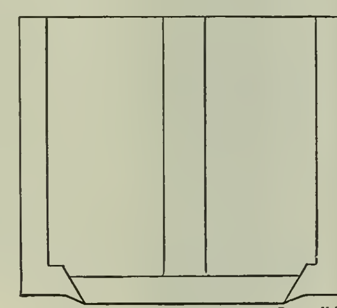

FIG. 2

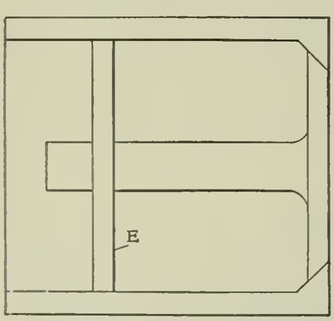

FIG. 3

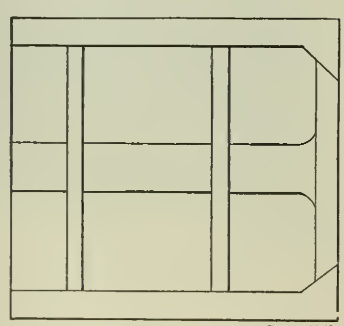

FIG. 4

Fig. 3 shows another form of valve that has a guide disk fast to it. This is somewhat better than the others and will work fairly well on a vertical compressor; but its use on a horizontal compressor would not prove of much value. When they become slightly worn, they will lower on the seat and will hang and leak. The disk *E* might have been made thicker, as it would form a better guide than when so narrow. When narrow in section it tends only to hang the valve when it becomes worn.

In Fig. 4 will be seen a better construction for a horizontal compressor valve, and if these guide disks are placed the proper distance apart, the valve will work satisfactorily, as these guide wings will hold the valve in a true horizontal position. The thickness of these disks should be sufficient to stand the wear.

Fig. 7 illustrates another fault that has been noticed in compressors, that is, the making of the valve too thin as shown by the dotted lines. Were the valve made as shown by the solid lines, the result would be satisfactory. In Fig. 6 will be noticed the Corliss type of compressor valve. I fail to see the advantage gained by the use of such a valve on a compressor cylinder and I think a poppet valve will certainly close more quickly and remain quite as tight. When properly made, the back flow from the compressed air will be less on the poppet type than on the Corliss operated by a crank lever. The Corliss valve will work well at one hundred pounds pressure, but in working air above this pressure it will be hard to lubricate, while the poppet valve can be worked to the limit.

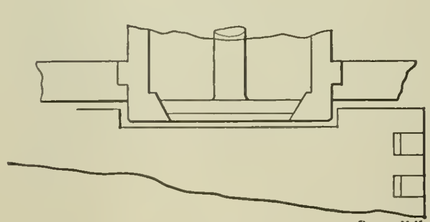

FIG. 5

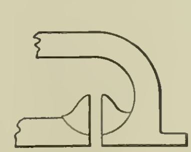

FIG. 6

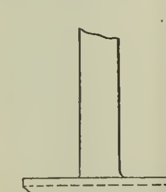

FIG. 7

One other point in relation to compressor valves should be noted; that is, the diameters in which they are made. The same rule will apply here as in a pump. It is better to have two valves than one large one, as the concussion becomes too great when the load is laid on the one. The diameter and the distance traveled by the poppet valve should be watched; too large a diameter and too much travel will cause great pressure and be the means of driving through the seat.

Lynchburg, Va.

What Is Trouble?

In a recent editorial it was asserted that trouble is frequently the result of ignorance. Undoubtedly the statement is true, but it is not necessarily wilful ignorance. There is a graduation of knowledge from the most ignorant to the most learned and the combined knowledge of every generation is probably but a speck in comparison to infinite knowledge.

There are those who seldom, if ever, have the same trouble the second time. One experience is usually needful to stamp a thing indelibly on the mind. After that it is wilful ignorance to let the same thing happen again. Many engineers make their own trouble as they go along. They haven't learned the lesson of letting well enough alone. They are forever keying up this thing and that, setting valves, regulating governors and "experiencing" generally. There is also a limit to letting things alone, as they will certainly deteriorate with use.

The conservative man who keeps a keen eye out for every evidence of coming trouble, with the view of preventing it, is the man who has the least trouble.

After every phase of the subject has been gone over, however, we must still admit that the best and wisest of men have their troubles.

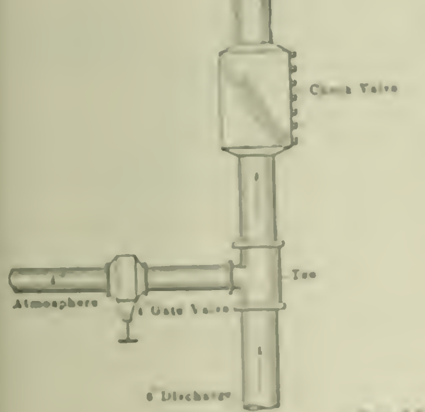
Centrifugal Pumps

I recently placed an engine in a small water-works plant to run a belt-driven centrifugal pump of the vertical type placed in the bottom of a circular pit 40 feet deep and connected to a 10-inch well. The discharge was 6 inches in diameter and extended vertically to the surface of the ground, thence horizontally for about 100 feet and discharged into a standpipe 118 feet high. A check valve was placed in the horizontal pipe to keep the water from returning to the well, and as there was always a little sand



CENTRIFUGAL-PUMP CONNECTIONS

when first starting, a 6-inch tee was placed between the check valve and the pump and reduced to 4 inches and a 4-inch pipe led to the sewer. A gate valve was placed in the 4-inch line and closed after the water had cleared. There were no other valves than those described and shown in the sketch.

In starting the pump, the gate valve is opened and the water allowed to flow into the sewer, which it does without lifting the check valve, although it takes more power than it does when pumping into the standpipe. When the gate valve is closed the check valve opens automatically and the load on the engine is decreased 12 per cent., while the amount of water handled is increased 18 per cent.

If it takes more power to pump through the 4-inch pipe to the sewer, why does it not lift the check valve and pump into the standpipe?

Electrolysis and Superheat

I was interested in reading the article by Thomas Sawyer in the March 2 number, under the heading "Electrolysis and Superheat."

It reminded me of several experiences I had which, although electrolysis was not the culprit the action was similar, in eating away brass fittings, etc.

Several years ago the boilers in a certain steam plant were fed from a well on the premises, which gave excellent water containing no scale-making matter, but after this water had been in use for about two years, the plugs in the front manifolds of the down-draft furnaces would blow out. These plugs were brass, and the firemen had several narrow escapes from being scalded. All brass valves and gage cocks were attacked and looked and the affected parts had no resemblance to brass, but looked like dull zinc, and the screwed portions could be crumbled off by rubbing with the hand. An investigation showed this water to be strongly impregnated with ammonia.

In another instance, a boiler in a hotel was being opened for inspection, the engineer was taking out the manhole plate, the inspector standing just behind him. As the plate was taken out, the torch in the engineer's hand ignited a rush of natural gas, which painfully burned both men. Investigation showed that gas was pumped into the boiler from a well, and as the whole house got its supply of water from this well, the gas was distributed throughout the piping. As there was danger of many accidents this well was abandoned.

One engineer was killed in a factory due to an accumulation of sewer gas in his boiler, which had a blowoff pipe leading directly into the sewer. The boiler was blown off on Saturday night, and on Sunday morning the engineer went down to clean it. On taking out the manhole plate above the tubes [illegible] back and his torch set fire to the gas which evidently blew him against the brick wall in the rear of the boiler, crushing his skull. He was found lying across the [illegible]

The theory was that as the boiler was blown empty and, cooling over night, a vacuum was created inside and the sewer gas sucked in through the blowoff pipe.

[illegible]

Knock in Engine Crank

Regarding the knock in the crank of J. W. [illegible] [illegible]

[illegible]

[illegible]

or three thicknesses of paper to allow for future adjustment. We then sweated a thin piece of brass on the side of the brasses, filing them down to a fit, after which we put them together and tried the engine out again. After making a few changes, as regards taking out or adding more paper packing, the pound disappeared and has not appeared since.

In some cases where the collar on the outer end of the pin is a part of the pin itself the brasses may be taken out and a piece of sheet brass sweated onto the sides and then fitted as stated.

CHARLES H. TAYLOR.

Relative Rate of Heat Transfer to Water

The article in the issue of January 12 on "Relative Rate of Heat Transfer to Water at and below the Boiling Point," by W. H. Sawdon, is a good illustration of the very erroneous conclusions that are liable to be drawn from rough and ready experiments. My reasons for thinking that the conclusions the author comes to are erroneous, are as follows:

The temperature of the air on the day of the "bare" test was about 10 degrees lower than when the test with hair-felt covering was made, which of course will account for a large amount of radiation.

That the experiment was very carelessly carried out is evident from the following results:

Bare Test.		Covered Test.	
Time.	Rise of Temp.	Time.	Rise of Temp.
3 min.	31.5° F.	3 min.	18.5° F.
6 min.	30° F.	6 min.	42° F.
9 min.	31° F.	9 min.	31° F.
12 min.	27.5° F.	12 min.	25° F.

In the covered test the rise of temperature in 3 minutes varied from 18.5 degrees Fahrenheit to 42 degrees Fahrenheit. Comment is needless.

The heat capacity of the vessel, the stand and the iron rods, etc., was neglected, which would seriously affect the result and render the test absolutely worthless.

The bunsen burner was sending up a large volume of hot gas, which in passing upward surrounds the vessel to be heated and forms an inclosing wall from which heat will be radiated *to* the vessel during the tests, but the writer of the article assumes that the radiation will be the same when the gas is turned off and heat is being radiated *from* the vessel instead of to it.

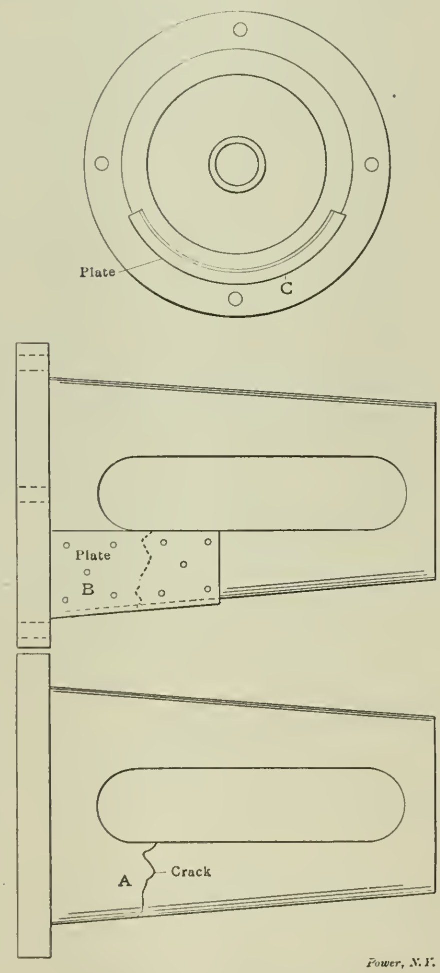
It may interest the writer of the article to know that when very careful tests of this character are made, in which every precaution against error is taken, the rate of transmission during heating of the water is only 2 or 3 per cent. lower than when the water is boiling.

JOHN GOODMAN.

Leeds, England.

Repairing a Broken Bracket

One morning while starting up a large Corliss engine the head-end dashpot became stuck in some manner, and as the trip rose the steam bracket was cracked at *A*. Of course it was necessary to shut down to repair the break, as the bracket was very shaky and liable to crack off at



REPAIRING A BROKEN BRACKET

the top at any moment. Upon telephoning to the representative of the builders of that particular style of engine we were informed that it would be at least four days, and possibly a week, before a new bracket could be obtained. We therefore decided to repair the old one.

The bracket was taken off and carried to the machine shop, where a sheet of iron, about 5/16 inch thick, was found. A piece about 4 inches square was cut from this and bent to fit and inclose the portion of the bracket that was cracked, as shown at *B* and *C*. The plate was then doweled onto the bracket, 10 pins being put on each side of the crack. After this, the plate was smoothed down, polished, and the bracket replaced. It has been run for three years and appears to be in as good condition and as strong as a new bracket, if not stronger.

WALDO L. WHITMARSH.

Phenix, R. I.

Difference in Economy in Large and Small Engines

On page 602, of the March 30 number, William E. Snow gives a graphic illustration of the difference in economy of a large and a small engine for the same work.

Mr. Snow carries the conditions to extremes, but there is one point that is usually lost sight of and that is the resistance to the piston in noncondensing engines to which I understand he refers.

Assume that we had an engine with 160 square inches piston area and 500 feet piston speed. With 33 pounds mean effective pressure it will give 80 horsepower.

An engine having the same piston speed and mean effective pressure would require 50 inches of piston area to do 25 horsepower. Suppose the larger engine should be loaded to 25 horsepower, it would require but 10 pounds mean effective pressure. Add the back pressure, which would amount to 16 pounds, and we have 26 pounds, and

$$\frac{26 \times 160 \times 500}{33,000} = 63$$

horsepower. If, to the 33 pounds we add the 16 pounds to the smaller engine we have 49 pounds, and

$$\frac{49 \times 50 \times 500}{33,000} = 37$$

horsepower. This shows the effect of atmospheric resistance, and is one reason why the small engine shows up so well, everything else being equal.

When it comes to a condensing engine the same thing, but in a different form, enters into it. Previous to 1870, the independent condenser was almost unknown, and the most ordinary engines were run noncondensing.

A man had an engine with 24-inch cylinder and at about this time a barometric column, known as the Ransan condenser, came out and this manufacturer attached one to the 24-inch cylinder and it showed up a saving of nearly 30 per cent.

He reasoned that if the vacuum would show such a result with a 24-inch vacuum, a much larger saving could be effected with a 30-inch cylinder with so much larger area, so he replaced the 24-inch cylinder with a 30-inch one and lost on economy instead of gaining.

This was not caused by any extra cylinder condensation, although that may have helped a little, but it so happened that with the 24-inch cylinder, the terminal pressure was at about atmospheric pressure and he had the benefit of the vacuum the full length of stroke, while with the 30-inch cylinder the cutoff was shortened so much as to reduce the terminal pressure and cut out the effect of the vacuum for a portion of the stroke.

The same thing is done in many cases on a compound engine by carrying a high receiver pressure with a short cutoff in the low-pressure cylinder and cutting out the effect of a large amount of vacuum. It also adds resistance to the high-pressure cylinder and does not get the highest efficiency from it.

Many engineers have learned that the highest economy in a compound engine is obtained by carrying the receiver pressure so that full atmospheric pressure shall be carried as near full stroke as possible in the low-pressure cylinder.

Broadalbin, N. Y.

Oil Frothing Test

In carrying out an oil frothing test a small amount of mercury was placed in a test tube and heated slowly, stirring with a thermometer until the temperature of the steam was reached. See Fig. 1. A drop of oil was then allowed to run down the side of the tube. See Fig. 2. If it frothed, the oil was rejected as containing volatile elements which would be vaporized and which could not therefore be arrested by the oil separator. It was found, however, that if the oil should

FIG. 1

FIG. 2

contain a small amount of water this test would be misleading since the water produces a similar effect. Where the oil froths, therefore, the frothing tests are supplemented by the more complicated flash test.

This matter of testing cylinder lubricants is something well worth knowing by the operating engineer, as it occasionally happens that cylinder oils are used which make the complete separation of oil practically impossible. An oil which is vaporized at steam temperature is to that extent valueless for cylinder lubrication, since the oil gas has no lubricating value, and it would be better economy in every respect to buy the more suitable, although perhaps more expensive oils.

New York City.

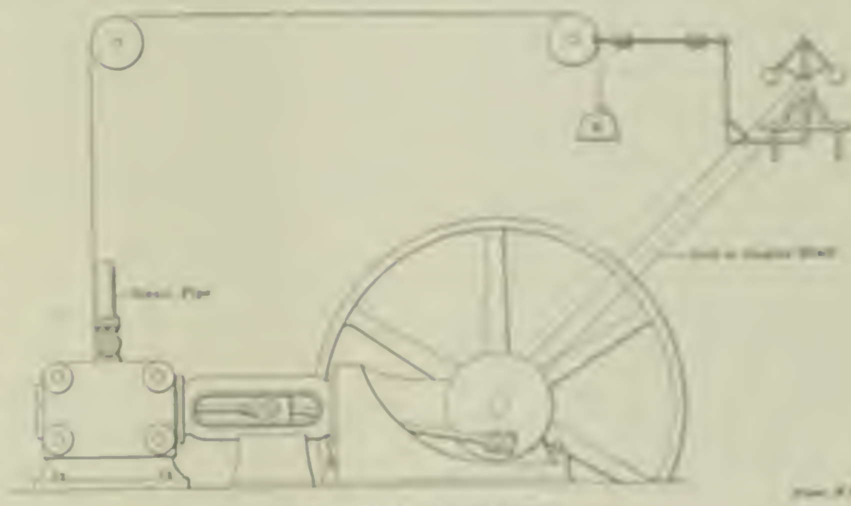
Homemade Engine Stop

Some time ago the writer happened to be in the engine room of a manufacturing plant when his attention was attracted to a rather ingenious device in the way of a homemade engine stop. The engineer explained that from some cause the engine had run away several times and in each instance disaster was narrowly averted. Accordingly, he had set about to produce an automatic engine stop at small cost. The accompanying sketch gives an idea of his apparatus. It is said to have fulfilled its function faithfully several times.

There is a detachable drum secured to the throttle of the engine with enough soft cord wound on it to correspond with the threads on the stem of the valve. The

cord is run over pulleys and connected with a weight of sufficient size to unwind the cord from the drum as it descends, thus closing the throttle. Ordinarily the cord is wound on the drum and the weight suspended at sufficient height to allow the engine to run at its full speed. The drum comes off for starting and stopping and is placed on a hook out of the way.

The scheme for releasing the weight is that of a sliding bar, the end of which is caught under a pin on one edge of the pulley directly over the weight. As it is loosely caught, an inward movement of 1/4 inch will release the weight. The other end of the bar is connected to the upper end of a bell crank which is hinged at the elbow. The longitudinal arm of the



A HOMEMADE ENGINE STOP

bell crank is in contact with the arm of an ordinary flyball governor, which in turn is connected by a belt to the engine shaft. The stud of this governor is adjusted so that it will not act until the engine has reached a speed beyond the range of the regular governor, at which time the arms is passed downward, causing the weight to be released and a prompt shut-down is the result.

Philadelphia, Penn.

Rope Drive

In commenting on Mr. Myers' "Rope Drive" with which the Wisconsin Central engine is equipped, I was not surprised of "knocking" the rope drive. For the one reason, I think it is a good thing, but of it is an effort to insert a more reliable governor, belts, who will go farther and make it better still. Either you consider the strength of a rope drive you don't stop knowing how its strength is a weakness.

If a governor would not be equipped with a rope drive there is going to be something wrong and then something will be a belt or broken governor shaft.

I believe this risk could be avoided if the friction could be eliminated and I believe a roller bearing would do the trick. If Mr. Myers wishes to do a good act, let him get hold of the "badger's" ear while the animal is in a receptive mood and suggest a roller bearing as a team mate for the rope drive and then he will have something to talk about.

R. McLaren.

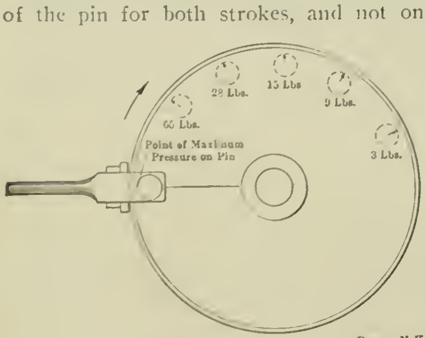
Berlin, Ont.

Flat Crank Pins

Crank pins, in my opinion, always wear more or less flat, according to the amount of pressure exerted on the pin and the material of which the boxes are made. This may be better illustrated by referring to the circle representing the path of travel of the crank pin. Steam is admitted while the piston is at the end of its stroke and carried, presumably, to one-fourth stroke before cutoff is obtained. Consequently, during this period of pin travel, it is subjected to the maximum pressure. After cutoff has occurred the remaining force acting on the pin is produced by the expansion of the steam imprisoned in the cylinder, and as the piston nears the opposite end of the cylinder this propelling force becomes correspondingly smaller until the point of absolute release is reached. This would seem to me to prove that the most wear must be at the point of maximum pressure.

Crank pins fitted with babbitt-lined boxes will not wear as fast as those constructed of bronze, owing to the fact that the babbitt, being of a softer nature than the pin, will more readily wear away. But even in this case, in time a flatness, however slight it may be, will be found at the maximum point of pressure on the pin.

Another point is that the maximum wear on the crank pin is on the same side of the pin for both strokes, and not on



PATH OF TRAVEL OF CRANK PIN

opposite sides, as is very often supposed. This may be understood in a better manner by referring to the pin travel in the illustration and following the supposed travel of the crank pin from one center to the other.

Bridgeport, Conn.

Locating Ground in Line with an Ohmmeter

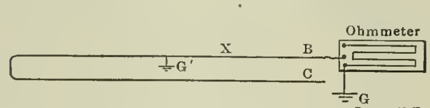
The accompanying sketch shows how to use an ohmmeter for locating a ground on line circuits. The B and C represent the ends of a circuit which is grounded at G', the distance of ground from B being unknown. To determine the distance from B to G' connect the ohmmeter across the line from B to C and get the total resistance of the line which, for example, we will call 4 ohms. Connect one side of the ohmmeter to the ground and the other side to one side of the line B, as shown in the sketch, and read the resistance, which will be the resistance through the line B to ground G' and through to G; call this 11 ohms. Then disconnect the line B from the ohmmeter, connect the line C and take the resistance through the line C to the ground G' and through to G; call this 13 ohms.

The formula for resistance of the line to G' from B, or X, is:

$$11 - \frac{11 + 13 - 4}{2} = X,$$

or 1 ohm.

This resistance divided by the resistance



LOCATING A GROUND WITH AN OHMMETER

of the line per foot gives the distance in feet from B to ground G'.

R. L. Mossman.

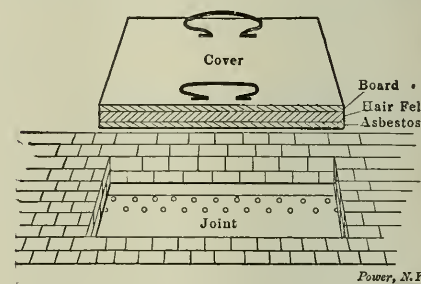
Fremont, Ohio.

Uncover the Joints

In view of the large number of boiler-joint troubles of late, I think it should be made a United States law that in all boilers, whether lap-seam or butt-strap, there should be some convenient way of inspecting the outside of the joint, and especially is this necessary with the butt-strap joint, as it is utterly impossible to detect a crack along the outer row of rivets, which are in single shear, because the inner strap covers a wider area on the inside, and a crack from one rivet hole to another is entirely hidden except from the outside.

Three years ago I was told by an inspector that the company had no record of a triple- or quadruple-riveted double butt strap having given trouble, but from recent reports published in Power, three cases were reported from one company alone. In these cases steam was seen coming up through the brickwork and after removing the bricks a long crack was found. It is singular that all of these cracks have been about 18 inches long, and it is reasonable to believe that these cracks start by degrees.

With the idea carried out as shown in the sketch, the joint can be looked at as often as desired by lifting out the covering with the handle. There are scores of boilers in operation today that are twenty years old and the joint has never been



MR. WALDRON'S SUGGESTION FOR UNCOVERING JOINTS

seen; if uncovered, I have no doubt they would disclose longitudinal cracks.

A. C. Waldron.

Lynn, Mass.

Engine Stopped by Rat

In a large tannery a rat took lunch from the rope-transmission line. The engineer blew the whistle for starting in the morning, but the rat failed to get away and became caught in such a way that his tail extended beyond the rope like a strand.

The rope was protected by a telltale wired to an automatic engine stop so that should the rope strand, it would operate it, and the rat's tail, operating the automatic stop, shut down the engine.

F. S. Palmer.

Chicago, Ill.

A Cause of Engine Wreck

In the letter, "A Cause of Engine Wreck," published in the March 23 number, page 563, by W. E. Crane, the question is asked: "If the long rod of the governor be lengthened and the short one shortened what will be the result?"

The result will be according to the mechanism of the valve gear. Take for instance one type of Corliss engine; to lengthen the long rod and shorten the short one will shorten the cutoff, and if changed enough, the engine will not take steam at all, as the trip collar would be forced under the disengaging hooks.

The proper and only right way to change the speed of a governor of this type of engine is to change the size of the pulley. A weight arm can be attached and a weight added to it, but this makes the engine sluggish. The thing to do is to set the cutoff at the proper point for the load to be carried, and the governor will do the rest.

JOSEPH F. SUMMERS.

Duranga, Colo.

More Frequent Internal Inspection

In answer to H. E. Gansworth's letter in the March 9 number, under the heading, "More Frequent Internal Inspections," I wish to state that there are two sides to this story.

He starts to say there are inspectors and inspectors, etc., but all through his letter he condemns them generally. He may or may not have a grudge against boiler inspectors, or perhaps he sells boiler-cleaning devices. No doubt there are inspectors who do not do their full duty, but there are plenty who do.

In the case he cites where ten wheelbarrows of scale were taken out of the boilers, the inspector was at fault if he did not order a cleaning, but the other case where four 150-horsepower boilers were pushed to their utmost and, after cleaning, three boilers did the work, shows that these boilers must have been in pretty bad shape, due to scale, and no inspector worthy of the name would have called them clean. These three boilers are certainly wonders, as in preceding numbers of Power authorities have shown that experiments with scale showed that a boiler would be in a very dangerous condition due to thickness of scale, without showing perceptible increase in the use of fuel.

I know of one case in particular where the boilers had a slight covering of scale, and the inspectors so reported. These boilers were in good hands, and the scale was kept down to a small amount, and no recommendation was made by the inspectors for better cleaning; in fact, these boilers were in a good general condition, and no fault could be found with them. An "enterprising salesman" came along, induced the manager to buy his tube cleaner, with the usual guarantee, etc. The engineer objected to using it, but the manager insisted. One boiler was experimented on, with the result that all the tubes were loosened in the back head, and as the boiler was 18 years old it had to be retubed, and the owner paid the bill. The cleaner was thrown under the bench.

As to taking out 265 pounds of scale, a large boiler can easily contain that amount without one calling it a dirty boiler, as the scale might be plastered very thinly over the surfaces.

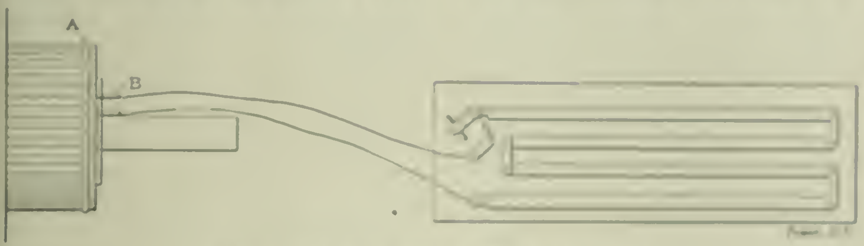
Another phase of this question is that a great many owners, managers and superintendents become very indignant when told by an inspector that the boilers need better cleaning, maintaining that they have a good engineer, who knows his business, and that the boilers have never given trouble from being dirty; and there it ends. I know of many cases where the insurance was promptly canceled until the boilers were cleaned, and kept in a less dangerous condition. I also know that insurance companies are always willing to make suggestions, analyze feed water, and in other ways try to help the owner keep his boilers in good condition.

MILTON HELLER.

Cincinnati, O.

Using the Ohmmeter for Testing Armature Coils

The accompanying sketch shows how to use the ohmmeter (described in a



TESTING ARMATURE COILS WITH AN OHMMETER

late issue), for locating faults in armature coils.

Two small copper clips *B B* are connected to the ohmmeter as shown, these clips being held to each segment of the commutator by a rubber band *A*. Mark the segment as the starting point and take the resistance of the coils between each segment. If the readings show the same all the way around, the coils are in good condition. If one coil is short-circuited its resistance will be less than the others. If a coil is open the resistance will be higher. By connecting one clip to the armature shaft and the other to the commutator the resistance to the shaft can be measured.

In testing the armature coils the lowest resistance in the ohmmeter [illegible] be plugged in as the resistance of the coils is very low. In testing the grounds [illegible] the coils and shaft plug in the highest coil in the ohmmeter. I have [illegible] this one to [illegible] armature [illegible] and [illegible] the commutator.

A Case of Bagging

Some months ago I saw a boiler in a repair shop that had given an unusual history. The sheet over the fire was bagged down 2½ inches over a fairly [illegible] section.

The boilermaker had an order for three [illegible] foot boilers of the return-tubular type. The engineer of the firm from which the order was received directed that the blowoff pipe be inserted in the rear head, 2 inches from the bottom. The engineer stated that he had had 25 years' experience in handling steam plants, and that they could install them as he wanted or some other firm would get the job. In addition he directed that the boilers be set with the front ends 2 inches lower than the back ends. The result was that, in course of time, all three boilers bagged.

EDWARD T. [illegible]

Repairing a Worn Guide

Mr. McCauley's letter in the April 13 number, about a worn guide, particularly interested me as I am a crank on that part of [illegible].

If Mr. McCauley would cut oil [illegible] of both ends of the lower guides, the guide would never wear concave, and if he got it just right, it would not wear enough in years to need taking up, much less re-scraping.

Engineers [illegible] the advantage of [illegible] but they will not listen to the [illegible] and cut off the guides. When I was [illegible] people [illegible] me [illegible] they will do so.

Engineers have [illegible] "How much should I cut off?" Keep cutting them off until they stop wearing concave. [illegible] the surface of the guide. If the [illegible] [illegible] were cut in the [illegible] the guide [illegible].

[illegible]

[illegible]

[illegible]

[illegible]

Will the Load on the Bolts Change?

Referring to G. A. Glick's problem appearing in the March 30 number, I should say that the stress on the bolts in either cylinder would be exactly the same, provided the elastic packing was cut to the exact size of the cylinder, so that there would be no recess between the cylinder and head owing to the packing being cut larger at the inside edge than the diameter of the cylinder, or so that the steam would have the same area to work.

Each of the twelve bolts is placed under an initial stress of 1000 pounds, consequently the head is held against the cylinder by a force of 12,000 pounds and the initial stress on the bolts would not be increased until the total pressure of steam on the head exceeded 12,000 pounds.

One hundred pounds steam pressure per square inch, in this case, would neither increase nor decrease the stress on the bolts, since a pressure of 100 pounds on an area of 120 square inches is 12,000 pounds, and as long as the pressure does not exceed 100 pounds per square inch there would be the same stress on the bolts without the steam pressure as with it, or 1000 pounds on each bolt.

If in this case, however, the pressure should exceed 100 pounds per square inch, more stress would be put on the bolts, as the total pressure of the steam would then be in excess of the 12,000 pounds with which the head is held against the cylinder by the bolts.

RALPH F. BLANCHARD.

Fitchburg, Mass.

We will first consider the case with the ground joint. When the flanges are pressed together they are far less yielding than the studs, and can therefore be considered as noncompressible, and the studs, due to their elasticity, can be considered as springs. In the case of a ground joint with the substitution of springs for bolts, the total area of the cylinder is, as given, 120 square inches and the pressure per square inch as 100 pounds.

Then

$$120 \times 100 = 12{,}000$$

pounds, the total pressure acting against the cover from the inside.

The initial tension on the 12 studs or springs is 1000 pounds each, hence the total pressure holding the cover against the cylinder is 12,000 pounds. This pressure acts in an opposite direction to the internal pressure. To increase the tension on the springs or studs, they must be subjected to a further elongation, and to do this the total internal pressure must be greater than the total initial pressure. Since the external force applied equals the initial stress, the tension on each stud for the ground-joint case is 1000 pounds.

With the packing between the cover and cylinder, we have a different state of affairs. Here we have the flanges and packing in compression and the studs in tension. Substituting springs in place of the elastic packing, the total initial tension on the studs is 12,000 pounds, hence the total stress in the springs acting against the cover is 12,000 pounds, or 1000 pounds per stud. The total internal pressure is the same as in the first case. The direction of the initial and internal forces is the same, hence the total stress on the studs (considering that relatively to the packing the stud is inelastic) will be the sum of the initial and internal stresses, therefore:

$$12{,}000 + 12{,}000 = 24{,}000$$

pounds, or 2000 pounds per stud.

JOHN B. SPERRY.

Aurora, Ill.

Replying to G. A. Glick's problem, we find that the total pressure of the steam is

$$120 \times 100 = 12{,}000$$

pounds. Each of the twelve studs carries 1/12 of 12,000 pounds or 1000 pounds of the steam pressure. This 1000 pounds will be called the external load. Under the conditions of a ground joint, there is practically no elasticity of the parts held together, the stud is comparatively elastic and there is a certain elongation due to tightening up. It is evident that the initial stress, due to tightening the nuts, holds the head in contact with the flange of the cylinder. There can be no separation of the parts until the internal load per stud exceeds the stress due to tightening up, and until the parts separate there can be no additional stress in the studs. Therefore, a load up to and including the pressure due to the stud nuts puts no additional load on the stud. Any load beyond the initial stress will cause a stress in the studs equal to this load. For any pressure less than 100 pounds per square inch, no stress beyond the initial stress is induced in the bolt. As soon as the pressure exceeds 100 pounds per square inch, the surfaces of the cylinder and head will separate.

Consider the parts with a packing between, compared to the elasticity of the gasket, the studs may be considered inelastic. In this case, there is an initial stress due to screwing up, and any additional pressure in the cylinder will act directly on the stud causing an additional stress, and at 100 pounds pressure, there will be a stress of 200 pounds in each stud. The load on the studs is intermittent.

HARRY ANDERSON.

New York City

There are 12 studs from the flange of the cylinder through the head, and the nuts are tightened until there is a tensile stress of 1000 pounds in each of them; there would, therefore, be a force between the head and flange exerted mechanically through the wrench and nuts of

$$12 \times 1000 = 12{,}000$$

pounds, which we will call the "mechanical force."

When a charge of steam is admitted to a cylinder it acts similar to a spring under compression, and tends to separate the head from the cylinder. This has the effect of decreasing the mechanical force, for the simple reason that it takes a part of the stress on the studs remaining constant. And if the steam acts upon an area of 120 square inches on the head and a charge is admitted at 100 pounds pressure, then the mechanical force would be entirely removed because a force of

$$100 \times 120 = 12{,}000$$

pounds, would be exerted against the head and the mechanical force neutralized, leaving the same stress on the studs as before. Therefore, the stress on the studs would be constant for all steam pressures above atmosphere up to 100 pounds. But if there were an increase of steam pressure above 100 pounds, then the stress on the studs would increase an amount proportionate to the increase in steam pressure, and if the steam pressure were below atmosphere, or a partial vacuum within the cylinder, the stress on the studs would decrease a corresponding amount.

CHARLES F. CLARK.

Hartwick, N. Y.

I should say that the strain on the stud bolts is exactly the same when a pressure at 100 pounds per square inch is admitted into the cylinders. As there are twelve studs and each is under 1000 pounds strain we have 12,000 pounds.

This 12,000 pounds is exerted against the end of the cylinder when there is no pressure in the cylinder. When pressure is in the cylinder at 100 pounds per square inch, it gives a total pressure on the cylinder head of 12,000 pounds, which is opposed by 12,000 pounds on the studs. This relieves the pressure between the cylinder head and the end of the cylinder, and I should expect the packing to blow out of cylinder No. 2. The load in pounds per bolt is the initial strain in both cases.

FRANK W. CERNY.

Mesa, Ariz.

I should say that the stress on the studs of each cylinder will remain the same regardless of the style of joint, ground or otherwise; as any stress due to the elasticity of the packing is included in the initial stress of 1000 pounds.

For either cylinder, the stress per bolt due to the steam in the cylinder at 100 pounds pressure would be 100 times 120, divided by 12, or 1000 pounds. The total stress per bolt would be 1000 plus the initial pressure of 1000 or 2000 pounds.

New Rochelle, N. Y.

Some Useful Lessons of Limewater

More about the Chemistry of Carbon; Its Connection with Gas Producer Work; A New and Simple Oxidation Table; What a Heat Unit Is

BY CHARLES S. PALMER

In the study of chemistry, go as far as you will, you will never get beyond the chemistry of carbon. We have seen that it has its simple series of compounds, from reduced to oxidized extremes, in which it is imitated by many of the other elements, and several minor but large series of compounds, from reduced to oxidized extremes, in which it is not imitated by any other element. Indeed, in a sense, the compounds of this one element, carbon, are more in number than all the compounds of all the other elements put together. This looks like a large and extravagant statement, and like most large statements it has its qualifying clause, which is that when one speaks of the "compounds of carbon," he implies its compounds with oxygen and hydrogen, and also with certain other helpers, such as sulphur, nitrogen and the like. No element can have compounds without borrowing the union of itself with other elements, and so carbon must borrow the help of other elements to count up its really enormous list of series of compounds.

In these elementary lessons we shall quickly go on with the natural study of nitrogen, sulphur, chlorine, sodium, potassium, calcium, iron and so forth, but one must remember that just around the corner stands carbon with its almost infinite possibilities. If one were asked how one little mind of common students like yourself or myself can hope to master even a small part of all that, the answer is plain and easy. When you are ready for it—not now, but later—just pick out one or two of the simplest hydrocarbons, such as methane and ethane, and master these fairly well, paying attention to the others and higher ones only just enough to see what complexities they offer which are not illustrated by methane and ethane. Then the great subject becomes fairly easy and intelligible. But before we do that we should get some notion of the chemistry of the more important things, such as the common acids and bases, the common reducers and oxidizers, the common water absorbers or "dehydrators," and so on. Also, one must know something of analysis, which is the finding out what are the ingredients of common things.

Analysis is called "qualitative" if it aims simply to find out what ingredients are in any special compound; analysis is called "quantitative" if it aims to find out how much there is of any ingredient in any compound. Thus, one might attack common limestone to find out what elements are in it. One would soon find out that limestone carries only calcium, carbon and oxygen—that would be "qualitative" analysis. But if one should go farther and find out how much there is of each ingredient, calcium, carbon and oxygen, in the limestone—that would be called "quantitative" analysis. As a matter of fact, quantitative analysis does not usually really go on to the exact quantity of the elements themselves, but stops short at certain compounds of the elements. Thus, the composition of limestone is usually not stated in terms of calcium, carbon and oxygen, but simply in terms of carbon dioxide and lime or calcium oxide, thus: One hundred per cent. of pure limestone is made up of some 56 per cent. of calcium oxide and some 44 per cent. of carbon dioxide. That is to say, it acts as though it contained these things in these proportions, for the carbon dioxide is so firmly "fixed" with the oxide of calcium and the calcium oxide is so firmly bound to the fixed gas that they act like one pure substance which is like no other thing in the world. One can easily calculate from the per cent. of carbon dioxide and calcium oxide in limestone or marble how much there is of each, carbon, calcium and oxygen, and if the results of the analysis are calculated out to that point, then the analysis is called an elementary or "ultimate" analysis. But there is another reason why the analysis is usually stopped at the halfway house of calcium oxide and carbon dioxide, rather than at the terminus of carbon, calcium and oxygen, and that is that the substance, limestone, actually falls to pieces in analysis, and the pieces picked up are much like carbon dioxide and limestone; and the results are so stated. If heated strongly, limestone falls into the gas, carbon dioxide (which is collected in a solution of strong caustic soda), and lime (which is weighed as lime). The carbon dioxide unites with the caustic soda to make sodium carbonate, but one does not stop to separate the soda carbonate from the rest of the caustic soda, but simply weighs the caustic before and after the absorption of the carbon dioxide, thinking all the while of the carbon dioxide as an acid anhydride, which it is. The gain in weight of the caustic soda is the carbon dioxide which the heated limestone has given off, and that taken from the original weight of the limestone gives the weight of the lime which is left.

All this appearance of come-happy-go-lucky analysis is all right, if one has first proved by careful "qualitative" analysis that the limestone contains nothing else in it but calcium, carbon and oxygen. If these points are first proved, then the subsequent reasoning as to the carbon dioxide and the lime is all right. But there are some peculiar things about common analysis. One of these strange things is that there is no simple, easy and sure test for most of the oxygen that is contained in the many things about us. It is odd that this thing, oxygen, which makes up one-fourth by weight and one-fifth by volume of the air, which makes up about one-half in weight of the rocks, clay, sand, etc., about us, which makes up about one-half of such things as wood, paper, cotton, bread, etc., it is odd that there is no certain and direct way of testing for this thing, oxygen, except by indirect reasoning and showing that other things are not present in amounts sufficient to explain all the weight of the thing being analyzed. But if this careful searching for other things is once done, and if the reasoning about them is well done, then the inference that the rest of the per cent. not accounted for must be oxygen; this is certain and reliable.

However, the history of chemistry has some good stories to tell about how some good chemists made mistakes in their first analysis and reasoning. The great Liebig once neglected to search for sulphur in a compound which he was analyzing; I believe it was taurine or some similar organic compound, but at all events it was an object lesson for lesser lights to go slowly in their preliminary work of proving the presence or absence of oxygen in things examined. A similar thing happened in reference to the composition of the atmosphere over a century ago, when the great Cavendish tried to absorb a tube of inclosed air by electric sparking of the oxygen and nitrogen over strong caustic soda. He noticed that he could never get complete absorption of the tube of common air, and also noted that there was always a small bubble of what he called "nitrogen" left in his measuring tube or eudiometer. But this small bubble was really argon, the "lazy" gas in the air, which imitates nitrogen in some of its properties and which makes up about one pint in 100 pints of the air. This argon is peculiar in that it makes no real compounds with any other element; and it took a hundred years and some of the best measuring ever done to get on the track of the fact that there is such a thing in the air as argon. It was the English physicist, Lord Rayleigh, who found a funny little decimal, way out in the third or fourth place, in weighing his samples of nitrogen from various sources, which put him wise to the clue. Rayleigh called in the help of Ramsey; the two together discovered the inactive argon, common as air, making 1 per cent. of common air, to the glory of science and the humiliation of the centuryful of chemists who had overlooked it.

The Gas Producer

There are other romances in the history of chemical analysis, but we will go on with the chemistry of carbon, and one matter which you probably are right on the point of asking yourself about is regarding the new-fangled gas producer around the corner. You know something of the burning of coal under your own boiler. You know that you get good combustion, without many calls from the smoke-nuisance officer, and with approval from the "Old Man" at the way you save his coal. But you hear wonderful and almost incredible stories about the large horsepower and the small coal consumption of the new furnace (whose only chimney seems to be the exhaust of the gas engine), which needs to be fired only once or twice a day. Certainly there is something here which is worth noting, and it comes right out of our oxidation tables.

For example, look at the first table which gave carbon, carbon monoxide and carbon dioxide at one end of the table. All that was not for nothing. When carbon burns in the two stages, first to the one-oxide, and then to the two-oxide, it does it work with perfect regard to two things: The exact amounts of carbon and oxygen concerned, and the amount of heat given off; these two conditions of the burning of carbon with oxygen are fixed. Now when carbon first burns to the one-oxide, and later to the two-oxide, it is as though a definite weight has fallen down—first to one precipice, and then to another—just as though the fall of carbon to one-oxide and then to two-oxide were a two-step waterfall. Now in the first step of this chemical waterfall, the heat given out is about 4450 heat units for every one pound by weight of carbon concerned, whereas, the heat given out by the chemical fall of carbon monoxide to dioxide is some 10,050 for every one pound of carbon concerned.

Now, it takes oxygen to let the carbon perform its two chemical falls, and if the furnace is closed then the carbon can get only enough oxygen to make the first fall, namely, to the one-oxide. Then this heat is given off in the furnace, the "producer" it is called, and this heat might be wasted if it were not used in a shrewdly economical way. The heat is used to heat the carbon molecularly next door to the partly burnt carbon; this unburnt carbon is supplied with steam, and this second part of carbon acts with the steam much like a miniature water-gas plant. It makes water gas, carbon monoxide and hydrogen, just as shown in the last lesson. But this tearing apart of the hydrogen and oxygen in the watery steam takes up heat or energy, and this heat is supplied by the first carbon which tumbled down its first step of the two-step chemical waterfall.

The whole of this part burning of one carbon and the water burning of the other carbon is that two parts of carbon have gone over to one part of hydrogen and two parts of carbon monoxide. As far as the heat given out by one carbon and taken up by the other carbon is concerned, that is a case of one hand washing the other. As far as the part burning of two carbons is concerned, which must be set down to the debit side of the chemical account, for coal burned is coal burned, one cannot eat his cake and still have it—all that is true. But, now, just look at the credit side of this double-entry bookkeeping: We have the credit of one part of water decomposed by the extra heat of the first carbon; this is not stolen, but simply taken from one pocket and put into another. As a result, we have the power of two carbons, put into the gas form—note that—the gas form, at the expense of only one carbon burning part way; it figures out about 15 per cent. theoretically used from the total 100 per cent. in the coal.

This coal has got into the gas form, and there is where the economy of the gas engine stands ready to use what good chemistry has produced. It is not our plan to go into the physics or mechanics of the producer-gas engine, but simply to stop here and explain this two-stage chemical waterfall until you see the chemical side of it. I have nothing but hearty encouragement to give to all honest and earnest students of the gas engine. If you have your troubles, so do steam engineers. If the gas engine is sometimes wanting in reliability, so is the steam engine. It took a century of steam practice to get you where you are now, and it may take a few years to get the producer-gas engineer where he wants to be; but one thing is clear, you have got to understand this oxidation table of carbon so that you can see it in your mind's eye at any time.

A Simple Oxidation Table

Now we are ready for a new and simple form of the oxidation table of carbon, that is, the heat table of carbon. Here it is: If the other tables of carbon were worth noting, this one is simply indispensable to you. The one thing that you ought to know about coal is what heat you can get from it. Heat is the one thing that the old world needs, of the material things. Coal is practically heat energy stored up. Here is the problem right up against you. That boiler, that furnace, that engine, with steam waste, with steam economized, may not be the most useful form of saving what Mother Nature has stored up. Note this table. When carbon burns to the first oxide, it gives off some 4450 heat units. Learn that. When this first oxide of carbon burns to the second, it gives off about 10,050 more of heat units. Well, if you put your first oxide into the producer-gas cylinder, which is only a sort of a

HEAT OXIDATION TABLE OF CARBON.

C (1 lb. Carbon) → + O → CO (Carbon Monoxide) + 4450 B.t.u. Heat. + O → CO_2 (Carbon Dioxide) + 10,050 B.t.u. Heat.

Two Stages.

One Stage. → 14,500 B.t.u.

gas cannon, you have all that extra 10,050 heat units to use where it gets in its work. But if you put *two* carbons, in the monoxide form, into the producer-gas engine cylinder for the heat cost of only one carbon, that is, two for 4450 heat units, then the average for each carbon is only some 2225 heat units used, leaving, theoretically, the other 85 ($2 \times 14{,}500 = 29{,}000$; $29{,}000 - 4450 = 24{,}550$; $24{,}550 \div 29{,}000 =$ 84.76 per cent.) per cent. of the heat to be used where it can do its work. Can you beat it?

When a small engine, of some 50 or 100 horsepower can reach an economy which is reached in steam work and practice only by the very largest and most complicated engines, what do you think of this oxidation table? There is a chemical as well as a mechanical side to the burning of coal. Indeed, there are both sides; but I am talking about the chemical side, because it is the side that you need most. You can learn the facts, get them right; the figures are approximately correct. You can figure the ways and means of this wonderful story of the two-stage burning of carbon. One thing to which I want to call your attention is what a "heat unit" is. If we are talking about the B.t.u.

(British thermal unit), that refers to the heat taken up in raising a pound of water 1 degree in temperature Fahrenheit. If you are talking about the French heat unit, the calory, that refers to the amount of heat taken up by one kilo (kilogram, a little over two pounds) of water, in raising itself 1 degree of the thermometer Centigrade (or Celsius, the inventor) and marked C°. In the figures given above, the heat units are of the B.t.u. sort; but whichever way one takes to tell the story of the energy squeezed out of the coal in its degradation from carbon to carbon one-oxide, and then to carbon two-oxide, there is the same chance for economy; and the producer-gas problem has started one of the most interesting possibilities which has appeared in recent times.

All this is the text for much similar study of heat units which will come in from time to time. It is only recently that chemists have realized that the study of compounds and neglecting the heat or energy connected with them is like saving the shells of nuts and throwing away the meat. But now that we are well started, we will be ready to look at either side of the game as it comes on the field. One begins to see that the chemist must not only have his fumes, his balance and all the other suitable apparatus, but also his thermometer. We weigh stuff or matter on the balance. We cannot weigh heat or energy on the balance, but there is one way by which one can measure heat or energy, that is by his thermometer and pocketbook. Coal costs money, because it stands for stored-up energy, and energy, "the power of doing work," is something which we all want. The reason for the great importance of these oxidation tables is that each compound, in its way, stands as a marker of energy lost, used, given out or absorbed. So, after all, one cannot get away from the chemical side of matter and things. We will go right on the next time with the study of sulphur, because it concerns the best of the "king of chemicals," sulphuric acid.

The ninth session of the summer school for artisans of the University of Wisconsin begins June 28, continuing for six weeks. Courses are offered in steam and gas engines, electricity, machine design, mechanical drawing and allied subjects. There are no entrance requirements, the purpose of this school being to offer practical instruction by lectures and laboratory practice to young men in the trades. Certain advanced engineering courses are offered for those having the requisite preparation, and the general university summer session held during the same period allows opportunity for a wide choice in subjects of instruction. Information may be obtained from F. E. Turneaure, dean, College of Engineering, University of Wisconsin, Madison, Wis.

General Electric Company's Report

In his annual report to the stockholders, President C. A. Coffin, of the General Electric Company, states that for the year ending January 31, 1909, the net profits of the company, exclusive of dividends, amounted to $4,802,252.07. There was paid in dividends during the year, $5,214,025, leaving a deficit, to be charged to the surplus account, of $411,773.13, thus making the total surplus on January 31, 1909, $16,102,062.81. The net profits for the year of manufacturing and other companies controlled by the General Electric Company, other than the affiliated companies, in excess of dividends paid by those companies during the year, amounted to about $900,000. Of this amount $750,000 has been taken on the books of the General Electric Company and is included in the foregoing figures.

President Coffin also states that 1908 was marked by severe and continual depression in the business of the company and in consequence since the last report the business has depended largely upon current renewals and supplies, with occasional additions to plant on the part of the older and more prosperous companies. The result has been that the orders received during the year were only 7 per cent. of those received for each of the two previous years, and the shipments were only 63 per cent. of the shipments of 1907.

Vice-President Lovejoy reported total sales billed of $44,540,676, and total orders received of $42,189,017. Orders received during the first half of the year were the smallest since 1904. The outlook for the ensuing year is encouraging, however.

Boiler Defects Due to Bad Feed Water

In the January issue of the *Locomotive*, published by the Hartford Steam Boiler Inspection and Insurance Company, it was stated that of [illegible] boilers examined internally by the company's inspectors during 1908 the following defects, among others, were discovered, all traceable to bad feed water:

Nature of Defects.	Whole Number.	Dangerous.
Cases of deposit of sediment	24,879	1,342
Cases of incrustation and scale	47,[illegible]	1,[illegible]
Cases of internal grooving	[illegible]	[illegible]
Cases of general corrosion	[illegible]	[illegible]
Burned plates	[illegible]	[illegible]
Leakage around tubes	[illegible]	[illegible]
Leakage at seams	[illegible]	[illegible]

The available iron-ore supply of the United States is estimated at [illegible] long tons, and the production of iron ore from the mines of the country in 1907 was [illegible] tons, the largest total ever produced in a single year.

Cost of Installation and Operation of Electric Plants

The cost of the Greenwich station of the London County Council Tramways is given by John Hall Rider, in a paper recently presented to the Institution of Electrical Engineers, as follows:

	Cost.	Per Kilowatt.
Land and buildings	$1,028,920.00	$47.0[illegible]
Piers and river work	200,875.40	8.8078
Engines, turbines, alternators and condensers	[illegible]	26.[illegible]
Boilers and economizers	[illegible]	14.[illegible]
Main and auxiliary switch gear, accumulators, station wiring, lighting, tools, etc.	174,[illegible]	[illegible]
Steam, exhaust and condenser piping, pumps, [illegible] and tanks	167,[illegible]	7.[illegible]
Coal and ash conveyors and [illegible]	22,[illegible]	1.[illegible]
Cranes, turntables, railway track, etc.	[illegible]	1.[illegible]

The operating costs for the year ending December 31, 1908, as given in the following, relate to the first half of the station only:

		Per Unit.
Coal (including unloading and removal of ashes)	$118,206.26	0.4751c.
Salaries and wages, running staff	48,019.20	[illegible]
Oil, waste, water and stores	10,[illegible]	[illegible]
Repairs to plant and buildings (labor and materials)	[illegible]	[illegible]
Management, insurance and [illegible]	8,281.[illegible]	[illegible]
Rents, rates and taxes	[illegible]	[illegible]
Total	[illegible]	[illegible]

Units delivered to substations [illegible]*
Maximum load in kilowatts [illegible]*
Station load factor 47.75 per cent.
Coal [illegible]
(Partly at [illegible] per ton, and partly at [illegible] per ton.)
Coal per unit delivered to substations [illegible]

*It is estimated that, for the year ending March 31, 1910, these figures will be, respectively, [illegible] units and [illegible] kilowatts.

In the answer to Question 2 of an Inquiry regarding "Angle of Deflection, etc., in Crank Shafts," published on page 793 of the April 13 number, there were two typographical errors. In the third column, "M_1 = C" should have been M_1 = C, and in the equation "M_1 = ½ M_2 + ¾," etc., the plus sign should have been used, making it M_1 = ½ M_2 + ¾, etc.

The twenty-seventh annual convention of the Street Railway Association of the State of New York, will be held at Fort William Henry Hotel, Lake George, N. Y., June 29 and 30, 1909.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for April, 1909, was (weekly and monthly) 153,000.

May 4 42,000
May 11 37,000
May 18 37,000
May 25 36,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

"Power" Sued for Libel and Acquitted

In the summer of 1907 one John E. Carroll, of Philadelphia, undertook the exploitation of an engine to run with carbonic-acid gas. There was no harm in this, for an engine will run with carbonic-acid gas as well as it will with air or steam—but no better. The half-page advertisements of the CO_2 Development Company, however, described the carbonic-acid gas which pours out of every chimney and arises from every fermenting tub as a vast "source of energy." So is water a source of energy, if it is elevated and free to fall. So is air a source of energy, if it is compressed and free to expand. But out of neither the water nor the air can more energy be got than has been expended in elevating or compressing it.

When, therefore, Mr. Carroll maintained that if he charged his engine with carbonic-acid gas under pressure it would continue to run forever if the gas did not leak out, and that under the ordinary condition of stuffing boxes it would continue to run and develop power in large and useful amounts for some thirty days, without any source of energy to draw upon, he stated what was opposed to all the known laws of physics and mechanics; something which, if true, would mean more to POWER and all that it represents than the invention of the steam engine; something which was so thoroughly revolutionary that its possibility could be admitted only after a demonstration positive and satisfying enough to warrant upsetting the principle of the conservation of energy, and all the sciences which are founded thereupon. The demonstration which we attended signally failed to fulfill these conditions. It was a farce. The inventor talked the most arrant nonsense and refused to make the simplest tests to prove that his "demonstration" was honest. The conclusion that the CO_2 engine was a clumsy trick for obtaining money by false pretenses was inevitable, and we did not hesitate to say so. The whole affair was too ridiculous for serious treatment, and so in a two-page article in our issue of September, 1907, we laughed it off the stage.

In consequence of the publication of this article, F. R. Low, its author and the senior editor of POWER, was arrested something over a year later, upon a charge of criminal libel made by Carroll, when Mr. Low was in Philadelphia testifying to what he had seen in behalf of officers and stockholders of the company who had been honestly deceived into lending their names and money to the enterprise and who were then suing the alleged inventor.

We waived examination and were in due course formally indicted by a Philadelphia grand jury. Right here we wish to extend our grateful acknowledgments and thanks to the many friends who have assisted and offered assistance in the matter, especially to Jay M. Whitham, M. E., and A. C. Wood, M. E., whose testimony that they had examined the device and advised clients against investing in it would have been particularly valuable had it been admitted. As it was, however, the judge, after having heard enough evidently to satisfy himself of the nature of the case, ruled out all of our expert testimony and instructed the jury to find for the defendant.

The outcome is a victory for technical journalism, and for the honest inventor and investor. Anything less than so prompt and complete an acquittal might have tended to make editors over-cautious and prevented the prompt and complete exposé of the various get-rich-quick schemes which it is the function of the technical press to investigate and inform its readers about. One can well accept some indignities, and be put to some trouble and expense, for the reassertion of the right of the editor to expose in the broadest and most positive terms what he concludes, after careful investigation, to be a fraud.

First Be Sure You're Right

Engineers of isolated power plants are in many cases seriously handicapped by the inability or unwillingness of their employers to recognize what is necessary or desirable in the way of plant improvements or conveniences. On the other hand, the owners of such plants are not always safe in following out the recommendations of their engineers. For example, a certain engineer, with the laudable desire to increase the operating economy of his plant, urged the owner to discard the existing boiler-and-engine equipment and put in a more modern class of equipment. The old plant included horizontal return-tubular boilers and simple single-valve engines, and his plan was to substitute water-tube boilers and four-valve compound engines, raising the boiler pressure from 100 to 175 pounds. The equipment which he suggested would have been admirably suited to the work and if it had been a question of installing a new plant his ideas would have been eminently practical. He failed to consider, however, that the interest on the net cost of making the change would have been considerably more than the saving in operating expenses. In view of this fact and the additional important fact that the existing equipment was by no means worn out nor seriously out-of-date, the owner refused to make the change. A regrettable result of the discussion was that the owner's confidence in the judgment of the engineer was greatly reduced, although the latter was a thoroughly competent and industrious operating man.

We have known of several similar instances of recommendations based on a conscientious desire to further the owners' interests but not sufficiently well thought out and analyzed before presentation.

The moral is, not to refrain from making any suggestions at all which involve additional investment, but to consider thoroughly *all* of the possible results of carrying out an idea, weighing the disadvantages carefully against the advantages and being prepared to show that the latter would surely predominate. After you are dead sure of your ground, make your recommendation and urge it as vigorously as circumstances will permit.

Boiler Inspections and Explosions

Boiler inspection which does not inspect is worse than none at all, for it issues certificates of inspections which have not been made and guarantees the safety of apparatus which may or may not be safe.

It has been stated on what appears to be good authority that in some localities the inspector walks into the engine room, takes from the wall the old certificates of inspection, replaces them with freshly written ones duly sworn to, and goes to the office to collect the legal fee without even ascertaining if there are boilers in the plant. This is not a report of an isolated case but is a statement of what is claimed to be common practice. In fact, in the report of a recent boiler explosion in one of the Western States the public prints boldly asserted that not only was this the method of "inspection" employed in that instance, but it was generally known to be the customary procedure, a statement which is corroborated by our own correspondence. Of course, hanging would be much too good a fate for a scoundrel who carries on such a conscienceless game. Equally of course, that sort of thing would be impossible without the connivance of someone in authority around the plant, and that someone is fully as culpable as the potentially murderous thief who issues the certificate.

So often has the necessity for competent boiler inspection been urged and so often has the enactment of suitable inspection laws been advocated that anything bearing upon this subject seems almost, if not quite, platitudinous. But it is not easy to sit silent while from Maine to Texas and from Florida to Washington there come almost daily reports of loss of life and destruction of property from boiler explosions that in a majority of instances would have been prevented by intelligent inspection. Boilers have been found operating without safety valves or gage cocks and in one case because the safety valve leaked to such an extent that the fireman could not maintain the required pressure, a plug was screwed into the outlet.

In the territory of absent-treatment inspection for revenue only, where the combined certificate of inspection and perjury is nailed to the wall of the engine room and the fee collected in the office, mysterious boiler explosions occur, while in New York City failures are so rare as to be practically unknown, and in Massachusetts not a single boiler under the jurisdiction of the Massachusetts District Police has exploded.

There have been some boiler explosions in Massachusetts since the enactment of the inspection law, but by a peculiar construction given to the law not all boilers in the State were subject to State inspection and it was amongst the "exempts" that the explosions took place. On the other hand boilers which had been found unsafe and condemned by the State inspectors have been taken outside the State where there were no inspection laws and there erected, operated and burst.

Epidemics which annually cause much loss of life and cost practically nothing in the destruction of property are made subjects for national solicitude and special appropriations, while the dance of death in the inspectionless sections and in the wake of the incompetent or grafting inspector goes merrily on.

The Benefit of Reading

The engineering journal lay on the table unopened. The engineer sat in a discarded office chair, with his legs sprawled out in a manner denoting either laziness or a bad attack of "spring fever." Nothing seemed to trouble the serenity of his musings, not even the thumping of the engine twice at each revolution, nor the hissing of steam from several leaking valve stems and ancient flange packing.

This engineer has no time to read. He frankly said so, and more than that, "readin' an engineerin' journal didn't do no good anyhow."

Someone has said that most of us allow others to do our thinking for us, but here was a case where the engineer did not even go as far as that. He neither thought for himself nor allowed others to think for him, by reading what they had written.

The man who never reads will never amount to anything. If inventors had never read, there would never have been inventions. The greatest inventions known were not the outgrowth of chance, but the result of study, reading what others had to say pertaining to the subjects. If this were not so, the old stage coach would still be in vogue instead of flying machines, the old birch-bark canoe instead of the "Mauretania," the old Watt engine instead of the Corliss and steam turbines.

The clam, by shutting itself up in a shell, never gets anywhere unless "in the soup." It lies buried in the mud and is oblivious to all things. There is no sense in any engineer taking the part of the clam, shutting himself up, content with what knowledge has been drummed into his head. There is no good reason for being buried in the mud of ignorance because it is easier to doze in an arm chair. A man who will take the time to read for one hour each day will be surprised at the improvement that will be made in his knowledge regarding matters of which he was before ignorant.

The smartest man in the engineering profession does not know it all. There is always something coming up that either was not known before or was imperfectly understood. It does not, therefore, reflect any credit on the part of the man who comes to the conclusion that it is not worth his time to read the results of experience and experiments of others who are far above him in the work, and allows his engineering journal to remain unopened and unread.

In the average steam plant, the man in charge may claim, and truly think, that he knows all there is to know about everything in the place, but the chances are one hundred to one that in ninety-nine out of one hundred cases the engineer does not know how many heat units there are in each pound of coal he is using, nor the actual horsepower delivered per pound of coal day after day. Few are certain of the amount of water evaporated per pound of coal, or combustible, what the percentage of ash is, or how much moisture is contained in the coal that his company is paying good hard cash for.

Most engineers know a whole lot about a steam plant, but when they stop to analyze their knowledge they find that there are a good many things they do not know. If there is any doubt about it, take up a copy of your engineering journal, turn to the Question and Answer column and attempt to answer offhand the questions found there. The chances are that the reader will get a jolt that will open his eyes to the fact that there are yet a few things for him to learn. The better read a man is, the easier it will be for him to have a ready answer, but the man who is content to let his journal lie in its wrapper will find himself at [illegible] at all stages of the game.

Everyone is, or should be, looking forward to the time when his salary will be increased or a better position will be tendered him. To the well read man the possibilities are great, but to the ignorant man such times are few and far between.

On April 21 and 22 Florida electric-light men met at Orlando and formed a State electrical association with the following officers: President, H. A. Grant, Orlando; vice-president, W. H. Bostwick, Jacksonville; secretary and treasurer, G. F. Craig, Gainesville.

Boiler Explosion at Fond Du Lac, Wisconsin

On April 27, the warehouse and finishing plant of the Winnebago Furniture Company was totally destroyed by a boiler explosion and resulting fire, the estimated loss, including that to neighboring property by concussion, flying debris and heat, being $100,000. Nobody was hurt, the explosion occurring at 4 o'clock in the morning; had it taken place later in the day there surely would have been some fatalities. Only one man, the night watchman, who had been employed in this capacity but a few days, was in the factory at the time. He was in the boiler room and was blown clear of the building, landing on a pile of ashes, but escaping practically without injury.

Of the boiler room and setting not one brick was left on top of another, as shown in Fig. 1. The top half of the back head and the top part of the shell, supported by diagonal braces, shot up into the air, through the roof, completely over a five-story brick courthouse and down into the main street of the town, two block away, cutting in two like a straw a 10-inch telephone pole and burying itself in the sidewalk. Tubes were scattered in all directions in the courthouse yard, and nearly every window in the structure was broken by the concussion.

As is usual in such cases, the old story about pumping cold water onto the hot sheets of an empty boiler gained circulation as an explanation of the castastrophe. On the contrary, all indications point to the fact that there was plenty of water in the boiler at the time of the explosion, otherwise there could not have been let loose the tremendous amount of energy which must have been necessary to accomplish the destruction. An investigation of the conditions under which the boiler was operated, and an examination of the boiler itself, serve to indicate with considerable accuracy the reason for the disaster.

In the first place the boiler was used for heating purposes only, no power being used in the building, and has served this purpose for years. The boiler was 48 inches in diameter by 14 feet long, being built of ¼-inch iron plates, with ⅜-inch heads. The shell consisted of a large number of small plates, about half the longitudinal seams being double-riveted and the other half single-riveted. In Fig. 3 both types of joint can be seen. The size of plate was not uniform, probably no two plates having the same dimensions, and taken altogether the boiler was of a type commonly built 40 or 50 years ago when materials and manufacturing facilities were meager.

Examination of the metal showed that it was rotten through and through. This was shown not only by the parts of the boiler remaining on the ground and which passed through the fire, but also by the piece that went over the courthouse and

FIG. 1. SITE OF BOILER ROOM, AT BASE OF STACK

FIG. 2. TELEPHONE POLE CUT IN TWO BY PIECE OF BOILER

FIG. 3 FRONT HEAD AND BOTTOM OF BOILER

FIG. 4. PORTION OF BOILER, SHOWING SIZE OF PLATE AND RIVETING

which was not subjected to the fire. As far as could be ascertained, not a single seam let go; the rupture in all cases being in the sheet itself, showing that deterioration of the plates had made the seams the strongest part of the boiler.

When asked at what pressure the safety valve was set, the fireman who had charge of the plant in the daytime asserted that there was no safety valve of any kind on the boiler. A few pounds pressure was all that was necessary for heating purposes, but in order to pump up the boiler it was customary to throttle the stop valve down, so that the pressure would raise high enough easily to operate the duplex feed pump. It is known that the boiler carried 60 pounds pressure by the gage on the Sunday previous to the explosion.

The Rice Roller Relief Bearing

This is something decidedly novel in the bearing line, differing both in construction and application from the usual methods employed and, while not supplanting the regular roller or ball bearing in its legitimate field, has the advantage of being applicable to any overloaded bearing in a very few minutes, such as at noon or night.

These bearings can be applied at either side of an engine flywheel and by the use of calibrated springs can be made to sustain the weight of the flywheel, which would greatly relieve the duty of the journals as commonly applied. They can be applied to any idler having heavy duty at either side of a main driving pulley, carrying both the weight of the pulley and opposing the stresses of the belt.

The bearings can also be placed progressively, trailing from a central power station outwardly to the shafts of lesser duty and at each important point, i.e., where a subdrive exists and as far as may seem feasible in any given case. They are made in three sizes, and in their proportions bear no fixed relation with the diameter of a shaft; size No. 1 is calculated to carry a maximum pressure load of 2000 pounds, size No. 2, 4000 pounds, and size No. 3, 8000 pounds at any reasonable speed. They can be applied in sets of one, two or four, four of the larger ones being necessary in some cases, such as at an engine shaft and wherein the flywheel load might equal or exceed their combined rated capacity, the set of four giving a safe carrying capacity of 10 tons.

FIG. 2. COMPLETE BEARING

In the application of these relief bearings none of the regular bearings is in any way disturbed but simply aided in the performance of its work so that in almost every case the relief bearings could be displaced in a moment's time and without a shutdown, simply throwing the full duty back on the regular journals. These bearings have been tested for three years in one factory, where they are applied to both ordinary shafting and on heavy engine and flywheel duty, as shown in Fig. 1.

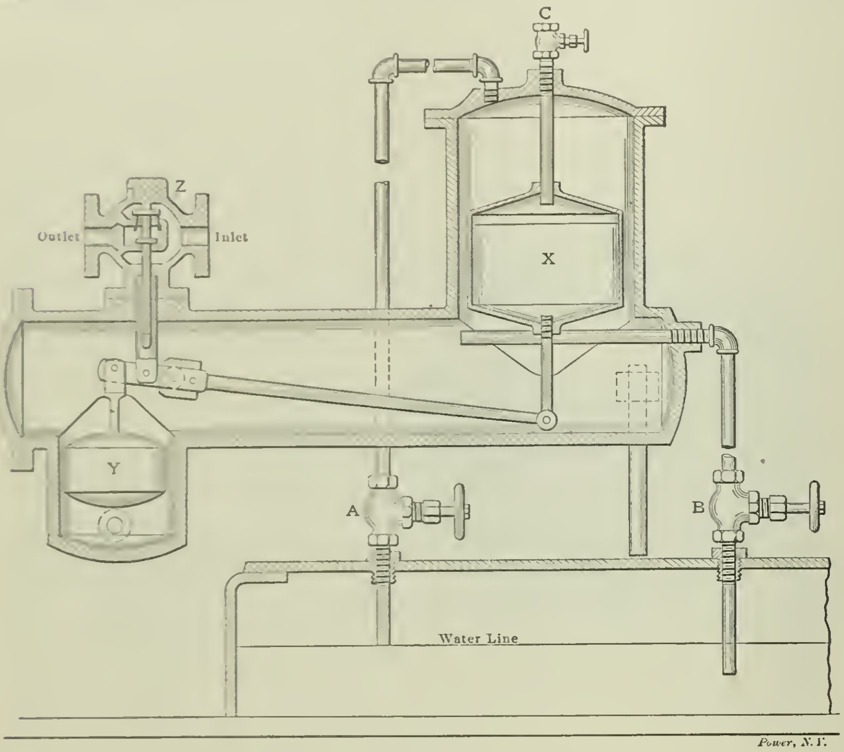
The friction relief bearing is made up of a cast-iron housing, an outer steel roll and a central main roll pin which is stationary in the housing. Between the main roll and the main roll pin are 16 rolls, eight upon each end of the housing and carried in a cage. At each end of the main roll are eight hardened-steel balls. These balls bear upon two hardened-steel washers, one at each end, and take care of the end thrust in the main roll. The smaller intermediate rolls have also at each end a hardened steel washer which takes the end thrust. The main roll pin is hollow, is partially filled with felt and forms an oil reservoir which lubricates the inside of the bearing. One end of this main roll is provided with a series of holes and a stop pin which permits of the oil tube standing in a vertical position, no matter at what angle the roll may stand. All of the other materials with the exception of the intermediate roll cage are of hardened steel and ground to fit.

In service the housing is carried upon a tiller rod, the outer end of this being carried to an overhead support on the upper end of which there is a heavy spring which is calibrated so that by measuring the compression, or giving it a certain amount of compression, a certain load will be carried by the relief bearing. In locating the relief bearing in relation to the shaft upon which it runs, it is so placed on one side or the other of the journal bearing that its action upon the shaft is directly opposed to the forces acting upon the shaft, that is to say, the weight of the pulley and the direction of the belt pull. It is made by the Pickering Governor Company, Portland, Conn.

FIG. 1. APPLICATION OF THE RICE ROLLER RELIEF BEARING

The Senter Feed Water Control

This device consists of a cast-iron body shaped as shown in the accompanying illustration located at some convenient point above the water line in the boiler



SECTIONAL VIEW OF SENTER FEED-WATER CONTROL

and connected thereto by means of the pipe *A*, known as the siphon pipe, extending to the water line, and also with the connection *B*, or gravity pipe, extending somewhat below the water line.

In starting, the gravity connection *B* is opened first, allowing water to fill the apparatus, the air escaping through the vent *C*. As soon as the water reaches the top of the open bucket *X* it will flow into the bucket and fill it. The vent may then be closed and the siphon connection opened, when no farther attention will be required.

Assuming that the level of the water is below the siphon pipe, the water will run back into the boiler by gravity. This empties the housing down as far as the gravity pipe, as shown, and leaves the bucket completely filled with water, exerting a downward pressure on the end of the long lever. Owing to the long leverage, the bucket is much heavier in this filled condition than the weight *Y* on the short end of the lever; consequently, the balanced valve *Z* is opened, allowing feed water to pass to the boiler.

When the water line has been raised until the siphon pipe is sealed by water, the steam in the upper part of the housing condenses and water again fills the space, rising around the bucket and neutralizing the weight of its contained water. As the counterweight *Y* is considerably heavier than the bucket itself, the weight naturally drops and the bucket rises when both are submerged, thereby closing the feed valve.

A blowoff is provided in the drop leg under the weight *Y* and means are also provided for blowing sediment out of the bucket, the vent *C* being continued down by a pipe which acts as a guide when the bucket rises and falls. Blowing out when at its topmost position thoroughly cleans the bucket.

The balanced regulating valve may be reground by removing the top guide plug and inserting a screwdriver in the slot made for that purpose on the top disk. This device is not attached to the water column in any way, but directly to the shell of the boiler as indicated. The regulating valve has an area considerably larger than the feed pipe, and all parts of the control are designed to operate with the minimum amount of attention for long periods. It is made by the Senter Manufacturing Company, Chattanooga, Tenn.

"Firma" Compound High Pressure Water Glass

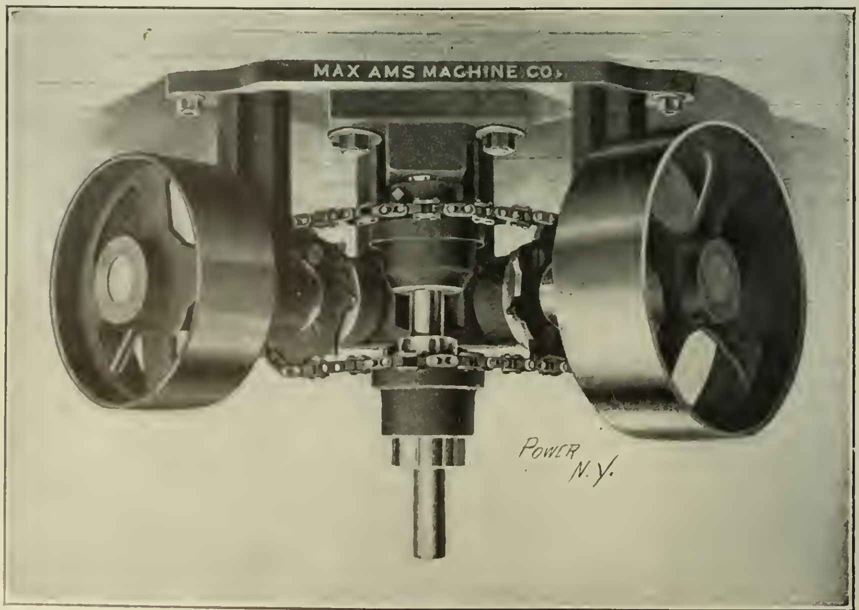
The "Firma" compound high-pressure water-gage glass is simply a glass tube which comes in various diameters and lengths. In appearance, it is a tube of clear white glass, the walls of the tube being about 3/32 inch thick.

The superiority claimed for it is because it is a double tube; that is, one glass tube is drawn over another, the whole being fused into a solid mass. While this junction cannot be seen in the glass, the result is that the inside tube will expand in proportion to the temperature of the water or steam and the outside tube will contract according to the sudden change of temperature which water-gage glasses are called upon to withstand in boiler rooms, locomotives, etc.

This gage glass is manufactured by the Advance Packing and Supply Company, 123 Franklin street, Chicago, Ill.

A Chain Angle Drive

The driving of shafting at right angles is often a serious problem, the latest solution being that of the Max Ams Company, Mount Vernon, N. Y., and illustrated herewith. It consists of four sprocket wheels and a special chain, built with link openings in both directions. This is neces-



NOVEL ANGLE DRIVE

sary to mesh with the idle sprockets on the short vertical shaft and at the same time mesh with the driving and driven sprockets. It is a very simple device and is built to transmit various amounts of power.

American Society of Naval Engineers

The American Society of Naval Engineers held a banquet on Friday evening, May 7, at Rauscher's, Washington, D. C., in celebration of the twenty-first anniversary of the organization of the association. Covers were laid for about 150. While the dinner was attended by all branches of the naval service, the engineers predominated, and among them were many representatives of the American Society of Mechanical Engineers, who were in convention at Washington. The formal toasts were: "The President," Senator M. E. Clapp; "The Navy," Rear-Admiral C. S. Sperry, U. S. N.; "Naval Engineering," Rear-Admiral Richard Wainwright, U. S. N.; "The Navy and the People," Hon. W. E. Roberts. The following also spoke informally: Albert Dawson, representative of Iowa; Prof. F. R. Hutton, of Columbia University, and honorable secretary and past president of the A. S. M. E.; Robert Patchen, newspaper representative, U. S. N.; Hon. Beekman Winthrop and Hon. L. A. Coolidge. The general trend of the addresses seemed to favor concentrated action and harmony between the line and staff. The speeches were all most emphatic and frank and were enthusiastically received.

After the addresses, J. W. Armour entertained with songs and recitals. Rear-Admiral J. K. Barton, president of the association, presided, and Commander W. S. Smith was the toastmaster.

"Power" Editor Acquitted on Libel Charge

The libel suit brought by John L. Carroll, of Philadelphia, against F. R. Low, senior editor of Power, was tried before a Philadelphia grand jury on May 13 and the editor was acquitted, the judge instructing the jury to find for the defendant. Carroll, it will be remembered, is the inventor of the CO_2 motor, which was described in Power for September, 1907, as being a "mechanical fake." This week Carroll himself is to be tried on several counts for obtaining money under false pretenses.

Hans Holzwarth, the inventor of the Holzwarth steam turbine, has perfected a gas turbine which has been tried at Hanover, Germany, with such results that the proprietors have been encouraged to undertake a 1000-horsepower unit.

Ohio Society of M., E. and S. Engineers

The nineteenth annual meeting of the Ohio Society of Mechanical, Electrical and Steam Engineers was held Friday and Saturday, May 21 and 22, at Canton, O., headquarters being at Hotel Courtland. Besides the business sessions, entertainment features, inspection trips, etc., the program included the following papers: "Heat Insulation," by L. O. Hoag; "The Interpole Motor," by Prof. H. B. Dates; "Hot, Soft Water for Steam Boilers," by G. H. Gibson; "Lubrication of Steam Cylinders by Grease," by B. F. Fisher; "Some Practical Points on Power Plant Piping," by Justus Roesser.

Passaic Association's Ladies' Night

Passaic Association No. 15, N. A. S. E., of Passaic, N. J., held a ladies' night in honor of the twelfth anniversary of the founding of the association. Harry Clark, the president, in a few brief remarks, introduced Mayor Fred R. Low, who made an effective address of welcome. An entertainment, which was greatly enjoyed, was given by the "bunch," after which refreshments were served. The members of the arrangement committee are to be congratulated.

BANQUET OF AMERICAN SOCIETY OF NAVAL ENGINEERS, WASHINGTON, D. C., MAY 7

Keystone Association's House-warming

Keystone Association No. 50, N. A. S. E., of Buffalo, N. Y., held a housewarming Wednesday evening, May 12, in observance of the opening of new and beautiful headquarters on the ground floor of the Mutual Life Insurance Company's building. There were fully 400 in attendance and No. 50 should feel justly proud of the success of the event.

Walter McKnight made the address of welcome and Joseph N. Gregory presented the hall to the association.

The following musical program was rendered: Charles Morton, baritone solo; Ethel Smith, piano selections; Arthur Smith, tenor solo; Gertrude Rumage, piano selections. Miss Mary Crage was accompanist. At intervals the following past presidents of No. 50 made brief addresses: William Eskin, John Sturnor, B. C. Miller, Joseph Bubach, Frank Desett, John Hager. Edward Lawler and Winifred Graham, of No. 16, also spoke. Dancing closed the festivities.

Business Items

The third edition of the Smooth-On instruction book No. 7 has recently been printed by the Smooth-On Manufacturing Company, 752 Communipaw avenue, Jersey City, N. J., and a copy will gladly be sent to any engineer or other interested person on application.

The Electro-Mechanical Engineering Bureau has opened offices in the Monadnock Block, Chicago, Ill., for consultation, inspection and tests along mechanical, electrical and chemical lines and is in a position to give expert attention to any technical subject, including the development and design of devices, processes and patentable ideas.

The Fred M. Prescott Steam Pump Company, Milwaukee, Wis., has established a district sales office in the Chandler building, Atlanta, Ga., in charge of R. L. Radcliffe, who has been connected with its sales department for some time. The establishment of the new office was necessary on account of the large volume of business emanating from the southeastern and southern portions of the country.

McEwan Brothers Company Whippany, N. J., has ordered from the Hewes & Phillips Iron Works, Newark, N. J., an 18x34x42 tandem compound-condensing Corliss engine with condensing apparatus. The Bernheimer & Schwartz Pilsener Brewing Company, New York, has ordered one 18x30 heavy-duty tangye-type direct-connected engine to run at 150 revolutions and to be equipped with the new "Franklin" valve gear.

John J. Harman has become a member of the Harman Engineering Company, of Peoria, Ill., the other member of the company being Jacob A. Harman. The company will give particular attention to mechanical-engineering problems, including examinations, reports, designs and tests of steam-, hydraulic- and gas-driven electric-generating plants and determination of mechanical efficiencies of manufacturing processes and machinery.

The Wisconsin Engine Company, of Corliss, Wis., recently put into service the second engine sold to the Oliver estate in Pittsburg. This engine, which is installed in the central power plant, is a 900-horsepower vertical cross-compound Corliss engine, operating at 120 revolutions and direct-connected to a 600-kilowatt direct-current generator. A Wisconsin-Corliss engine of the same capacity, but of the horizontal cross-compound type has been in very successful operation in the same engine room for several years. This company also recently put into service smaller engines sold to the J. M. Kohler Company, of Sheboygan, Wis., and to the Racine Manufacturing Company, of Racine, Wis.

What might be called a pocket-edition general catalog has just been got out by the Joseph Dixon Crucible Company, of Jersey City, N. J. This lists the company's principal products, such as crucibles, facings, lubricating graphite, greases, pencils, protective paint, etc., giving brief descriptions and prices. It is of value to the purchasing agent, engineer, contractor, superintendent and anyone, in fact, who uses or specifies graphite in any form. The booklet is of commercial-envelop size, and will conveniently go in the pocket or desk pigeonhole. It is substantially bound in tough cover stock and attractively printed. If you want a copy address the Dixon company at its home office.

Plans for a new power plant for W. T. Stevens & Sons Company, North Andover, Mass., have been completed by Charles T. Main, of Boston. The plant is to consist of turbine-generator, boiler and pump rooms, with a coal pocket in the rear. The walls are to be of brick. In the 25x50-foot turbine room will be installed a 360-kilowatt Westinghouse turbine generator with two exciters and a motor-driven Le Blanc condenser. The boiler room will be 40x50 feet and equipped with two 72-inch Bigelow horizontal return-tubular boilers with forced draft. Space is provided for a duplicate boiler installation. The pump room is to contain both boiler-feed pump and a 1000-gallon fire pump. The stack is to be of brick, 150 feet high, with a 6-foot flue.

James Beggs & Co., of New York City, manufacturers of the Blackburn-Smith feed-water filter and grease extractor, announce that an increasing demand for this specialty has made it necessary to appoint sales agents in all the principal cities. This filter may now be obtained through the following agents, all of whom have competent engineers to explain its operation and the advantages obtained by its use: Boston, Mass., Walter G. Ruggles Co.; Watertown, Conn., M. J. Daly & Sons; Buffalo, N. Y., Buffalo Mill Supply Co.; Pittsburg, Penn., National Valve and Manufacturing Company; Cincinnati, O., Murdock Manufacturing and Supply Company; Detroit, Mich., A. Harvey's Sons Manufacturing Company; St. Paul, Minn., R. B. Whitacre & Co.; San Francisco, Cal., Plant Rubber and Supply Company; Montreal, H. W. Petrie, of Montreal, Ltd.; Toronto, H. W. Petrie, Ltd.; Vancouver, B. C., H. W. Petrie, Ltd.; San Juan, Lebedjeff & Co.; Georgetown, British Guiana, W. G. Harry & Co.

Among the orders recently booked by the Crocker-Wheeler Company is one for two 1000-kilowatt, 6600-volt, 3-phase, 25-cycle alternating-current generators for the Nordberg Manufacturing Company, Milwaukee, Wis. These machines will be used for supplying light and power to the Miami Copper Company, Globe, Ariz. The Houston Electric Company, Houston, Tex., has purchased an 800-kilowatt, 575-volt direct-current generator. Two 3-phase, 2300-volt, 60-cycle alternators, having a combined capacity of 550 kilowatts, are to be added to the equipment of the municipal plant at Pasadena, Cal. A motor-generator set consisting of a 3-phase, 60-cycle, 2300-volt, synchronous motor and a 575-volt direct-current generator, having a capacity of 300 kilowatts, was sold to the Boise Valley Railway Company, Boise, Idaho. The National Tube Company, McKeesport, Penn., has added to its 22,800 horsepower of Crocker-Wheeler motors to the extent of 275 horsepower for the operation of saws and various rolling mill machinery.

New Equipment

The Michigan Buggy Company, Kalamazoo, Mich., is building an addition and will install new engine.

The San Antonio (Texas) Gas and Electric Company, it is said, will build a new power house to cost $200,000.

The Hill Manufacturing Company, Lewiston, Me., is erecting a new mill. A 700 or 800-horsepower engine will be installed.

The Ark Gravette Cold Storage, Canning and Packing Company has been incorporated with $50,000 capital. Incorporators, E. M. Gravette, J. T. Oswalt, E. L. Chatfield, etc.

The North Carolina Electrical Power Company is to erect a plant near Marshall, N. C., which is to cost about $400,000. C. E. Waddell, Biltmore, N. C., is engineer in charge.

The Original Ice Company, Middletown Township, N. J., has been incorporated with $20,000 capital to manufacture ice. Incorporators, Chas. A. Tantum, W. W. Tamlyn, B. F. Allen.

Plans are being prepared by J. D. Atkins, Department of Public Buildings, Treasury Department, Washington, D. C., for the installation of an auxiliary power plant at the San Francisco mint.

The East St. Louis, Columbia & Waterloo Railway Company will soon start work on construction of proposed electric railway. H. Reichenbach, Columbia, Ill., is secretary and treasurer.

The Cleveland Technical High School

Heating, Lighting, Power and Ventilating Systems in the $400,000 Building Devoted to Cleveland's New Departure in Technical Education

BY H. W. WOODWARD

The Cleveland technical high school, while a part of the public-school system of Cleveland, is in many essential respects unique in educational scheme, as well as in material equipment. The newness of this type of school and the magnitude of the undertaking presented many intricate problems, both educational and material, to those concerned in formulating its plan and in working out the details of construction. The courses offered differ radically from those in other high schools in the city, and are not molded to conform to college entrance requirements. It is intended that this shall be in itself a finishing school, with an atmosphere of manufacture and industry, and steamfitting, clay modeling, pottery, mechanical drawing, leather and art metal work and bookbinding. The department for girls in domestic science has courses in cooking covering the preparation and analysis of foods, the study of food values and the preparation and serving of complete meals, home decoration, physiology and hygiene, home nursing, household accounts, plain sewing, dressmaking and millinery. The full course may be completed in either four years of three terms each or three years of four terms. Night classes are carried on throughout the year in three sections meeting alternate nights. The same equipment and instruction used during the day is available for ments for class rooms, of one square foot of glass to five square feet of floor, although the measurement given includes corridors, basement and all portions of the building. The cost of the building complete, exclusive of shop tools and laboratory apparatus, was $[illegible], or about 15½ cents per cubic foot, a very low price for so complex a building with such elaborate equipment.

The completeness of equipment in drafting rooms and shops is evident from the illustrations. These rooms accommodate from 20 to 30 students each, and the arrangement of schedules keeps the rooms in service most of the day and evening. In the drafting room the designs are pre-

FIG. 1. CLEVELAND'S NEW TECHNICAL HIGH SCHOOL

whose graduates shall be prepared to enter a vocation. In the class room, studies are chosen which have the most immediate and direct bearing on life work, and during the last two years pupils are allowed to specialize in lines where tastes and talents run. The school year is divided into four terms of twelve weeks each, with one week intermission between each term. The school day is divided into two equal parts, one for class room and recitation work, and the other in shop, foundry, kitchen or sewing room. Full courses are given in woodworking, pattern-making, machine shop, foundry, forge and blacksmith shop, bricklaying, plumbing the evening classes. A two years' course in evening work warrants the issuing of a certificate as an evidence of character and workmanship.

The Building

The building contains 63 class and shop rooms besides offices, lunch, rest and toilet rooms, auditorium, gymnasium and power plant, and accommodates 1400 students. The total content is about [illegible] cubic feet, the floor area 125,000 square feet, the exposed wall area [illegible] square feet and the window surface [illegible] square feet. The window area for the entire building is nearly equal to the standard require- pared from which shop work is executed. Drafting tools and shop tools of every description are furnished by the school, and a system of hourly checking guards against loss and misuse. In all of the shops demonstrations of the work to be done are made before the tools are put into the students' hands.

Power Plant Equipment

In Fig. 2 the power plant of the building is shown in plan view. The boiler room, Fig. 3, contains three horizontal tubular boilers, 72 inches by 18 feet, built for 150-pound pressure, and Detroit automatic stokers, with draft-area outtings. The two automatic driving engines are so arranged that either engine will operate any or all of the stokers. A McDonough automatic damper regulator controls the stack damper, as well as the speed of the stoker engines. The stack, which is 150 feet high by 4 feet inside diameter, is octagonal in form and built of brick of the same color and quality as that used in the building.

In the engine room, Figs. 9 and 10, are one 17x10-inch center-crank and one 20x20-in side-crank Skinner engines, each equipped with an automatic oiling system. The engines are direct-connected to 125-kilowatt and 200-kilowatt Burke three-wire generators and run at 250 and 200 revolutions per minute, respectively.

The feed-water heater, Fig. 11, is of the Webster horizontal cylindrical type, with receiving, purifying and heating tank having 40 cubic feet of water storage capacity, and piped as an induction heater. The two boiler-feed pumps, 6x4x8 inches, furnished by the Platt Iron Works, are adapted to pump hot water and are so connected that they may be run separately or together. They are equipped with ratchet-drive lubricators, Squires pump governors, and have a Bristol thermometer in the discharge line. The oiling system consists of storage tanks for cylinder and engine oil located in the boiler room, and each is piped to a funnel on the outside of the building, so placed that an oil barrel can be emptied direct from the wagon, and to faucets on the wall of the engine room. A gage board with a full set of nickel-plated gages connected to the high-pressure steam lines and heating system, a switchboard and the auxiliary apparatus for the Power's temperature control and the Webster vacuum system complete the engine-room equipment.

Heating and Ventilation

The system of heating and ventilating is a combination of direct radiation and mechanical ventilation, the direct radiation being proportioned to supply the heat losses through walls and windows with steam circulating at or below atmospheric pressure. The ventilating system is designed to supply fresh air at a constant temperature of 70 degrees Fahrenheit to each room. The direct radiation for each room was figured from outside wall area, window area and exposure to wind and points of the compass. The formula used was developed during the progress of design, being a modification of one generally employed, and results have proved its correctness.

Assuming an outside temperature of zero degree Fahrenheit, a room temperature of 70 degrees Fahrenheit, steam in the radiators at atmospheric pressure, and cast iron radiation emitting 250 B.t.u. per hour per square foot,

$$R = 0.28 \left(G + \frac{W}{4} + 0.02\ NC \right),$$

where

R = Radiation required in square feet,
G = Area of glass in square feet,
W = Area of exposed wall in square feet,
C = Contents of room in cubic feet,
N = Number of air changes per hour, due to leakage around windows =

$$\frac{G}{W} \times \frac{1}{(\textit{number of protected sides})}.$$

N has values varying from 1/2 to 1/7 depending upon window area and number of exposed sides. The radiation in rooms having a northern exposure and open to a free sweep of the wind was increased about 10 per cent. above that given by the formula. The direct radiation totals about 15,000 square feet in 265 units. Except in the auditorium, locker rooms and corridors, wall radiators of ornamental cast iron are used. These are tapped at the top for steam and at the bottom for returns, and are set with a pitch of 1 inch in 10 feet. Floor radiators are two-column cast iron and tapped for a single pipe connection. All cast-iron radiation was furnished by the American Radiator Company. In the gymnasium locker rooms are coils of 1-inch pipe, supported from the ceiling on roller hangers.

For the heating system the steam piping is laid out for overhead distribution and for downward flow both of steam and condensation, and is graded to 1 inch in 10 feet. Piping is of standard weight, National Tube Company's make, and fittings and valves were made by the Crane Company. Excepting risers, all piping is covered with 85 per cent. magnesia put on by the Philip Carey Company. A 6x12-inch Kieley pressure-reducing valve with a 2½-inch bypass connects the high-pressure steam line to the heating system, and a Davis 10-inch vertical back-pressure valve is placed on the exhaust beyond the point where connection is made to the heating main. The exhaust head is a Swartwout 10-inch cast-iron head, and the steam separators at the engine throttles are Swartwout vertical separators. A Webster 10-inch horizontal oil separator connects the engine exhaust to the heating mains, and this is drained by a Webster low-pressure grease trap. The steam lines are drained by Anderson traps.

The ventilating system was designed to supply to each room by means of blowers, 30 cubic feet of air per minute for each occupant, at a constant temperature of 70 degrees Fahrenheit, and to remove air from the rooms with exhaust fans. The horizontal ducts from the blowers to the risers are built of brick and concrete under the basement floor, and the risers, both supply and exhaust, are of galvanized iron. Each supply riser has an adjustable deflecting damper at the bottom to insure proper distribution of air, and starting at the floor level of the room which it serves, the riser is widened till it reaches the outlet, in order to secure a low velocity for the air delivered. The riser is coved at the top and has a coarse horizontal screen below the outlet, but the opening, which is about 7 feet above the floor, is not covered by a register face. On account of the large amount of air

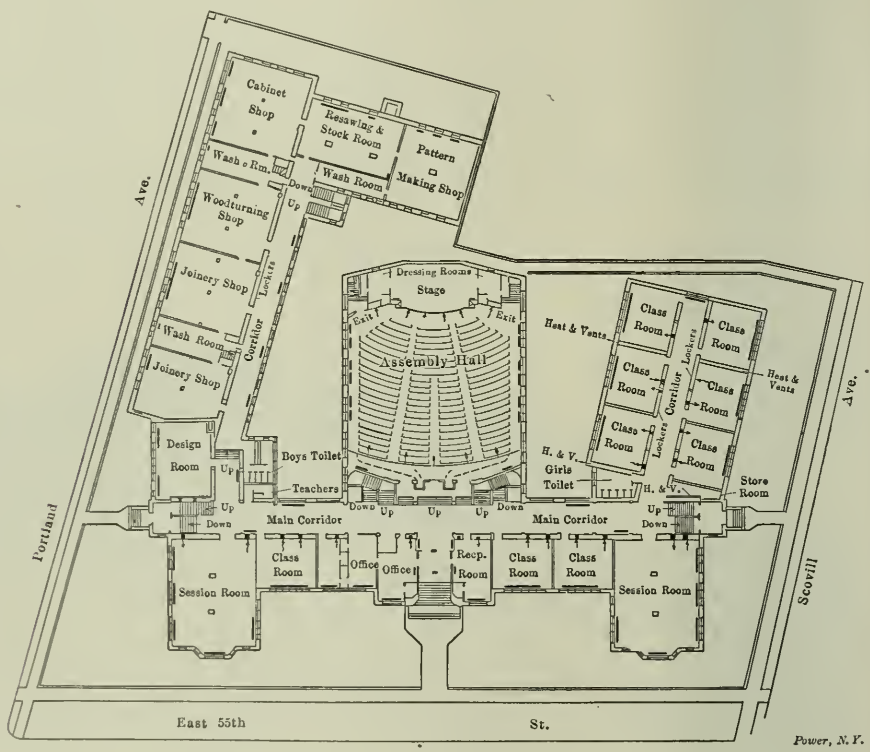


FIG. 2. PLAN OF FIRST FLOOR

FIG. 3. PATTERN SHOP

FIG. 4. MACHINE SHOP

required for the auditorium and the gymnasium, special plenum chambers are provided at the entrances to those rooms. The vent flue in each room starts from the floor level, and the opening is covered by a register face, just inside of which is placed a curtain of light aluminum flaps hanging horizontally and overlapping each other by about 1 inch. This acts as a most effective check valve on the vent system, allowing the air to pass freely from the room, but preventing any backward flow. Vent flue outlets for the auditorium extend across the full width of the stage and open into a special vent chamber under the stage floor. The vent flues discharge into the attic spaces, and at the upper ends have volume dampers to regulate the amount of air drawn from each flue. The tiers of closets on either side of the building, and the chemical laboratory have each its special exhaust system.

Air is supplied by three 8-foot and one 9-foot steel-plate single-inlet bottom horizontal discharge fans with housings specially designed to suit the conditions of the building. Each 8-foot fan delivers 41,000 cubic feet of air per minute at 160 revolutions per minute, using from 15 to 20 horsepower, and the 9-foot fan delivers 54,000 cubic feet per minute at 160 revolutions per minute with 20 to 25 horsepower. Three of the fans are belted to Burke motors, while the one supplying the shops is direct connected to an 8x10-inch horizontal center-crank engine with automatic throttling governor, designed to run at 200 revolutions per minute on a steam pressure of 100 pounds. The exhaust fans comprise four 60-inch electric propellers running at 200 revolutions per minute and delivering 30,000 cubic feet of air per minute; two 45-inch steel-plate exhausters, with a capacity of 4500 cubic feet of air per minute at 1100 revolutions per minute, connected to the closet exhaust system; and a No. 3 Monogram exhauster with a capacity of 1500 cubic feet per minute, on the exhaust system of the chemical laboratory. All fan motors are provided with Cutler-Hammer standard fan regulators with automatic overload release, which are capable of reducing the speed of the fan to one-half of the normal rating. The tempering coils for the 8-foot plenum fans contain 5000 lineal feet of 1-inch pipe, and those for the 9-foot fan contain 7200 feet. The plenum and exhaust fans, direct-connected motors, steam engine and tempering coils were furnished by the B. F. Sturtevant Company.

The Webster vacuum system is applied both to direct radiation and to the tempering coils, each unit of radiation and each drip point having a Webster water-seal motor which prevents the escape of steam while permitting the discharge of air and water. An 8x12x12-inch Webster vacuum pump brings all condensation back to the engine room, and a vacuum governor controls the pump speed and maintains any desired degree of vacuum in the return lines.

Every important room in the building is provided with the Powers system of automatic temperature control. In the larger class and session rooms, automatic control is applied only to part of the radiators, while the balance have hand control. In shops, gymnasium and auditorium, the radiators are grouped on submains, each group having automatic control. The tempering coils at the fans are divided into three sections, each section with an automatic valve adjusted for a different temperature range, and under the coils

FIG. 5. FORGE SHOP

FIG. 6. DRAFTING ROOM

are the air bypass dampers. The diaphragm valves for radiators and tempering coils, numbering 120, have graduated control maintaining a partially open position and supplying just steam enough to do the heating required; the diaphragm gymnasium and apparatus rooms, carbon lamps are used. The shops have individual drop lights over each machine, and in the drafting rooms the adjustable lamps are wired from the floor. The gymnasium is lighted by ceiling clusters sential to match colors and fabrics at night. In the boiler and engine rooms are Cooper-Hewitt mercury vapor lamps. Sixty electric motors, ranging in size from ½ to 30 horsepower, are in use for shops, ventilating fans, elevators, etc. The

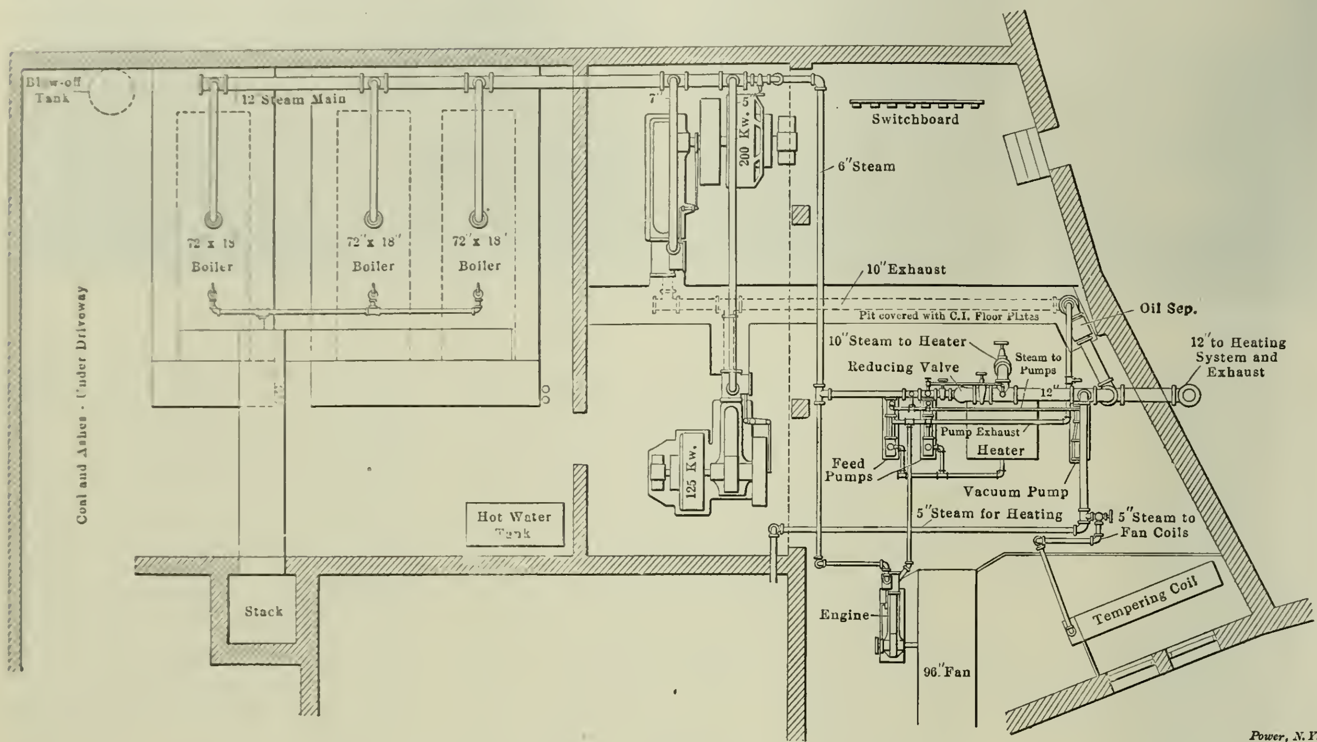

FIG. 7. PLAN OF ENGINE AND BOILER ROOMS

motors on bypass dampers operate with a graduated motion maintaining any intermediate position required. The thermostats controlling the direct radiation, numbering 70, have for a sensitive element a hollow corrugated-metal disk containing a highly volatile liquid, and operate the valves with a temperature variation of one degree. Compound-duct thermostats near the fan delivery control the diaphragm valves on the tempering coils and the diaphragm motors on the bypass dampers. At the delivery of the disk fans in the attic are doors operated by diaphragm motors controlled by air cocks. The air compressor, which furnishes the motive power for the system, the driving motor and automatic switch made by the Powers Regulator Company, the switchboard with air cocks for attic damper control and the storage tank under pressure of 15 pounds are located in the engine room. Piping of galvanized iron and armored lead tubing connects with each thermostat, valve and diaphragm motor.

FIG. 8. BOILER ROOM

Lighting

The scheme of lighting conforms to the specific requirements of the several rooms. For general illumination in class rooms, corridors and auditorium, there are 530 60-watt tungsten lamps. In shops, drafting rooms, locker and toilet rooms, of carbon lamps protected by metal cages; the auditorium by tungsten lamps in ceiling clusters with holophane globes and carbon lamps at the sides; the stage by carbon lamps. There are 34 single-glower Nernst lamps used in the art, millinery and dressmaking rooms where it is es- lighting system has three-wire distribution, with both two- and three-wire circuits for shop motors. Seventeen distributing cabinets for light and power are located at convenient centers of distribution and so wired that a very close balance is maintained on the lighting cir-

FIG. 9 SMALL GENERATING SET

FIG. 10 THE 200-KILOWATT UNIT

cuits; all lights not controlled direct from the cabinets are operated by Hart single-pole flush snap switches. The neutral is thoroughly and permanently grounded at the switchboard, and the neutral of the feeder circuits is not brought up to the feeder panel. All wiring throughout the building is in metal conduit, and the cables from the generators to the switchboard are lead covered and laid in vitrified tile.

Switchboard

The switchboard, Fig. 12, comprises two generator and two feeder panels, with the necessary switches, I. T. E. circuit-breakers and instruments, and provides for 21 circuits. The ammeters and voltmeters are Weston round-pattern back-connection instruments, the ammeter on the feeder panel being a two-way instrument with a 100-0-300 dial. On the end feeder panel are Sangamo 1500-ampere shunt total-output wattmeters. The first feeder panel contains voltmeter and ammeter switches of special design, by means of which the voltage can be read across the terminals of each generator, across the outside busbars, and from each outside bus to the neutral, and the current in any circuit can be determined. Shunts are placed in each circuit, and each feeder switch is labeled and numbered corresponding to the number on the ammeter switch. Fuses and cutouts for the feeder circuits are mounted on separate marble blocks at the back of the board. The board is of blue Vermont marble 2 inches thick by 7 feet high, and the ends are closed in by a heavy-mesh wire netting with oxidized copper finish. The switchboard and panel boards were built by the Cleveland Switchboard Company.

Test Data

During the winter of 1908-9 a series of tests were made on the heating and ventilating system and the power-plant equipment. The air supply to each room was found to be very close to the calculated amount. The plenum fans under normal running conditions handle 120,000 cubic feet of air per minute, and during the 9 hours' run deliver 3200 tons of air. The power required to drive them is 55 horsepower, and to drive the exhaust fans, about 20 horsepower. The air is delivered at a temperature of 70 degrees Fahrenheit and with outside temperature at 30 degrees Fahrenheit, 120 pounds of steam per minute is condensed in the tempering coils, requiring 200 boiler horsepower and 4½ tons of coal a day to heat the air for ventilation alone, with a correspondingly greater amount for a lower temperature. A chart from the recording thermometer is reproduced in Fig. 13. From 6:30 to 7:30 a.m., while the building was being warmed, the temperature regulation was out of service and the air heated to 130 degrees Fahrenheit, but during the rest of the day the temperature was maintained very close to the 70 degrees. During the month of January, 1909, 270 tons of coal were burned, 3,150,000 pounds of water evaporated and 17,000 electrical units used, and at no time was the exhaust from the engines sufficient to heat the building. Tests on boilers, engines and generators were made at intervals, of which the following are average results:

BOILER TEST.

Kind of boilers	Horizontal tubular
Size of boilers	72"×18'—72—4" tubes
Heating surface, each	1800 square feet
Type of stoker	Detroit automatic
Fuel	Bituminous slack
Number of boilers in test	2
Duration of test, hours	8
Average steam pressure, pounds	95
Average temperature feed water, degrees	[illegible]
Average draft in uptake, inches of water	0.28
Average per cent. of moisture in steam	2.2
Average draft over furnace, inches of water	0.17
Average CO_2, per cent	11.7
Average oxygen, per cent	7.8
Calorific value of dry coal, B.t.u.	11,000
Total horsepower, rated at 12 square feet per horsepower	400
Average boiler horsepower developed	[illegible]
Apparent evaporation per pound coal as fired, pounds	7.31
Equivalent evaporation per pound coal as fired, pounds	7.96

FIG. 11. AUXILIARY APPARATUS

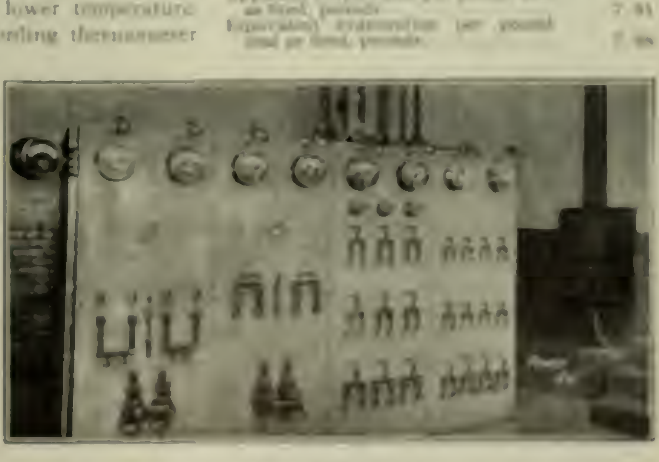

FIG. 12. SWITCHBOARD

Equivalent evaporation per pound dry coal, pounds	8.35
Equivalent evaporation per pound combustible pounds	10.13
Efficiency of boiler furnace based on dry coal, per cent	67.3
Percentage of steam used by stoker engine, per cent	2.25

ENGINE TEST.

Make	Skinner simple, noncondensing.
Type	Side crank.
Cylinder dimensions, inches	20x20
Average steam pressure, pounds	96
Average back pressure, pounds	1.33
Average speed of engine, r.p.m	196
Average indicated horsepower	306
Dry steam used per kilowatt-hour, pounds	46.8
Dry steam used per electrical horsepower-hour, pounds	35
Dry steam used per indicated horsepower hour, pounds	30.2

GENERATOR TEST.

Make	Burke direct-current, three-wire..
Rating at 250 volts, amperes	800
Average voltage	235
Average amperes	840
Average load, kilowatts	198

James F. Barker, under the general direction of Superintendent of Schools William H. Elson. The operation of the plant is in charge of the engineer, William C. Clark. The building was formally dedicated by the Board of Education and delivered to Director of Schools Charles Orr on April 15, 1909.

The Growth of the High Speed Engine

On Tuesday evening, May 11, an abstract of a stenographic report of a lecture on "The Growth of the High Speed Engine, or The Straight Line Engine in Particular," by Prof. John E. Sweet, was

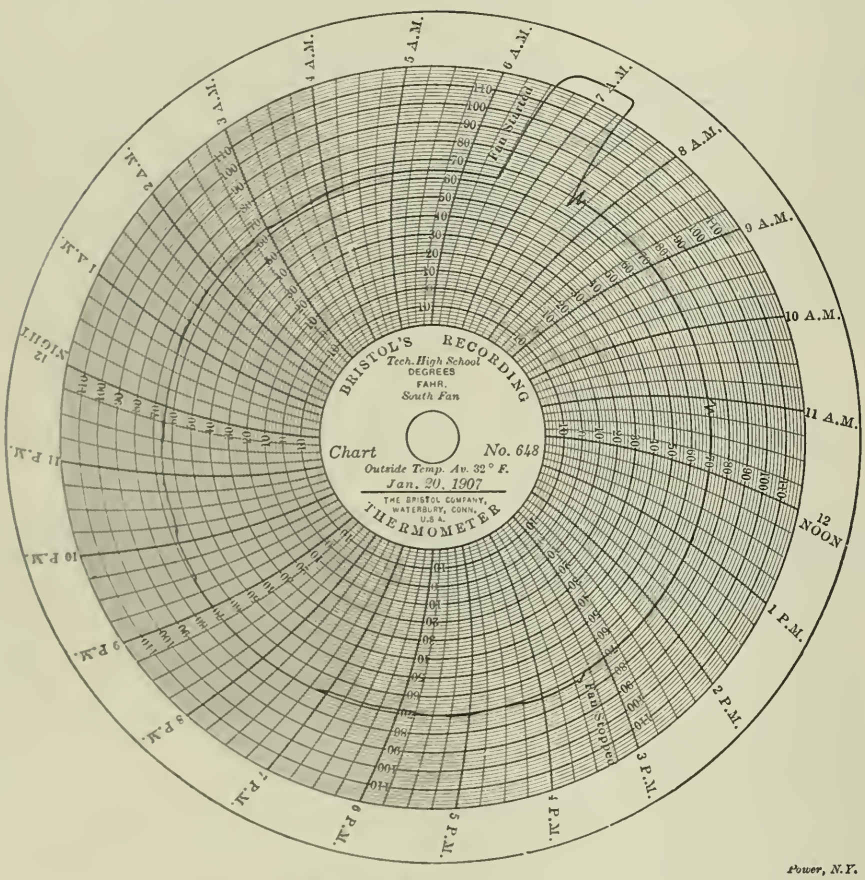

FIG. 13. CHART FROM RECORDING THERMOMETER

Temperatures at end of run, deg. C.	
Room	28
Commutator	53
Armature	49
Shunt field	41
Series field	56

The educational scope and material features of the school were outlined by a commission of prominent Cleveland men appointed for that purpose. The designs for the building were prepared by Architect of Schools F. S. Barnum, and the details of the heating, ventilating and lighting systems and power plant were worked out by Charles A. Cadwell and H. W. Woodward of The Cleveland Engineering Company. The administration of the school is in the hands of Principal

read before the Modern Science Club, of Brooklyn, N. Y. Thirty-five lantern slides were used. Professor Sweet was not present. An animated discussion followed the reading of the paper, which was in part as follows:

Professor Sweet's Paper

In treating of this subject I shall, both from necessity and choice, rely entirely upon my memory. Just who built and ran the first high-speed engine would be hard to determine, because it turns upon what we call high speed in revolution and what we now know as high speed originated in about this way:

At the time when Charles T. Porter was building steam-engine governors, Horatio T. Allen, who was later associated with Mr. Porter in building the Porter-Allen engine, conceived the idea that he wanted an engine with a positive valve motion that would give the results of the Corliss engine.

In their natural intercourse, Mr. Porter suggested to Mr. Allen that with his valve motion the engine could be run at a much higher speed. Mr. Allen had not thought of this, nor taken to it very enthusiastically. Mr. Porter worked out the idea, and among other things had built and exhibited one of their engines at the London exhibition of 1862, where he astounded the English engineers by the speed at which it ran, although it was

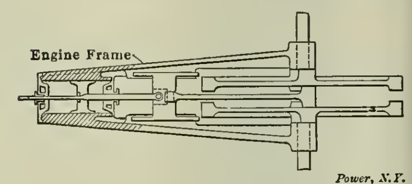

FIG. 1. FIRST PENCIL SKETCH, LATE IN 1869

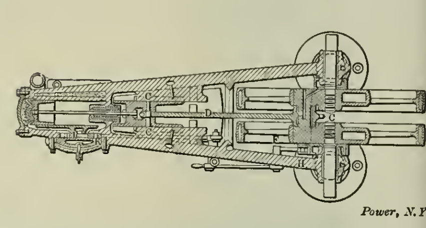

FIG. 2. HORIZONTAL SECTION OF FIRST ENGINE

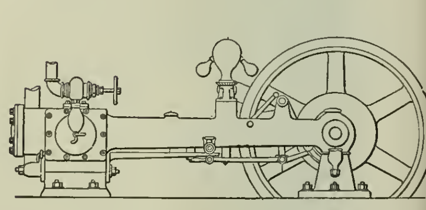

FIG. 3. ORIGINAL ENGINE, FLYBALL GOVERNOR

what we would now call moderate speed.

At that time I was a draftsman in the international patent office, London, and traced on parchment the drawings of the Richards indicator (of which Mr. Porter had charge). I believe I saw Mr. Porter, although I did not make his acquaintance. However, we met at the Paris exhibition, where Mr. Porter exhibited five engines built at the Whitworth works in England. The largest one, 12x24 inches, ran a portion of the machinery, and at the speed of 250 revolutions per minute, if I recollect correctly. This engine had a condenser of Mr. Porter's design, in which the pump plunger was connected directly to the tail end of the piston rod, and although running at that high speed, which no engineer but Mr. Porter believed could be made serviceable, the engine worked quietly and successfully. The secret was in making the end of the plunger pointed and running it under water.

Of the four other engines, all I think 6x12, one ran at a terrific speed. The attendant told me that they were going to run it at 1000 revolutions, although I do not know what Mr. Porter expected to

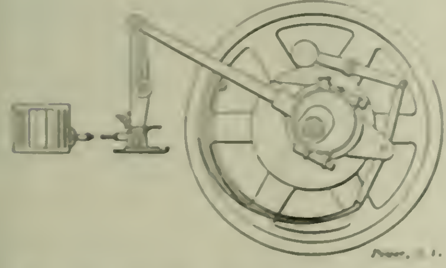

FIG. 4. CENTRIFUGAL GOVERNOR WITH ROCKER

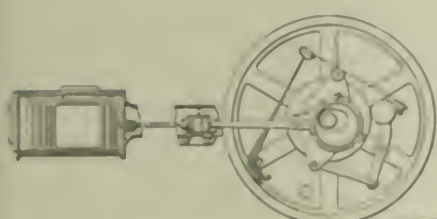

FIG. 5. GOVERNOR WITHOUT ROCKER

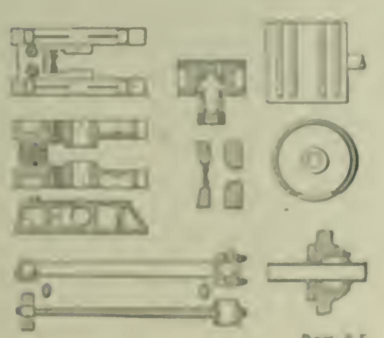

FIG. 6. PISTON, CROSSHEAD, ROD AND LONG SLEEVE

do, or did do, but anyway it went fast enough. Mr. Sprague says 1500 or 1600 but I don't believe it. Two were running dynamos for lighthouses, and another was a complete engine with one-fourth of the cylinder and steam chest cut away, driven by a belt to show the action of the valves, piston, etc. This was repeated by the Buckeye Engine Company many years later.

On Thanksgiving Day, 1870, I started on the drawings for the first Straight Line engine (Figs. 1 and 2), and finished and started the engine on the first day of April, 1871.

This engine had a varied experience, and for the last nineteen years has adorned, or disfigured the present Straight Line engine works. See Fig. 2. In the meantime Mr. Porter had come to New York, built a shop at Harlem, and was in the engine business, building and selling the Porter-Allen engine.

While at Cornell, in 1875, with only student labor, we built the second Straight Line engine and had it on exhibition at the Philadelphia Centennial. This engine had a shaft governor which was then, perhaps, the second or third one ever shown in this country. Mr. Hoadley's and Mr. Tabor's were earlier, and the Hartnell, of England, earlier still. Patents had been secured before, but I do not recall that any were so far advanced as to call general attention to them.

In the fall of 1879 the third Straight Line engine was built. See Fig. 3. In February, 1880, the Straight-Line Engine Company was organized, a name given to the engine, and the first one built by the company was started the first of July of that year. This engine is still running at the Lakeside power house in Syracuse, N. Y.

FIG. 7. PACKINGLESS VALVE STEM

At the Centennial there were shown three or four electric generators or "dynamos," as they were called then, and the one we had built at Cornell, the first Gramme machine built in this country, was shown driving an electric light, but such only as could be used for a lantern. Electric lights up to that time had been used only in lighthouses and lanterns. That fall electric lights were placed on the campus at Cornell, and others, to some extent, in the East.

The growth of the electric light and the growth of the high-speed engine came on together. The electric people have often claimed that the electric-light business built up the high-speed engine, but there are two sides to that story.

In the early days there was a good deal of flicker in the lights and the electricians claimed that it was all due to the unsteady speed of the engine.

We furnished an engine for the Brush people and after Mr. Brush and his superintendent worked a half day testing out a forty arc-light machine, Mr. Brush decided that the greatest variation was one turn in two minutes, and that led them to "sit up and take notice" and settle that the flicker was due to imperfect carbons. The better-governed engines helped out the electric people.

The slow-speed Corliss engines varied so at each revolution that the speed of the engines could be counted anywhere the lights were in view.

The next engines that bid for favor among the electric people were the Armington & Sims and the Ball. I think the Armington & Sims first, as they seemed to have a pull with Edison and were the first to make great progress.

The Ball builders made great claims for their governors, but they have changed them three or four times, while ours is

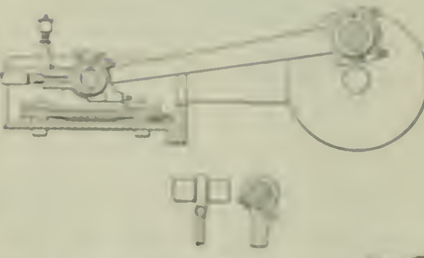

FIG. 8. LONG CROSSHEAD AND SHORT GUIDE

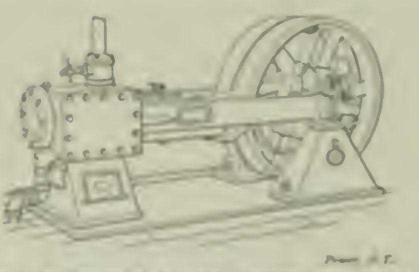

FIG. 9. PRESENT ENGINE, CENTER THROTTLE, ABSENCE OF FOUNDATION BOLTS AT CYLINDER END

FIG. 10. COVER PLATE AND RIBBING ON BASE

practically the same as that used on the first engine built by the company, twenty-nine years ago.

The Straight Line, Armington & Sims and Ball engines were center-crank, shifting-eccentric shaft governors; mine a single ball; the Armington & Sims two balls and in the Ball the governing was partially centrifugal and mainly by an ingenious arrangement whereby the eccentric was shifted by the load.

Soon after the four engines mentioned came the Porter, Ide, Westinghouse, Skinner and others.

The Porter-Allen and the Straight Line valves were mechanically fitted flat valves, depending on the mechanical fit for tightness. The Armington & Sims and Westinghouse piston valves and the Ball used a partially balanced valve.

At the Centennial the Buckeye Engine Company exhibited a small engine, such as they coupled direct to a circular saw, and ran it at a terrific speed. I think they said 400 turns a minute. It was something like a 6x12 or larger, and the saw of such size as is used for cutting lumber.

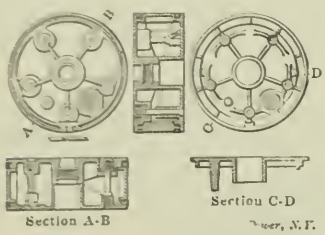

FIG. 11. POP PISTON

The Westinghouse two-cylinder single-acting engines were short-stroke, and ran at high speed, likely faster than any of the others, and as far as numbers were concerned the Westinghouse people turned out twice as many as any other builder, although possibly not as far as electric lighting was concerned. They were the first to adopt the inclosed crank case and splash oilers, and the first to introduce compounding. The continuous systems of oiling with pump and filter was introduced later, and I think by steps, but by whom first I do not recall.

J. C. Hoadley, who was the first, no doubt, to introduce the shaft-governed shifting single-eccentric in this country, determined by experiment that to have the engines run quietly from 10 to 14 per cent. clearance was necessary, and Bourne and Auchincloss that it was not possible to use the shifting eccentric and maintain a constant lead to the valve at both ends of the cylinder. This led me to "monkey" with the rocker arm and design the corrected valve motion which did maintain a constant lead at both ends of the cylinder.

Experimenting with our earliest engines showed me that a constant lead was exactly what we did not want, but a variable lead; and when we got the variable lead I became convinced that the constant lead was not worth the distorted rocker arm that it took to get it. See Fig. 4.

By the change from the original form of approximately constant lead to the variable lead, we were enabled to reduce the clearance to one half of the amount Mr. Hoadley had established, and as the clearance is one of the sources of loss, the new arrangement not only enables us to run quietly at a wide range of load, but much more economically. See Fig. 5.

While great stress has been laid on the superiority of the Corliss engine, and justly so, this gain in economy by the change in the valve motion did not give our engine the trade; and this, perhaps, because of a lack of able salesmen.

But there are in the small electric-light business three essential things that come in before economy. The most essential of all being that the engine must go, and with the briefest possible stop—when a stop is imperative. The engine must govern on the widest variation of load, and the engine must be quiet and in many cases practically noiseless. The question of steam consumption sometimes does not come in at all, on account of heating the place.

This history has extended over a period of about forty-five years. No one can realize the amount of study and experimenting that has been given to the development of the subject. The experiments we have tried, and found to fail, far exceed the successes and, as Edison says, "No failure is a loss, because you learn something;" so we have learned a lot of things that don't work as well as we could have hoped.

We tried long pistons (Fig. 6) which all said was right, but they did not do well; too many got to cutting. We tried various kinds of piston rings which had limited expansion stays. Mr. Porter's four-opening double valves with very short travel have eight chances for leakage, aggravated by the small lap. We cut it down to one valve, with two chances for leakage and long travel and wide lap, which is better, but none too good.

The compensating-pressure plate is too complicated. For the various steam-chest and cylinder-head joints, the narrow band, metal-to-metal, is the thing; also, the round rod in a reamed hole for piston and valve rods; the bushes, from wood to cast iron. Babbitt is best in some places, and lead bronze in others (Fig. 6).

Six or eight kinds of crossheads and guides; two or three different kinds of attachments of crossheads to rods; three

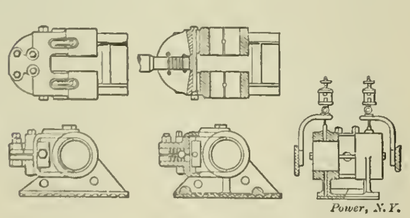

FIG. 12. PRESENT CROSSHEAD

or four kinds of takeups on crosshead pins; three or four crosshead pins; three different styles of frames; solid and bushed cylinders; three or four modifications in the design of the governor; three kinds of governor, before the final design (Fig. 5); three kinds of main boxes; two or three throttles before John Coffin's (Fig 9); two distinct forms of cross-section of the various parts; and a half hundred direct-connected bases; certainly as many, if not more marked departures from general practice on the part of other builders.

The original characteristic features of the Straight Line engine were the straight two-arm frame, three-point support, ring oilers (Fig. 1), flywheels on the throws of the crank (Fig. 2), single-ball governor (Figs. 4 and 5), absence of packing on piston and valve rods (Fig. 7), end play to all journals, long crossheads (Fig.

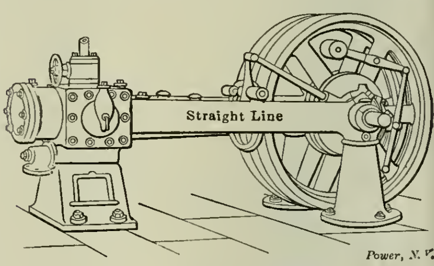

FIG. 13. ENGINE WITH ROCKER ARM FOR CONSTANT LEAD

8) and short guides, limited expansion piston rings, the absence of foundation bolts (Fig. 9), baffle plates in valve (Fig. 10), Coffin throttle and pop piston, balancing pockets in rim of flywheel (Fig. 2).

It is for us, whose shadows are growing fainter and fainter, to anticipate what is to be the final outcome of our fighting this battle for the high-speed engine. Grass grows up and dies down; trees grow and die; dogs grow and die; and man suffers the same fate. Countries spring up and flourish and fade away, and astronomers tell us that the moon is dead, and that there are dead stars. Each and every one of the old slide-valve engines has had its day, a thousand rotary engines have died "a-borning" and the glory of the Corliss engine is waning.

The high-speed and gas engines started together. The gas engine has matured much more slowly, and is about to have its innings. The high-speed engine is changing its coat, and must share the fate of everything else. It has served its purpose, proved its right to existence, been useful, and if it goes down with the Corliss engine it will die in good company.

Steam-turbine semi-portable units are built by the Allgemeirne Dampfturbinen Gesselischaft in Nuremberg. The turbine is above the boiler and direct-connected with the dynamo. The boiler has corrugated flue tubes, internal furnace and smoke tubes, and comparatively big water and steam spaces. The superheater, for 750 degrees Fahrenheit, is in the reversing chamber. It has surface condensation for getting warm water free from boiler scale. The boiler seat is constructed as a pump-case for the condensation pump. Portable units have jet condensation. For small work, pressure turbines are used, for larger work, overpressure turbines. At 700 horsepower a consumption of 1.3 pounds of high-grade coal is guaranteed.

Development of the Surface Condenser

The Surface Condenser before and after the Advent of the Steam Turbine. Factors Influencing Surface Efficiency and Condenser Design

BY GEORGE A. ORROK

The surface condenser owes its invention to what Neil Dow denominated the "Demon Rum," for wherever distilled liquors have been manufactured the "worm of the still" is known and its uses well understood. It may be considered certain that, as the still was introduced into Europe from Arabia before the ninth century of our era, it is a most ancient piece of mechanical apparatus being antedated only by the boiler, the invention of which must have been developed at some earlier time.

The earliest distilling apparatus probably consisted of a vessel of clay or glass for containing the liquid to be distilled and a pipe or receiver with cooling apparatus for condensing the distillate, or condensed vapor from the boiling liquid. Later the pipe or receiver was developed

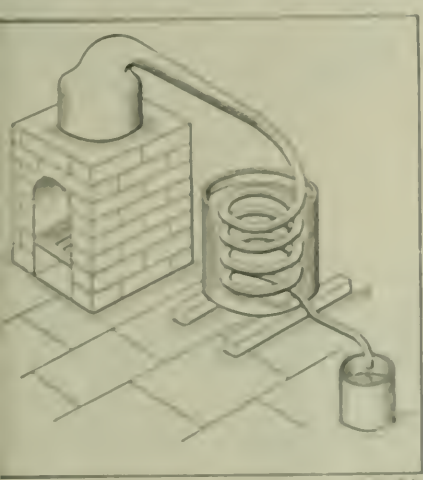

FIG. 1. THE HELICAL WORM

into the form of the helical worm so often used in the stills of a few years ago. It is said that a perfectly preserved glass worm was found in the excavations made at Tyre in Syria some forty years ago, the Tyrians being famed as glassblowers. The city was destroyed by Alexander in 332 B. C. With the introduction of Arabian learning in Europe, the science of alchemy was disseminated and the "retort and alembic" or chemist's still came to be well known. In later years Liebig modified the form of the alembic, or condenser, so that it consisted of a glass tube surrounded by a second glass tube, provided with means for circulating a stream of cooling water between the inner and outer tubes, thus producing the tubular condenser of modern form.

While alchemy had been developing into chemistry the art and science of engineering had come into being. Papin, Savery and Worcester had changed the retort into a boiler. Newcomen had applied the boiler to an engine, and in 1765 James Watt took out a patent for a steam engine with a separate condenser in which the steam was condensed by contact with a metallic surface cooled by a stream of water flow-

FIG. 2. CHEMIST'S STILL

FIG. 3. LIEBIG CONDENSER

ing over the outside, as well as a jet of water inside, a combination of surface and jet condenser. In [illegible] Cartwright patented a condenser in which the steam was condensed in the annular space between two cylinders, the cooling water flowing through the inner one and around the outer one. Brunel in [illegible] patented a surface condenser using groups of small tubes for cooling surface. Finally in 1831,

Samuel Hall took out his patent covering the surface condenser, properly so called, claiming among other things the use of the condensed water for boiler feed water and the distilling of fresh water for make-up feed. In his condenser the steam passed through the tubes and the water around them.

One of the first ships fitted with Hall's condenser was the "Sirius," which in 1838 made the first passage under steam from England to America. Hall's condenser was not a success, partly because of the low steam pressure carried (about 15 pounds gage) and partly on account of the use of tallow as a lubricant. The tallow, partly decomposed by the heat of the steam, volatilized and coming in contact with the tubes, which were made of copper, formed soluble copper salts which

FIG. 4. HALL'S CONDENSER

rapidly attacked the iron plates and tubes of the boilers. The change to brass tubes for the condenser did not help matters very much and besides, the tallow not decomposed frequently hardened in the tubes. Hall did not think of passing the water through the tubes instead of the steam, and his condensers were soon replaced by the ordinary jet condenser. In [illegible] John Bourne patented the counter-current principle for the steam and circulating water, used separate circulating and feed pumps, and passed the water through the tubes instead of around them.

Surface Condenser in 1880

It was not until 1880 that the increased boiler pressures made the surface condenser a necessity. Up to about this time the pressure carried did not exceed 30 pounds gage, and sea water was used for feed water. The amount of salt in the boiler water was tested from time to time by the salinometer, and when too concentrated the boiler was blown down and fresh sea water was added, the concentration always being kept below the point at which the calcium sulphate commenced to be deposited. When the pressure was increased to 45 pounds gage, the calcium sulphate was deposited at the ordinary concentration of sea water, so that it could no longer be used for feed.

About this time the surface condenser was tried by many shipbuilding firms with success and soon became the standard apparatus. The necessary makeup was at first carried in the ballast tanks, but evaporators were soon installed, and at the present time are an indispensable part of the outfit of every ship.

On land the surface condenser was not taken up by designers and manufacturers to such a degree as in marine work, for the incentives were lacking. Good feed water was usually cheap and plentiful. The jet condenser gave the 23 to 26 inches of vacuum required with a much smaller expenditure of power and cooling water,

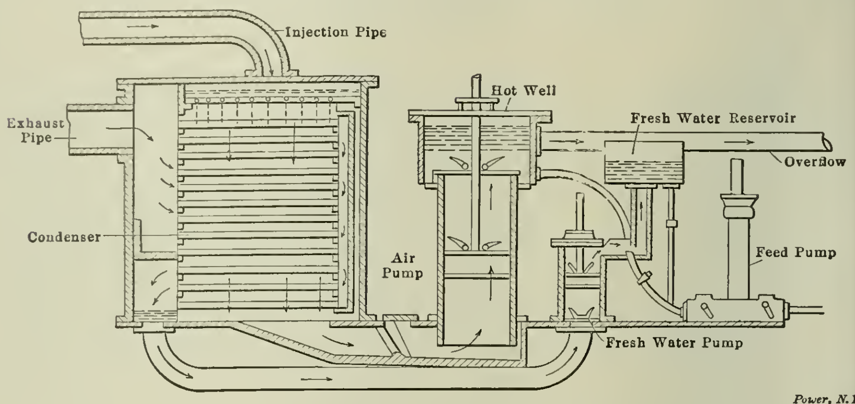

FIG. 5. PIRSSON'S SURFACE CONDENSER

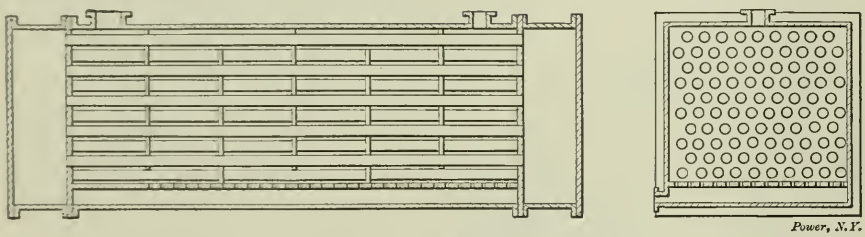

FIG. 6. LIGHTHALL'S STEAM BOILER CONDENSER

and withal the jet condenser was much less costly in first cost and maintenance. It was only where the feed water was bad or very costly that the surface condenser was used, and most of the large installations were near the seacoast or rivers.

As first built for land purposes the surface condenser followed closely the lines of marine practice. The shell, either circular or rectangular in section, was usually made of cast iron with end flanges. The tube plates were bolted to the flanges of the shell with sufficient bolts to hold them in place. The water boxes were placed on the tube plates and bolted through the tube plate to the flanges of the shell. From the lowest part of the shell the hotwell pipe led to the air pump. The circulating water was led into the water box at one end of the condenser and passed through the tubes and out through the water box at the other end. The exhaust steam entered the condenser through a nozzle at the top of the shell. The air pump was the usual bucket pump of the old jet-condenser type, or the horizontal piston type with flap valves developed in the sugar industry. Dry-air pumps were unheard of and not necessary. Most condensers had a provision for introducing a jet of cold water into the steam space, usually a rose nozzle at the steam inlet, in order to assist in the work of condensation, and to furnish the makeup feed. That this makeup water was warmed to the feed temperature was a well-known incidental saving, as shown by Bourne's patent in 1838.

By 1870 the surface condenser had attained the status of a standard machine differing but little from the description given above, and until the appearance of the steam turbine with its demands for better vacuum, only two additions of moment were made in the design of the apparatus. As early as 1850 it was known that the efficiency of the condenser depended on the velocity of the water in the tubes; the greater the speed the higher the efficiency, and the water was made to pass twice or three times through the length of the condenser by dividing the tubes into banks by means of partitions in the water boxes. This practice did not become general until after 1870. The better results obtained by this means and the bending of the upper rows of tubes by the force of the entering steam suggested the introduction of baffle plates and supporting plates inside of the condenser, these tending toward a better distribution of steam to the tube surface.

In navy condensers attempts were made to secure better steam distribution by providing steam passages into the tube banks, these passages being made by leaving out tubes. Although good results were obtained by this method, the manufacturers did not seem to take kindly to it. For this reason this method is rarely used although many condensers in actual service have been greatly improved by removing tubes to open a passage for the exhaust steam into the tube banks.

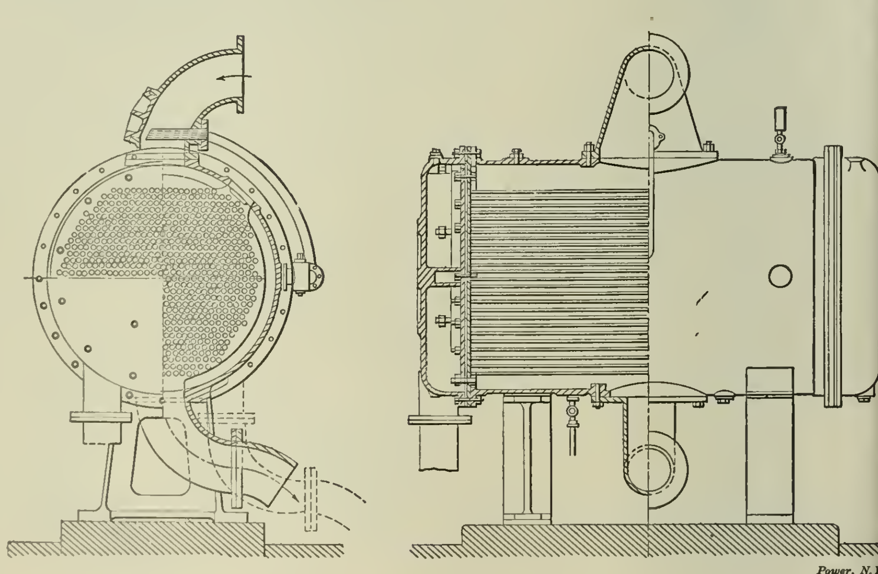

FIG. 7. SURFACE CONDENSER OF 1860

Wheeler, in 1883, patented a surface condenser making use of the Field tube principle. He made use of a double water box at one end of the condenser, the condensing water entering the outside tube and coming back by the inside tube. This condenser was not very successful, probably on account of the entering cooling water absorbing heat from the water on its return as well as from the steam.

The Air Pump

Since Newcomen's time, the air pump had made comparatively little progress, the single-acting bucket pump with three valve decks, one in the bucket and the others above and below it, being the most popular for use with the surface condenser, as it always has been in the case of the jet condenser. Occasionally either

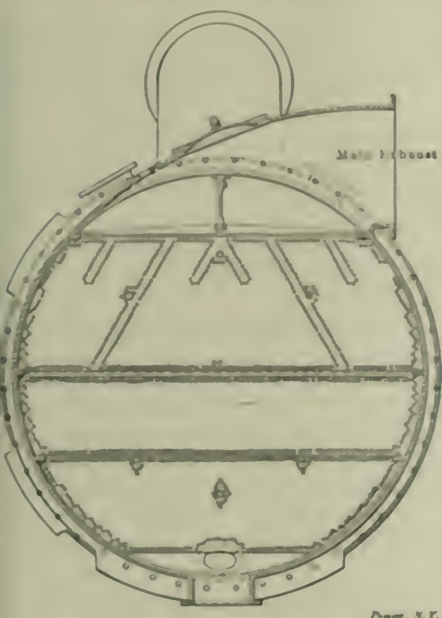

FIG. 8. PASSAGES IN TUBE BANKS

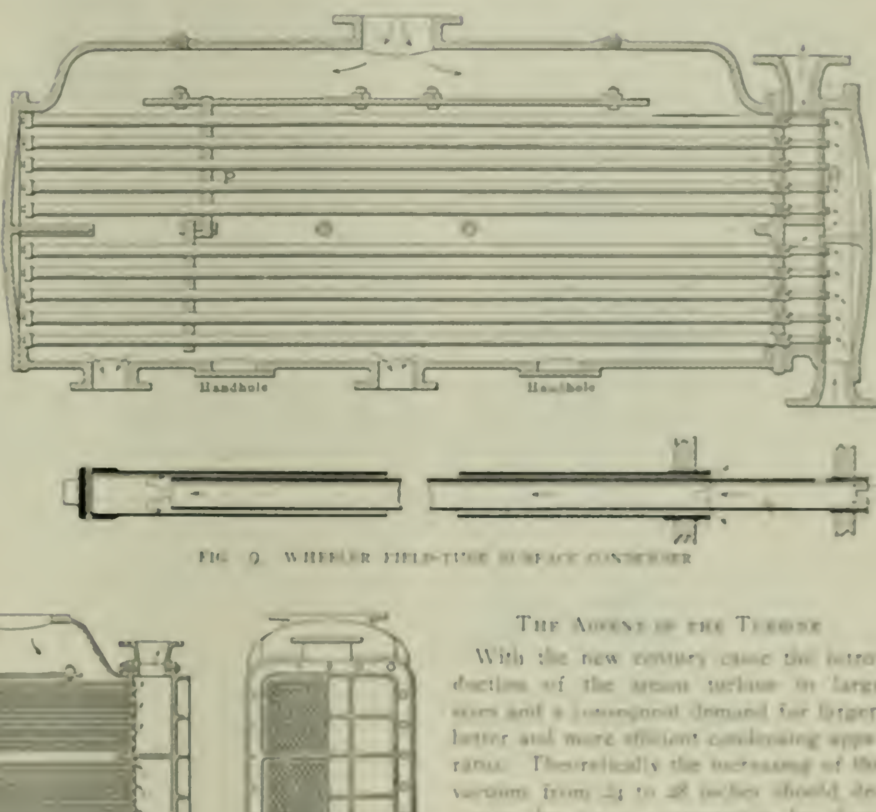

FIG. 9. WHEELER FIELD-TUBE SURFACE CONDENSER

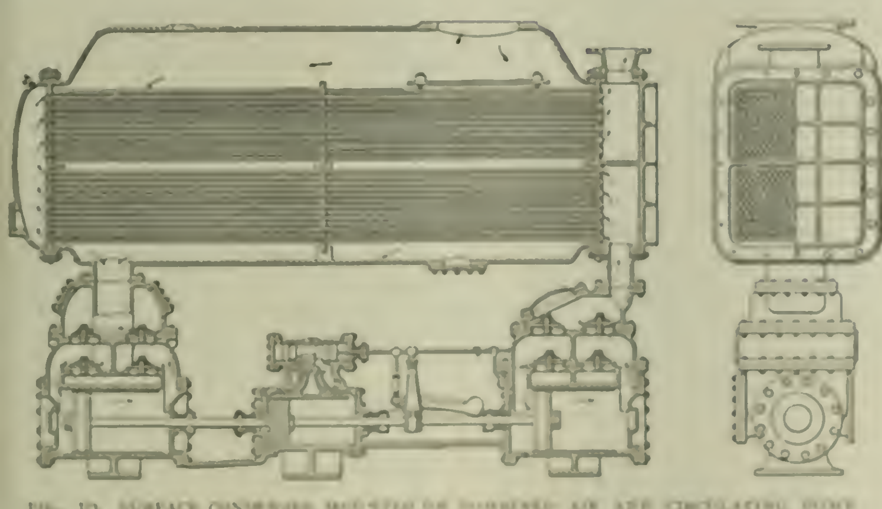

FIG. 10. SURFACE CONDENSER MOUNTED ON COMBINED AIR AND CIRCULATING PUMP

the upper deck of valves or the lower deck was omitted. These pumps were always built with vertical barrels, and for use with the ordinary vacuums of 24 to 26 inches are quite efficient when well designed and kept in proper repair.

The horizontal double-acting type, which had early been developed from the force pump as the bucket pump had from the ordinary house lifting pump, was also popular, especially in the sugar industry where indeed as much progress in condensation had been made as in marine work. This pump with its inclined flap valves and proper design was capable of exceedingly good work. It was also built with horizontal valve decks and vertical lift valves.

Generally the circulating pump was of this design also, and in marine work was uniformly driven from the crosshead along with the air, feed and bilge pumps. In land work the air pump was sometimes driven from the crosshead, but by this period the circulating and feed pumps were always independent where surface condensers were used. Some twenty years earlier, in 1850, Bodmer, the hydraulic engineer, had invented his single-acting valveless air pump, but it had not been largely used. The writer has as yet been unable to find when the horizontal double-acting valveless pump appeared, but it certainly was in use before this period in some few installations.

Such was the surface condenser in 1870. Such it was to remain except for small changes in constructive details. The condenser auxiliaries however had been materially improved. For circulating service the centrifugal pump had been introduced, found its field and was already well in the lead. Edwards and Brown had improved the Bodmer valveless air pump in England and Germany, where it had long been known, and it had been introduced into the United States. Brown had improved the horizontal valveless air pump and its use had spread both to England and the United States, where it has been known as the Bailey pump. The horizontal direct-acting pumps of the Blake, Knowles or Warren types had been developed and made considerable progress in displacing the single-acting bucket type for surface condensing work.

The Advent of the Turbine

With the new century came the introduction of the steam turbine in large sizes and a consequent demand for larger, better and more efficient condensing apparatus. Theoretically the increasing of the vacuum from 24 to 28 inches should decrease the steam consumption by about 15 per cent. With most types of turbine this theoretical increase is very nearly obtained and justifies the importance attached to high vacuums in steam-turbine work. With the reciprocating engine an attempt to approximate this saving would necessitate cylinder ratios greatly in excess of anything that has been employed, with the attendant initial condensation and friction losses. The attempt to utilize a vacuum higher than 26 inches on reciprocating-engine work has always resulted in no increase of commercial economy.

As the larger steam turbines were installed in electric-generating stations where the necessity for economy is always paramount, most of the condenser manufacturers approached the problem in the same way, i.e., by an increase of surface and then, not finding this sufficient, they had recourse to the dry-air pump which had been developed for the vacuum pan and triple effect in the sugar industry and later had been applied to the barometric type of jet condenser. The importance of the entrained air together with the additional air gaining access to the condenser through leaks in the shell and exhaust system, began to be understood and its effect on the efficiency of the condensing surfaces has been studied by many investigators. The difficulties of a few years ago may be better appreciated now that it is known that with a 5000-horsepower condenser, a hole of 1/32 inch diameter through the shell has quite a serious effect on a 28-inch vacuum.

Overcoming Clearance in Air Pump

The original dry-air pump was an air compressor with a rather large compression ratio. These pumps worked very well with compression ratios up to about

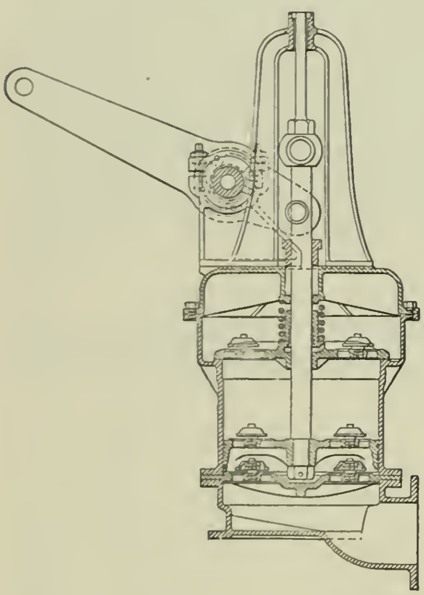

FIG. 11. STANDARD MARINE AIR PUMP

seven, but the clearance must be small. With higher vacuums than 26 inches the clearance becomes troublesome, and Weiss improved the pump by the expedient of bringing both ends of the cylinder into communication at the end of the stroke at the moment of valve closing. This allowed the air at atmospheric pressure in the clearance space to expand into a full cylinder of the air at condenser pressure, but shut off from the condenser, thus saving a portion of it and increasing the efficiency of the pump by that amount. By means of this expedient the pump will maintain a vacuum on a closed shell within 0.3 inch of the barometer without difficulty.

A second way of doing the same thing is by compounding, using a very low compression ratio in the first stage and performing the remainder of the compression to atmosphere with a larger compression ratio in the second stage. This method has not been used as much as the Weiss pump, but is equally as good except for the complication of the second cylinder with its stuffing boxes and the additional chance of air leakage.

Wet-air Pump

Of the pumps for handling both air and water, the Bodmer pump has been very successful in the hands of the American owners of the Edwards patents, and remarkably good results have been obtained by its use. This Bodmer pump has also been materially improved by the addition of a set of valves allowing the air to enter above the piston on its down stroke. This improvement has also been introduced in the Brown pump by Josse in Germany, and the horizontal Bailey pump in America has been adapted to the more efficient work made necessary by the higher vacuums; Tosi in Italy has also improved the valveless pump.

Another type of air pump for use with surface condensers is the Le Blanc pump. In this pump the air is removed by the action of a jet of water in an ejector, a device somewhat similar to the Parsons vacuum augmenter. The Le Blanc pump consists of an ejector of suitable size furnished with a partial-admission centrifugal pump similar to a reversed Girard turbine. The pump blades throw successive layers of water into the diffuser of the ejector, entraining the air between the water laminations as they pass into the ejector. Very good results are claimed for this pump. The Parsons augmenter consists of a steam ejector which pulls the air from the main condenser by the aid of a steam jet, passes it through an auxiliary condenser to condense the steam, and the mixture of water and vapor at perhaps twice or three times the absolute pressure of the main condenser is then removed by an ordinary wet-air pump.

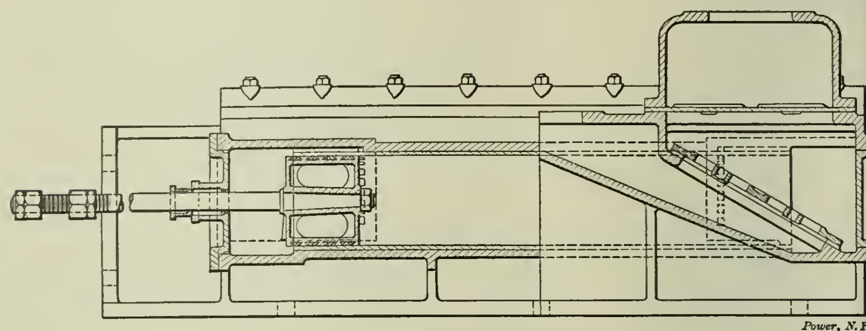

FIG. 12. HOLLIS WET-AIR PUMP

It had been observed that the vacuum fluctuated with the strokes of the air pump, and that this was more marked in those condensers, mainly of the counter-current type, in which the temperature of the hotwell water approached that due to the vacuum. Some condenser manufacturers correct this fluctuation by the addition of a dam or weir around the hotwell pipe, causing the flooding of the lower rows of tubes, thus insuring the cooling of the condensed steam below the vaporization point. Increasing the number of wet-air pumps to two or three of smaller size has also the same effect and has been largely used, but the most efficient and popular expedient is to use a centrifugal wet-air pump. These pumps are small in size, cheap in first cost even when made of bronze, and have been very successful when properly designed and installed. The double-stage pumps were most successful

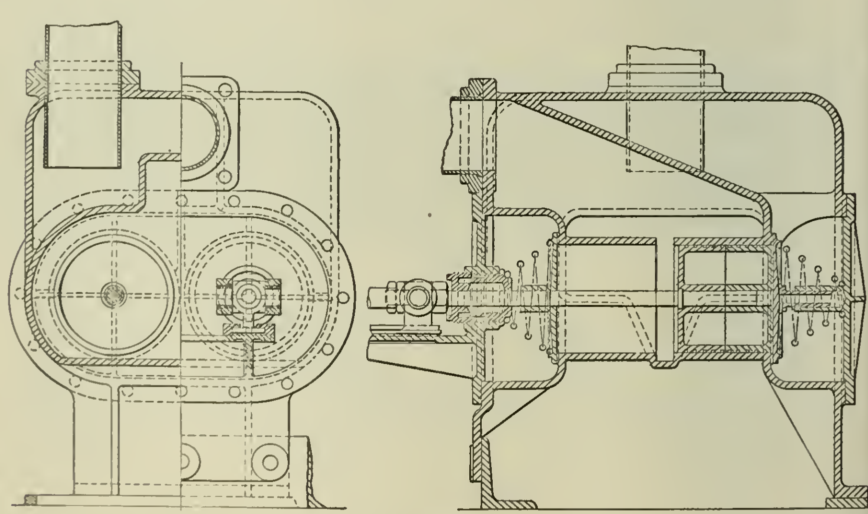

FIG. 13. BAILEY WET-AIR PUMP

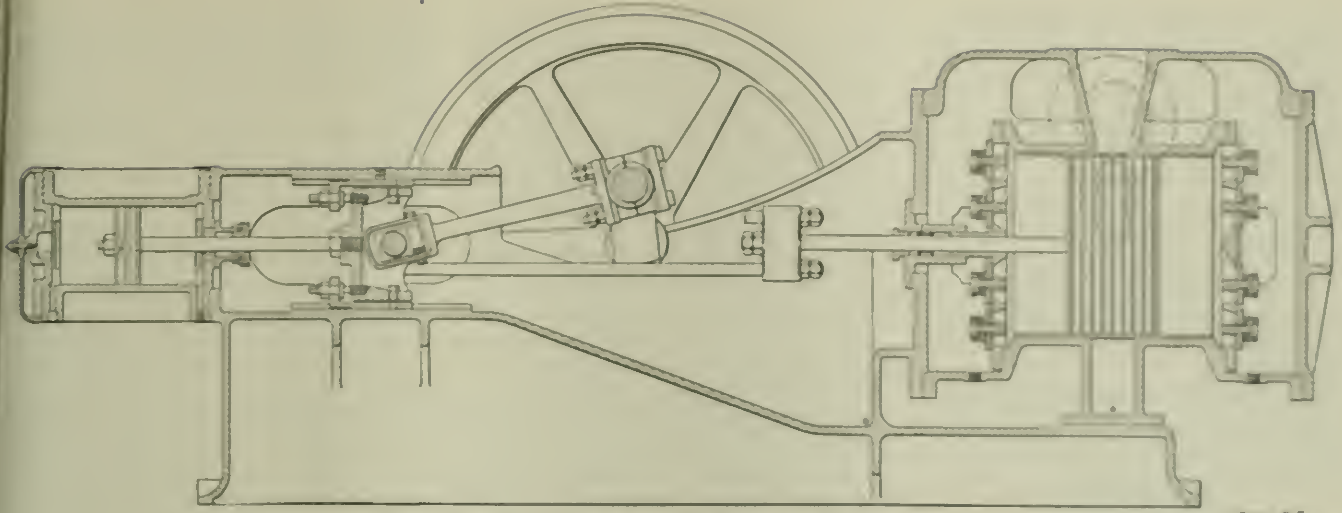

FIG. 14 MULLAN'S SUCTION VALVELESS AIR PUMP

at first, but, as the conditions for successful operation were better understood, the single-stage pump came into use and is equally satisfactory.

For success three conditions must be observed: the pump must be below the bottom of the condenser (no suction lift), the pump and hotwell pipe must contain no pockets for the collection of vapor, and the pump must always be submerged. With these precautions an even water line may be preserved in the condenser or hotwell at all loads within the capacity of the pump.

Small Steam Turbines to Drive Auxiliaries

Condenser auxiliaries for turbine work are always independently driven by engine, motor or steam turbine. Motor drives are not as common as formerly, and the excessive upkeep on high-speed engines is a drawback to their use. The small steam turbine has made a place for itself in this field and, as centrifugal-pump manufacturers have met the exigencies of the occasion by the development of pumps suited to turbine speeds, many of the later installations are provided with turbine drives for the circulating and hotwell pumps. The Le Blanc dry vacuum pump so far is the only pump for this service susceptible to a turbine drive, but without doubt others will be developed to meet the demand.

Factors Influencing Surface Efficiency

Notwithstanding the rapid and great improvement in condenser auxiliaries, the efficiency of the condenser itself was still quite low. The tendency was to increase the tube surface in the hope of getting a better vacuum. Since Rankine's time it had been known that 40 to 50 pounds of steam may be condensed per

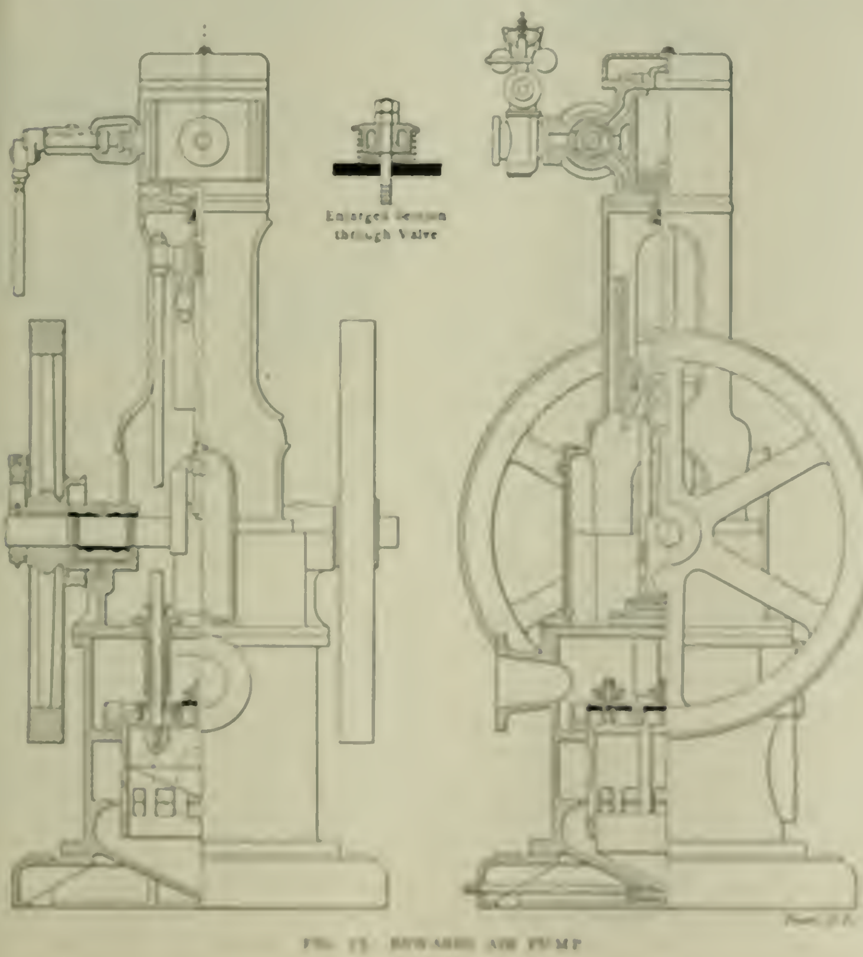

FIG. 15. EDWARDS AIR PUMP

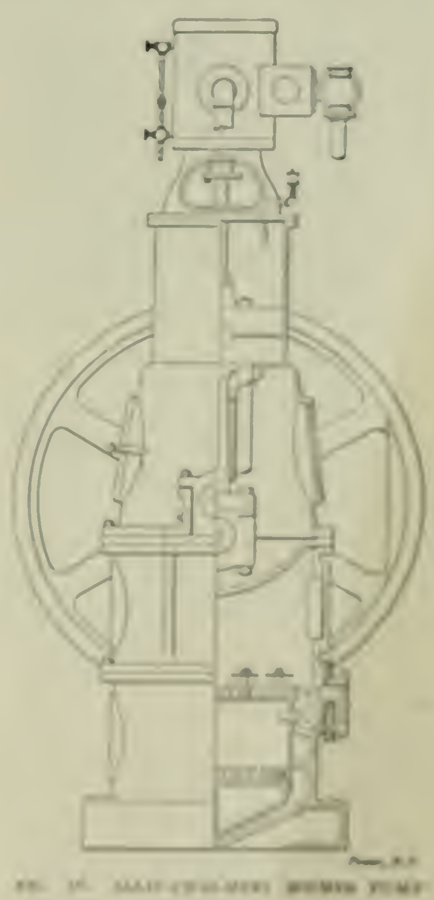

FIG. 16. ALLIS-CHALMERS [illegible] PUMP

hour per square foot of surface under condenser conditions, if proper arrangements are made, and in the face of this fact six pounds per hour was considered good practice with eight as a maximum. Purchasers were also in error in that they frequently specified the surface they required instead of the work to be done. In 1900 there were almost no condensers in which the heat-transmission coefficient U (B.t.u. transmitted per square foot per degree difference per hour) exceeded 300. In 1904 there were very few in which it reached 400.

The increasing difficulties and cost of maintenance of condenser tubes made the question of efficiency a subject of the

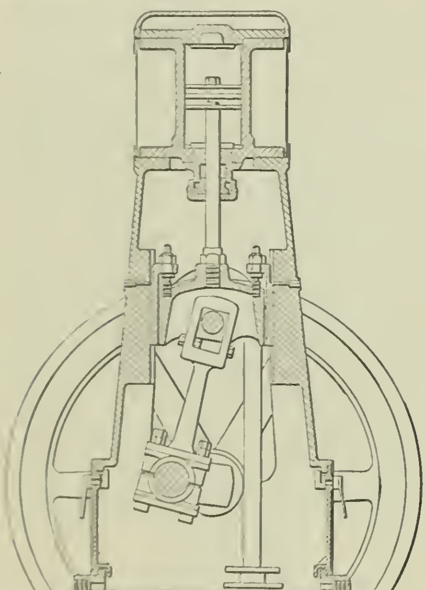

FIG. 17. MULLAN'S VERTICAL AIR PUMP

first importance. A 6000-horsepower engine usually had a condenser with about 9000 feet of tube surface and carried a vacuum of 26 inches. As these large installations are nearly always near the seacoast and use salt water for condensing, the deterioration of condenser tubes and consequent replacement, although a serious matter, was not a very costly one. The leakage of salt water into the condenser was not troublesome, as the condensed steam contained oil and was thrown away. But a 10,000-horsepower turbine with 25,000 square feet of tube surface was a more serious affair, particularly as 28 inches, or greater, vacuum must be carried with practically no leakage and the condensed water used for feed, this necessitating a much more frequent replacement of tubes. At the present time three years may be taken as the average life of condenser tubes, and in the condenser quoted above, about 8000 square feet of tube surface would be replaced every year. Such a condenser might have, say, 6000 tubes, and as Sunday is the only available time for maintenance work of this kind, an average of 40 tubes would have to be replaced each week when the water boxes were opened for cleaning. The question of tube deterioration has been investigated many times and the action proved to be chemical or electrochemical, but no satisfactory remedy has been found. Alloys approximating the "Admiralty" mixture of 70 parts copper, 29 parts zinc and 1 part tin, have refuse; third, flooding of the lower row of tubes with the water of condensation; fourth, the accumulation of air in the condenser drowning those tubes with which it is in contact. The second and third factors may be corrected by the designer, the first will not obtain if there is no oil in the exhaust steam, and the fourth concerns both the designer and builder. Careful workmanship and erection will reduce the air leakage to minimum limits and modifications of design have solved the air problem satisfactorily.

Among the most successful of these methods are the results of the experiments of Weighton and Morison which are illustrated herewith. The condenser has a circular or rectangular tube plate, the shell containing baffle or drainage plates which carry the condensed steam to the shell as quickly as possible and at

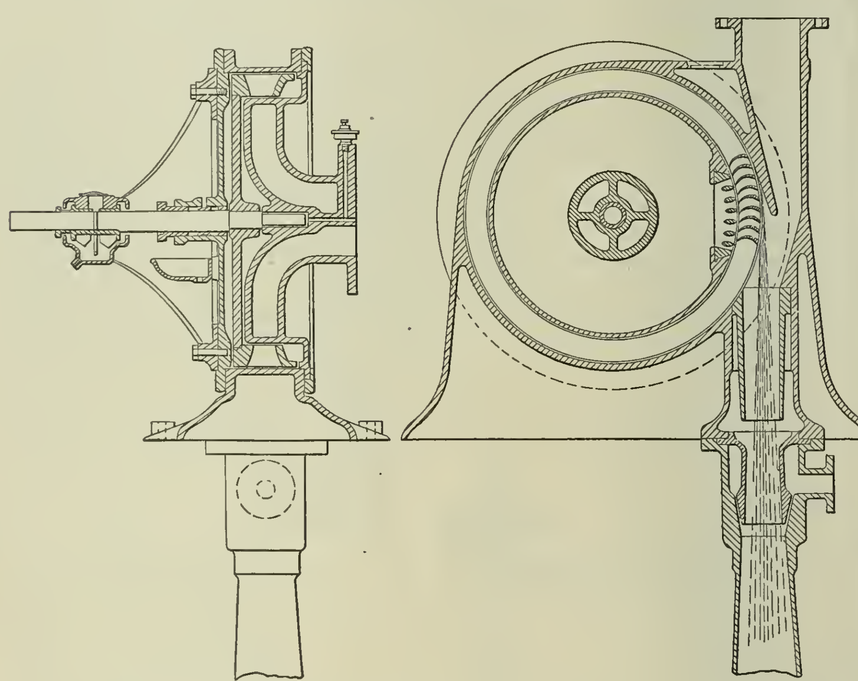

FIG. 18. THE LE BLANC AIR PUMP

been most successful when salt water is used for cooling.

These considerations have led to the investigation of surface efficiency, and many noteworthy experiments have been made leading to the increasing of heat transmission by a better distribution of the steam to the tube surface, a more rapid rate of flow of the condensing water and a more complete removal of the entrained air.

Maximum surface efficiency should occur when the tube surface is open in the most free and unrestrained fashion to the access of steam on the one side and the cooling water on the other. The factors influencing this freedom of access are, first, oily or greasy deposits on the steam side of the tubes; second, the choking of the water passages through the tubes with dirt, paper, straw or other

the same time control the direction of steam flow. The condensed steam is not allowed to collect on the tubes nor flow over more than a few rows before being led to the inner surface of the shell.

At the bottom of the condenser where the air must accumulate, a nest of tubes is set apart as a water cooler, the water level on the steam side of the tubes being held constant by a "dam" similar to that illustrated. The hotwell water is removed by an Edwards pump whose suction is taken off just above the lowest baffle plate or partition, and as the temperature of this hotwell water is very close to the vacuum temperature, the pump handles very little air. As the water collects in the lowest tube bank, it is cooled below the vacuum temperature and cools the air in contact with it. Another larger pump exhausts the cool air from this chamber nd also the excess water which flows into the pump suction over the dam. The discharge of the second pump is into a hotwell provided with a float actuating two valves, one of which allows a portion of the water to return to the cooling chamber; the other is connected to the inlet steam nozzle of the condenser and allows the excess to go through the condenser again, where it is warmed to the vacuum temperature and removed by the hotwell pump. A triplex Edwards pump is generally used, one cylinder acting as the hotwell pump and the other two as the air pump. It should be noted that the principle is similar to that of the Parsons vacuum augmenter, the auxiliary condenser being in the main shell and the lower temperature cooling the air to the proper point.

The draining of the condensed steam from the condensing surface has been a most successful way of improving the heat transference, and many of the later condensers have been designed with this in view.

In the August 11, 1908, number of Power and The Engineer, the writer summarized in brief the experimental work which had been done in the line of improving the surface condenser. The diagram showing heat transference under varying conditions gave the work of six investigators, and with these curves another was plotted from the formula

$$U = 17\sqrt{V_s} \cdot \sqrt{0.023 + V_w},$$

where

V_s = Velocity of steam in the condenser, usually taken as 625 feet per second,

V_w = Velocity of the cooling water in the condenser tubes.

The formula was taken from Hausbrand with modified constants to suit the results of the experiments, and quite a number of condensers have been designed on this basis. In service they have proved successful, showing heat transferences about as given by the formula.

The experiments of Professor Josse, published February 2, 1909, show even better results, and it may be that the constant 17 should be 20 or possibly 25. A chart adding Josse's curves to mine may be found on page 418, March 2, 1909, number of Power and The Engineer.

The "dry-tube" condensers shown in the accompanying illustrations are examples of the best modern design, and it is not too much to say that a value of U exceeding 800 may be obtained by good design with vacuums of 28 inches. It should be remarked that condensers seldom are tested to the limit of steam condensation, and the loss of vacuum is usually due to imperfect hotwell or dry-air pump arrangements, air leaks in the exhaust system, lack of sufficient condensing water, condensing water of too high a temperature or to failures of the circulating system due to dirt or rubbish accumulating in the tubes.

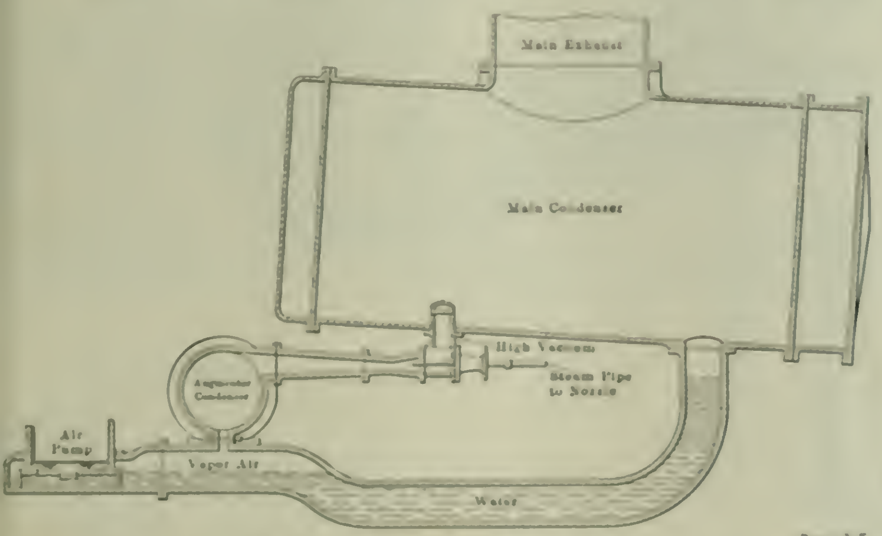

FIG. 19. PARSONS VACUUM AUGMENTER

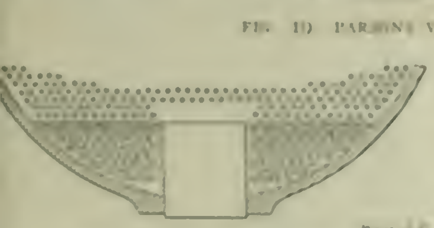

FIG. 20. THE ALLEN WEIR

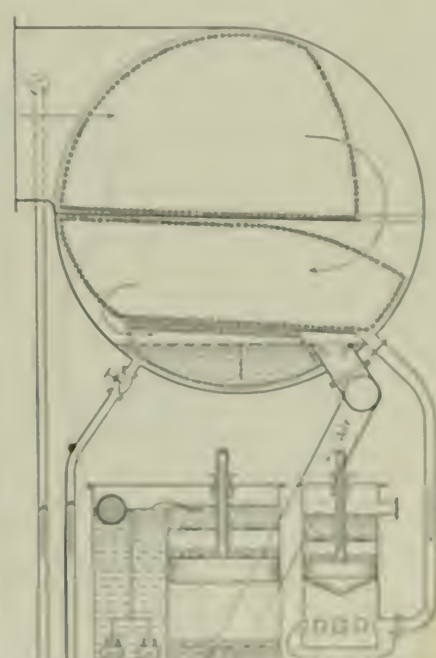

FIG. 21. WHEELER'S CONDENSER

CONDENSER DESIGN

In designing a condenser the following details should be considered:

Exhaust-steam System

The exhaust nozzle should be such a size that the steam velocity, computed upon the full weight at the volume due to the condenser pressure, should be around 600 to 700 feet per second.

The exhaust steam should enter from the top of the shell.

The shell should not be more than twice as long as the mouth of the exhaust nozzle where it enters the shell.

Sufficient steam space should be provided above the tubes to insure the entrance of the steam between the tubes throughout the whole length of the condenser.

Steam passages should be provided down through the body of the tubes so that every square foot of surface may be exposed to the steam flow.

Sufficient draining arrangements are required to prevent a film of water remaining around each tube.

A portion of the tubes near the hotwell and at the end of the steam travel should be protected from the water of condensation so that they may act as an air cooler.

A hotwell should be provided with a surface half as large as the exhaust nozzle area. The depth of the hotwell is not important but should be at least 18 inches.

The dry-air connection should be taken off about 3 feet above the hotwell water level, although 18 inches is usually successful.

The hotwell pump should be placed as close to the hotwell as possible with a direct connection and at least 3 feet below the hotwell water level.

Water Circulating System

Water should enter the condenser at the bottom and leave at the top. The lower edge of the discharge nozzle should be higher than the top of the upper tier of tubes to insure that the tubes will be full of water at all times. The circulating pump suction pipe should be large enough so that at maximum output the water velocity shall not exceed 10 feet per second and about 8 feet per second at normal output. The connection to the water box may be smaller and allow a flow of, say, 14 feet per second for maximum velocity.

Tubes may be of 1 inch outside diameter, never smaller in the neighborhood of large cities with salt water for cooling. With good clean water, fresh or salt, ¾- and ⅝-inch tubes may be economical.

water while properly holding the tubes.

The discharge pipe should be small enough to run full even when vertical, with 15 feet per second as maximum velocity.

A connection should be provided between the water box and the steam space and fitted with a valve so that the pump may be primed by the dry-vacuum-pump.

Condenser Shell

The shell should be tested by filling

that the water passage may be dry whe[n] not in use.

Gages and Thermometers

A final word may not be amiss regar[d]ing gages and thermometers. Vacuu[m] gages of the Bourdon variety are not[o]riously erratic. Use a good mercury co[l]umn of full length. A good thermomete[r] with a deep-winged well carried into th[e] center of the exhaust nozzle, with a me[r]cury column properly connected so as no[t]

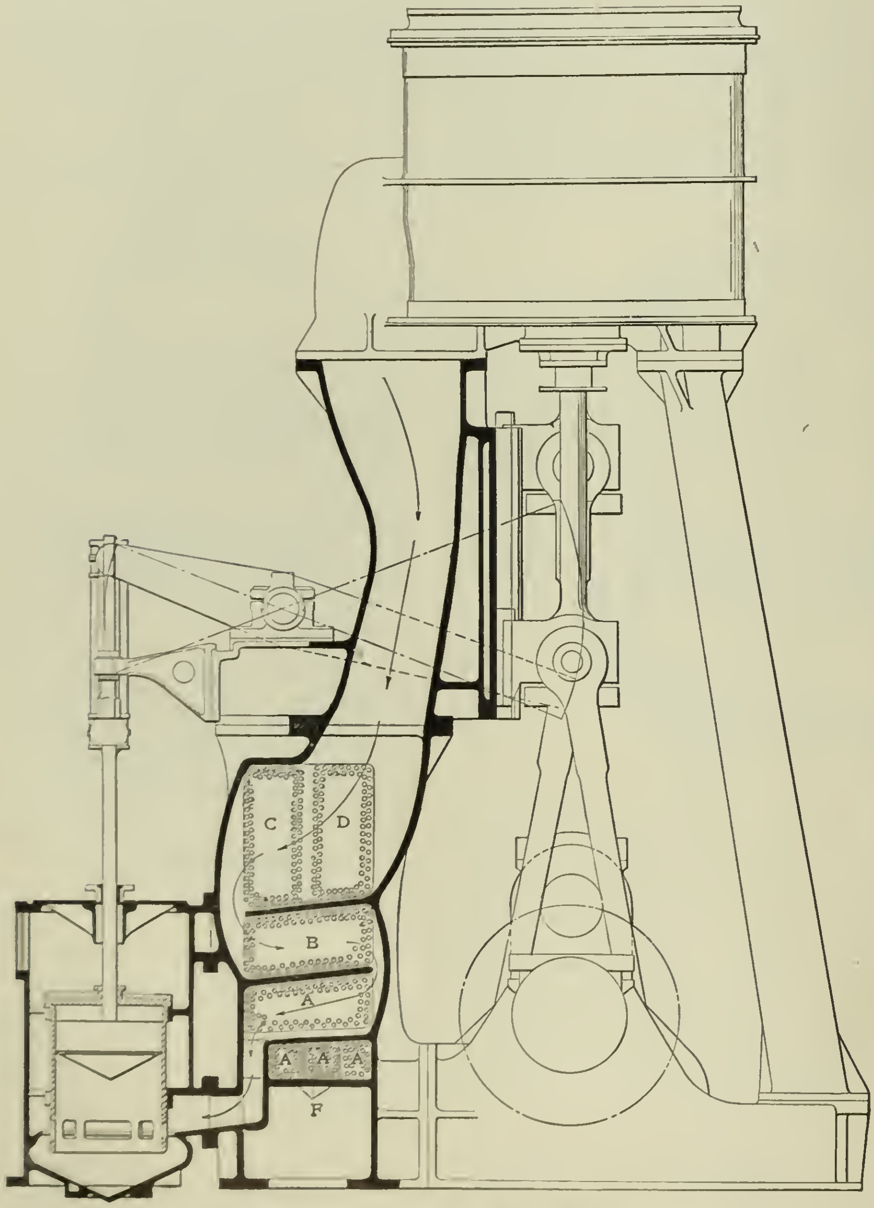

FIG. 22. WEIGHTON'S MARINE CONDENSER

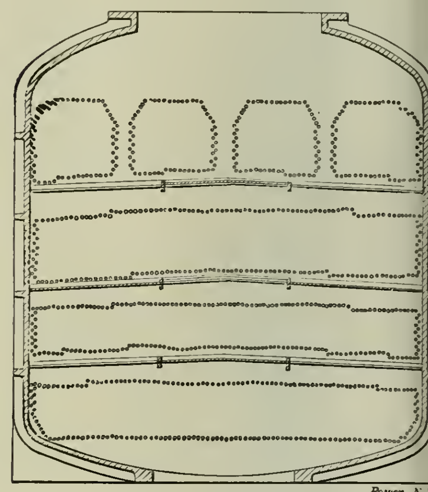

FIG. 23. WHEELER DRY-TUBE CONDENSER

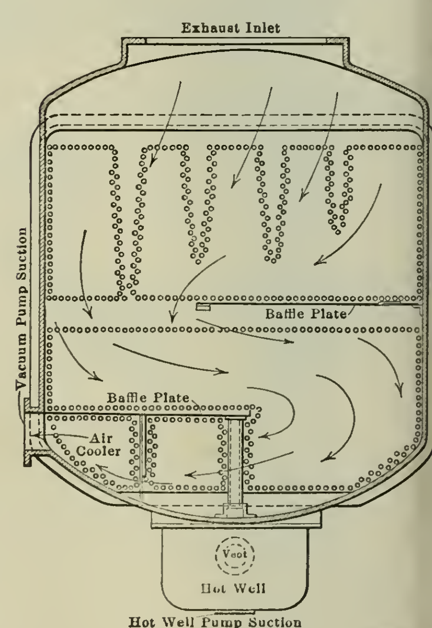

FIG. 24. WORTHINGTON IMPROVED TUBE PLATE

Tubes larger than 1 inch are rarely economical. Water velocities in the tubes should always exceed 4 feet per second, with 8 or 9 feet per second as a maximum. The length of tube and the number of water passes should be determined for each case from theoretical considerations.

Tube glands should be of such form as to add little obstruction to the flow of

with water under a head of 30 feet above the top.

The shell should be strong enough to stand a collapsing pressure of 10 pounds gage.

When in place the tubes should slope toward the pump end sufficiently to drain the tubes, and a ¼-inch hole should be drilled in each water-box partition so

to add the steam velocity head to the vacuum, will be the best index of the air leaks. Thermometers should also be placed in the circulating suction and discharge pipes, in the hotwell and the dry-air suction, and a second mercury column on the hotwell. With these instruments a very good idea may be obtained of what is going on inside the condenser.

A High-Pressure Turbine Operating at 30 Pounds Gage

It is not very often that a high-pressure turbine is required to operate at 30 pounds gage. This pressure, or slightly higher, is commonly used for ferry and river boats, and the "Robert Fulton," one of the new boats now being built for the Albany Day Line, is no exception to the rule. All machinery must, of course, be adapted to this pressure, and when it came to installing a ballast pump, the unit shown in Fig. 1 was chosen. This consists of a Terry turbine, of the same general design as the high-pressure machines, direct-connected to a 6-inch Alberger volute pump running at a speed of 1800 revolutions per minute. The duty of the outfit is to pump water from the river to either one of two ballast tanks of about 11,000 gallons capacity located on either side of the vessel.

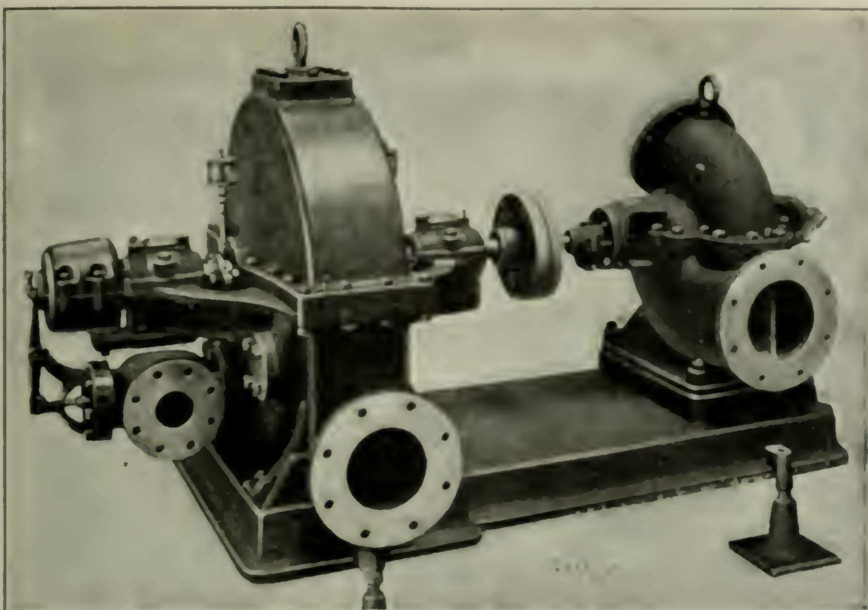

FIG. 1. TURBO PUMPING OUTFIT FOR THE "ROBERT FULTON"

When landing, passengers all move to one side of the vessel, and to keep an even keel, it is necessary to pump water in the ballast tank on the opposite side from the dock. This, of course, requires a large amount of water in a short period of time, and the pumping unit illustrated is guaranteed to deliver 1000 gallons of water per minute against a 25-foot head with the steam pressure as low as 20 pounds. Its range of operation is between 20 and 35 pounds gage. It is further guaranteed that after standing an hour, the turbine will clear itself of water and the 9-inch exhaust pipe rising to a height of 9 feet and will be running at full speed at a time not exceeding 30 seconds after the throttle is opened, and this without opening any drains to remove the condensation. The outfit is located in an inaccessible place in the hold and is controlled by a lever throttle valve at some distance from the turbine.

The construction of the turbine is shown to better advantage in Fig. 2, a sectional view showing the usual design, which is of the Reidler-Stumpf type. The jets of steam from the nozzles impinge tangentially on the buckets of the runner, and the steam is reversed by stationary guide buckets to be several times redirected upon the buckets of the same runner. The stationary buckets are mounted in the casing of the turbine in groups of four, and each group is supplied by a divergent nozzle, designed for a complete expansion of the steam between the initial pressure and the pressure of the medium in the case. With this subdivision of the process of abstracting the energy of the steam, the peripheral velocity of the runner may be kept down to reasonable limits and in the present case, with a speed of 1800 revolutions per minute and a single runner 2 feet in diameter, amounts to less than 200 feet per second.

FIG. 2. SECTION THROUGH TERRY TURBINE

With such a low steam pressure and a corresponding velocity of the steam, due to the less expansion, it was necessary to use a turbine which would ordinarily be rated at about 30 horsepower, and instead of using two nozzles, which is the number usually provided for this size, the turbine was equipped with four nozzles; the throat of the nozzle was also enlarged, and its shape changed to suit the conditions. These were the only changes necessary, and the turbine under existing conditions is capable of developing about 12 horsepower.

Before landing, it is usual to run the pump for about 8 minutes, which would mean 8000 gallons of water or over 60,000 pounds, and would be equivalent to the weight of nearly 500 passengers. The engineer, with his hand on the lever controlling the throttle valve, watches the telltale showing the list of the vessel, and to keep an even keel starts or stops the turbine as required.

On the "Hendrick Hudson," a boat of the same line, a similar outfit is installed, with the exception that the turbine operates on a steam pressure of 100 pounds. It is claimed to be giving the best of satisfaction, and as soon as the present installation is complete and in working order, it will be of interest to note its performance on a pressure as low as 30 pounds gage.

Supernatural Visitation of James Watt

How He Worked Out the Secret of Running an Engine Condensing; His Claim to Be the Father of the Rotary Engine Idea Substantiated

BY WARREN O. ROGERS

I have been considerably gratified by the recent publicity given the wonderful achievement of a photographer who succeeded in photographing a spirit from the other world. The photograph was published in a number of the leading papers of the country and, although the likeness resembled a potato, it is proof to some of us that spirits do surround us. I mention this merely to point out to those who are still skeptical regarding James Watt's visits to me that others have received supernatural visitations.

My third visit from James Watt was during one of the coldest nights last winter. I had settled down for a confortable evening with my books and, under the soothing influences of a "Perfecto" was rapidly forgetting the weariness of the day's toil. After a while I became drowsy; the half-consumed cigar fell from my fingers and I slept. How long I slept I know not, neither does it matter. When I awoke, it was with a start, as if my slumbers had been disturbed by some unusual noise. The room had grown icy and I could hear the house crack with the extreme cold. Other than this, not a sound broke the stillness of the night, except the occasional moaning of the wind as it was caught in an angle of the house and then whirled away.

Suddenly the silence was broken by a sound, as if the furnace door of the heating boiler in the basement had been opened forcibly, followed by the shaking of the grate, the unmistakable rattle of a shovel in the coal bin and the clanging of the furnace door, as it was slammed to. I listened in amazement. What could it be? Surely nothing mortal, for the doors and windows had been locked for hours. And certainly not a spirit, for a spirit would care little for fire or heat What, then?

As I remained motionless in my wonderment, the basement door creaked on its hinges, the click of the latch sounded and all was quiet again. As I arose to investigate, the portieres parted and James Watt stood before me, his phantom figure standing out against the curtain background. We shook hands, and with a sigh of intense relief I said:

"What in this world or the other possessed you to fire up that boiler?"

"Well," replied James, as he removed his mittens from his bony hands and carefully put them in his coat pocket, "from the feeling of this room the fire required attention. You make me think of that poem I wrote some years ago, 'Asleep at His Post,' or something like that. That is a strange kind of coal you use," went on James, as he removed his low-cut shoes and placed his transparent feet against the radiator; "has it been frozen, or what?"

"Oh no," I replied with a laugh. "That is a kind of coal known as anthracite. It is used extensively in the eastern States, burns without smoke and gives off considerable gas, which burns with a blue flame, something like brimstone."

"Ah!" said James, half to himself, "I knew there was something familiar about it—blue flame, brimstone—why, yes, of course."

As James thus soliquized he took a cigar and then remarked:

"This is the kind of a night no honest man should be abroad;" and he lit his cigar and began smoking in a manner that would put even the infernal regions to shame, I thought; "but I got lonesome, and having got into another circle, where I have greater liberty, I decided to come and talk with a fellow craftsman for a while."

James looked discontentedly at the table, on which reposed nothing but a few books, and rolled his tongue as if his lips were dry.

"Not tonight," said I.

James began to sulk.

"You had too much the last time you were here," I continued. "Tell me about your first attempt at running a condensing engine."

"All right," responded James, at once brightening up, and saying confidentially: "I *was* kind of soused wasn't I?

"My first condensing engine, as I told you at my last visit, was one of old Newk's model. Now, as you know, his idea wasn't worth a frozen tinker when applied as he had it. The idea of condensing the steam was all right, but it required a head to work the problem out so as to apply it to practical purposes. That is the way with a good many things nowadays, I fancy," and James nodded in a self-complacent manner as if he had a notion he could set a good many wrong ideas right if he only had the opportunity. As I thought of his achievements I felt that such a possibility would not be at all unlikely. Seeing that James was apt to become absorbed in meditation, I cleared my throat in order to attract his attention, whereupon he continued:

"Of course, you know that it was the hight of nonsense to put steam into an engine cylinder, turn in cold water and expect to get any economy. In those days we hadn't paid much attention to the conservation of natural resources, which you Americans seem to be making so much ado about. But I could see that if steam engines were to be a success, a different means of condensing the steam would have to be utilized."

"Not a very brainy conclusion," I said, just to "egg" James on; "but anyone could see that the idea was not brought out by Newcomen's method of condensing."

At this James straightened up with a gasp of surprise. "Brainy!" he roared, in his hollow grave-like tones; "Brainy! why, man, you may not think so, now that the problem of condensing steam has been solved. You just stop and think a moment and see if it wasn't brainy. Think of all the great engineers who have followed me; each and every one with the best of machinery and every facility for doing good work. And what do you see? What do you see?"

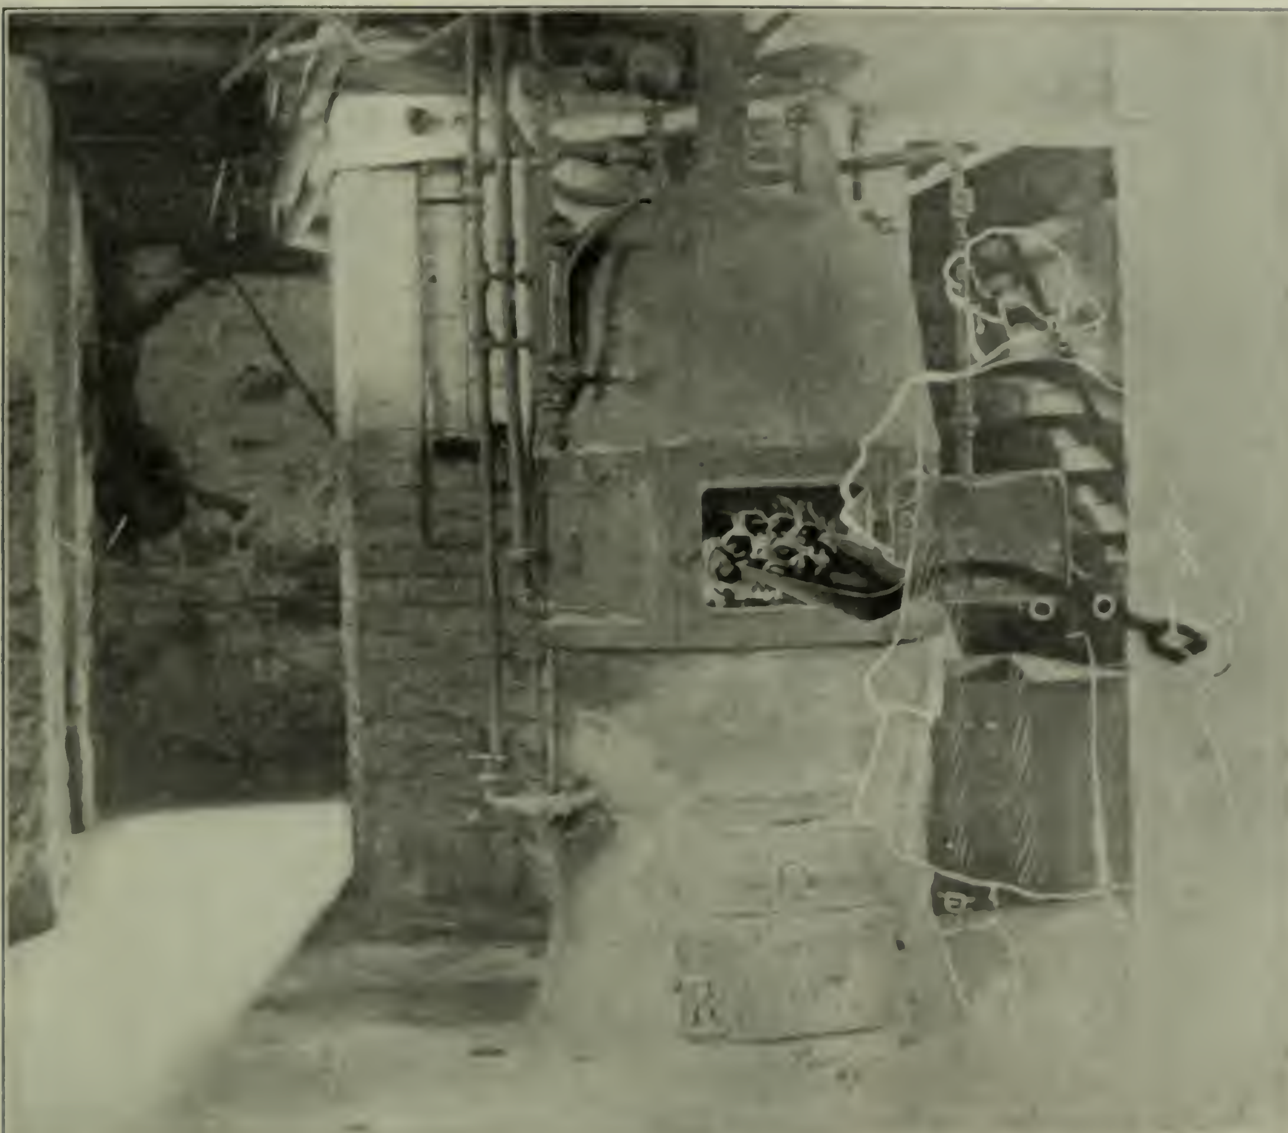
In his excitement James arose from his chair and cut the air with his fleshless arms, as he emphasized each word. His gumless teeth clicked together and a blue smoke that smelled like burning brimstone issued from his nostrils. The violence of James' resentment to my remarks regarding his thinking power alarmed me so much that I feared he might burst a blood vessel. Therefore, I assured James I had no intention of belittling his intelligence, but merely wanted to stir him up a little.

"Well," grumbled James in a mollified tone, "don't do it again. I am touchy about such things. The condenser has been improved somewhat since my day, but the idea is there, and if my patent hadn't run out I would prosecute every mother's son who is using the idea."

"That wouldn't do you any good," I replied; "it takes money to carry on a lawsuit. It wouldn't matter so much whether you were in the right or wrong, the party having the best lawyer would get the decision in the end."

"Yes, I know you are right," responded James. "I met some lawyers the other day, who were rather sociable chaps and told me considerable about the ways of making others believe that black was white, and that when you did, you didn't. St. Peter was for giving them a pass to the darker regions, but they began to argue the case in their peculiar jargon that nobody understood, and in less than half an hour had St. Peter so befuddled that he admitted it would take at least thirty years to decide their case. Then, I suppose, they will appeal his decision if it goes against them. If I had had such lawyers when I needed them, I finally came to the conclusion that I would about hit the nail on the head if I made a separate vessel and let the exhaust steam enter that to be condensed. I planned the thing out and had the condenser made according to my ideas. The first or second trial did not bring success, however; but I finally got the matter fixed so that the condenser was under the engine cylinder, with a very short connection between the two."

"What kind of a condenser did you first



THE SILENCE WAS BROKEN BY THE UNMISTAKABLE RATTLE OF THE COAL SHOVEL AND THE CLANG OF THE FURNACE DOOR.

I should have had money enough to invent things that would have made your engineers of today sit up and take notice."

"I don't doubt it," I replied in as conciliatory a tone as I could, as I saw the hair on James' head begin to rise. "It has always been a matter of wonderment to me how you carried out your many ideas in the manner you did. But go on about your condenser."

"Well," went on James, "I used to take my pipe and go out to some quiet place and sit down and smoke and think. experiment with," I asked as I passed the cigars, "a jet or surface?"

"Well, it was both; only it wasn't and it was. You see, I submerged the condenser body in a tank of water, so in a sense it was a surface condenser, seeing that the outer surface was acted on by the water surrounding it. Just how much steam was condensed by this means, I cannot say. The main feature of the condenser, however, was the jet, which condensed the greater portion of the steam. This jet was supplied with water from the tank, which was supplied by means of a pump connected with the beam of the engine. The condensed steam, injection water and air were removed from the condenser, through a foot valve, by means of an air pump and delivered to a hotwell. A boiler feed pump was piped to the hotwell and the water fed to the boiler. I calculate things haven't changed much since then, from what I can learn from new arrivals in our circle."

I was forced to admit that the idea of Watt had not changed materially, but did not say so, for James seemed to be developing a bump of self-admiration which was not doing him the least particle of good. Therefore, I said:

"Why, the condenser found in use today has no more resemblance to your condenser than the infernal regions has to a winter one. Condensers are now made not only with the aim of condensing the exhaust steam, but of maintaining a vacuum of not less than 26 inches for reciprocating engines and as high as now sible with steam turbines. Now, your condenser would be about as much use to a turbine as a dead skunk would be to a perfume manufacturer."

James did not like the observation, as I could see by the darkening brow and the way he bit his lip. But he mastered his feelings and said, in as natural a tone as possible:

"What do you mean by turbines? Is it a rotary engine? If that is what you are talking about, I want to tell you that I had a hand in that kind of a prime mover myself."

"You did!" I exclaimed in amazement, for James spoke seriously, and this was an assertion entirely out of the beaten path of claims for Watt.

"You can bet I did," was the emphatic reply. "I was going to apply the idea to my fire engine, making the connections to the rear wheels, but concluded I was altogether too far ahead of my time, and so I let it drop. Another reason was that the machine shops could not do the proper kind of work necessary for rotary engines. If they could, I would have had automobiles running over and killing people years ago."

I was fast learning that James made a grab for everything that belonged to him, but when it came to claiming to be the real originator of the automobile I concluded that it was about time to call him to account. Therefore, I said:

"Why, you can't lay claim to inventing the automobile, as well as rotary engines. Suppose you did, how did you arrange matters so as to regulate the speed of the machine?"

"The easiest thing in the world," replied Watt. "I designed the kind of interlocking gearing from the two different axles, so as to make the machine go fast or slow as I wanted it to. I did this by regulating the power applied to the shaft. That is about what they do today isn't it?" asked James, with a slight sneer on his ghostly features.

For some time I sat meditating upon the wonderful ability of Watt in the flesh, then, turning to ask a question, I found that I was alone once more.

Yasuzo Wadagaki, a Japanese engineer, read before the Northeast Coast Institution of Engineers and Ship Builders at Newcastle-upon-Tyne, recently, a paper on the "Adaptation of Steam Turbines for the Propulsion of Vessels of Moderate Speeds," in which he proposed two startling methods: (1) The putting of the propeller in the throat of a tube flaring in both directions so that the water at the throat would have a greater velocity relative to that of the ship and allow a faster running propeller to be used with efficiency, and (2) the use of a low-pressure turbine to compress the steam to a higher initial pressure and temperature before passing to the main engine.

Catechism of Electricity

Typical Forms of Direct-Current Generators

1058. *Are bipolar direct-current generators manufactured now?*

Yes; they are still being manufactured for small outputs. For outputs much above two kilowatts, multipolar generators have replaced them.

1059. *Illustrate and describe a bipolar generator as now manufactured.*

Fig. 290 shows a belt-driven bipolar machine which is made in capacities from ¾ to 1¾ kilowatts and wound to give 125 or 250 volts. The frame and magnet poles are cast in a single piece of gray iron. Fig. 291 shows the separate parts of the machine. The bearings are supported by arms *c*, *c*, etc., cast solid with the frame. The arms terminate in rings *m*, that are bored out at the same time and to the same diameter as the field-magnet poles *n* and *s* in order to provide seats for the circular bearing housings *b*. The armature *t* can be taken out by removing the four bolts which hold the rear housing. The circular bearing housings can be rotated to keep the oil wells under the bearings when the machine is mounted on a wall or ceiling.

The bearings are of the self-oiling ring type. Oil brought up from the wells by the rings is distributed by oil grooves to every part of the bearing. Covered openings are provided in the sides of the housings for inspecting the bearings and refilling the oil wells.

The field-magnet coils *h* and *l* are composed of cotton-covered wire, machine-wound on forms and then impregnated with insulating compound. They are protected by several layers of heavy tape and are held in place on the poles by clamping pieces.

The armature is of the drum type with slots to take winding, which is held in the slots by fiber wedges and by wire bands over the projecting end of the coils; no bands are used over the cores. The core laminations are punched from thin sheet steel and are assembled directly on the shaft and clamped between stiff

FIG. 290. WESTINGHOUSE BIPOLAR GENERATOR

end plates, one resting against a shoulder on the shaft and the other held by a nut on the shaft.

The commutator is made of hard-drawn copper bars separated by insulating strips of mica. The bars and insulation are assembled on bushings and clamped between V-shaped rings, from which it is insulated by mica; the clamping rings are set up after the commutator has been heated to a high temperature and while it is still hot, so as to hold every bar firmly in place. The complete commutator is pressed onto the shaft and pinned. The commutator leads are protected by tough canvas coverings and the ends are soldered into slotted projections on the bars.

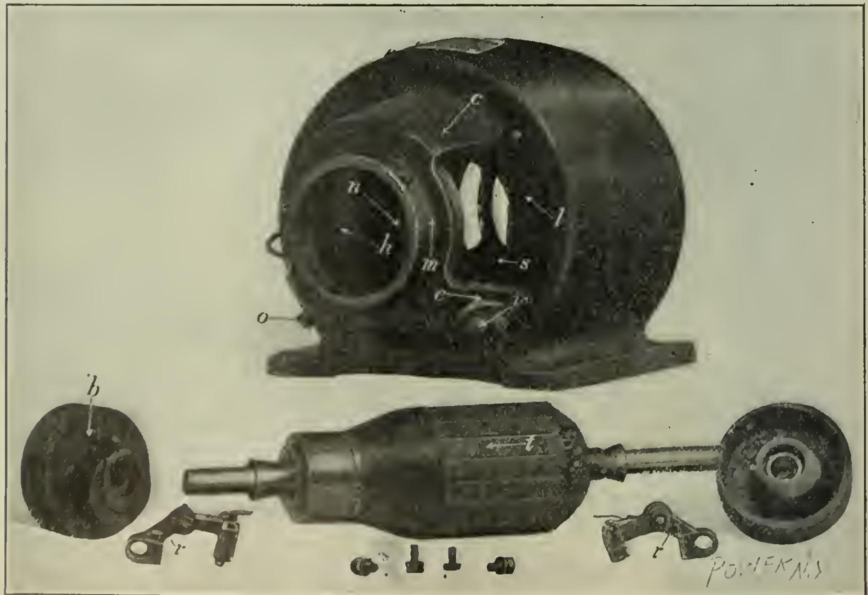


FIG. 291. PARTS OF THE BIPOLAR GENERATOR SHOWN IN FIG. 290

The rods on which the brush holders are clamped are supported by cast-iron rocker rings which are held rigidly against a machined surface on the front bearing bracket by set screws. The brush holders *r* are of the simple box type and the brushes are carbon blocks pressed radially against the commutator by flat spiral springs. The terminal wires are brought

FIG. 292. WESTINGHOUSE MULTIPOLAR GENERATOR

to binding posts *o* and *c* on the two lower arms supporting the front bearing.

1060. *Show a multipolar machine of the same type shown in Fig. 290.*

A four pole generator for outputs from 2 to 7½ kilowatts at 125 or 250 volts is shown in Figs. 292 and 293, the former illustration showing the machine assembled and the latter the separate parts. The magnet poles are cast with the frame and the field-magnet coils fastened to them as in the bipolar machine. The bearing brackets *a* and *c* are separate castings and are held to the frame by four equally spaced bolts. The armature *m* is built up in much the same way as before, but the stampings forming the core, being larger, are keyed to the shaft; ventilating ducts in the core and openings through the spider afford paths for cooling air currents. The armature coils are wound and shaped before being placed in the slots and the commutator, instead of being mounted on the shaft, is pressed on an extension of the armature spider and keyed to it. The rocker ring *s* is clamped over a machined seat on the inside of the front bearing bracket so that the brushes can be moved around the commutator.

The terminal wires *e* and *n* are brought out through an insulating bushing *o* in the side of the frame. As shown at *h*, a bedplate, equipped with belt tension adjusting screws *l* and *t*, is supplied with the generator.

The Gas Engine in Blast Furnace Practice

By George A. Orrok

The modern American blast furnace is the most perfect gas producer. These furnaces are 100 feet high from the hearth to the stack line, 17 feet in internal diameter at the top, 24 feet in diameter at the base, with a hearth 10 feet high by 14 feet in diameter, the volume being about 25,000 cubic feet. Such a blast furnace, when running well, produces about 600 tons of pig iron each twenty-four hours and uses 1100 tons of 58 per cent. iron ore, 500 tons of coke, 200 tons of limestone and over 2000 tons of air. The gases discharged from the furnace amount to more than 3000 tons per day, or about 4,000,000 cubic feet per hour. About 30 per cent. of this gas is used in the hot stoves to heat the blast, 7½ per cent. is burned under the boilers to make the steam needed around the plant and about 2½ per cent. is used in the washers and scrubbers, leaving 60 per cent., or 2,400,000 cubic feet per hour, available for power purposes. The gas-driven blowing engines use about 15 per cent. more, leaving 1,800,000 cubic feet per hour available for the electric-generating plant. Assuming the gas to contain 80 B.t.u. per cubic foot and that 10,000 B.t.u. are required per horsepower-hour, 14,400 horsepower may be secured from the electric plant.

A 3000-Horsepower Gas Engine Pumping Station to be Installed for Fire Service in Philadelphia

By J. R. Bibbins

During March an important contract was closed by the city of Philadelphia for the equipment of a new high-pressure fire-service station, practically a duplicate of the Delaware avenue fire station, which has given satisfactory service for several years. The new plant will be located at Seventh and Lehigh avenues, in the Kensington mill district. It will take water from the old Fair Hill reservoir, as it is located some distance from the river.

The work is in charge of the Millard Construction Company, which is the general contractor, while detail-engineering work is being carried out by the Sanfield Engineering Company. The first contract covers ten 300-horsepower Westinghouse vertical single-acting gas engines, direct-connected to Deane triplex pumps, and a 150-horsepower unit for auxiliary purposes. The engines will take gas from the city mains, as in the case of the Delaware avenue station.

The decision again to employ pumps driven by gas engines for this high-pressure fire service is distinctly interesting in view of the discussion which took place previous to and after the installation of the Delaware avenue station, and which was mostly in favor of electrically driven pumps such as those in New York City.

A study of the first year's operation (1904) of the Philadelphia station indicates the kind of results that are obtainable from an installation of this kind. As this was the first year's operation of the plant, it was to be expected that the maximum interference from troubles, operative and otherwise, would be encountered. The year's record shows not a single case of failure to start, either in the actual fire service, or in the numerous experimental runs which were made to test out the equipment. During the year there were 37 alarms and nine actual services of any considerable duration, the services varying from a few minutes to 24 hours. The large pumping units ran [illegible] hours, and the small units [illegible] hours, during the year, with a total pumping service of [illegible] gallons. The average cost per thousand gallons pumped, including all the experimental runs, which were by far the major portion of the service, was 12.8 cents; but for a large fire of five or six hours' duration, the cost of pumping is barely over 3 cents per thousand gallons. The total cost of repairs on the gas engines, aggregating [illegible] horsepower, since their installation up to December, 1905, was $3.05.

On the average, one unit could be put upon the system at any [illegible] delivery pressure in from 45 to 60 seconds from the time of giving the signal from fire headquarters, and the entire station could be got under way in from 7 to 10 minutes. In ordinary operation, however, only one or two units are started on the first signal, as these are sufficient to start operations, and further units can be put on as the service may require.

A highly important feature of the Philadelphia situation is the attitude of the insurance authorities. Prior to the establishment of the Delaware avenue station the insurance underwriters had imposed an additional charge of 25 cents per $100. On the completion of the test of the high-pressure pipe line in May, 1902, a reduction of 15 cents per $100 was made, and on the final test of the gas-power station on April 18, 1905, the balance of the extra "pink slip" charge was removed and the system was declared approved. Formerly of a most decided conservatism toward gas engines, the authorities then expressed their complete confidence in the new system by suggesting extensions to the initial equipment

Commutator Brushers and Sparking

By H. B. Hadfield

Several letters have recently appeared in Power and The Engineer regarding sparking of commutators. While a widely diversified experience is shown along that line by the different writers, I am firm in the conviction that fully 95 per cent. of the trouble is caused by brushes and brushholders, while the remaining 5 per cent. would be ample to cover all the old timers and improperly designed machines which have no excuse for present existence.

I have had my troubles with "sparky" commutators, and while my present practice includes nothing of a wonderful nature, it is productive of excellent results, which is what we are all after.

I have handled machinery with brushes which have been boiled in engine oil, paraffin, beeswax, turpentine, tallow and what not, and while this "dope" seemed to give some improvement, it surely did not strike at the root of the evil; for while it would lubricate the brush it also increased the contact resistance with the brushholder and commutator and gave rise to trouble worse than that which it was intended to cure.

After the brushes are set at the correct point on the commutator, spaced evenly all around, and the load is not excessive, the commutator is true, the brushes fitted carefully to the holders and commutator, and still they spark, that is a condition productive of gray hairs and insomnia. But a careful analysis (or should it be diagnosis?) will usually trail the trouble to the door of the brushholder or the brush.

Some time ago I fell heir to several sparkers, and my experience with them has been productive of evidence against the brush and holder. A 55-horsepower type S-10 Westinghouse compound-wound 225-volt dynamo was carrying a load of 125 amperes. The brushes worked red hot most of the time, and frequently ran so hot as to melt the brushholders. This was so common that it had ceased to call forth even a moderate amount of profanity from the attendant. Today this machine carries 230 amperes and is as cool as could be desired. We are using the same brushholders that were furnished with the machine, and the same grade of carbon. The contact between carbon and

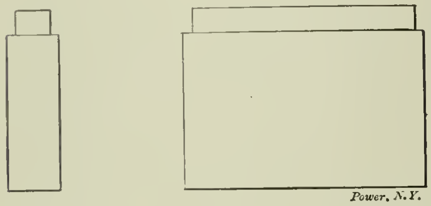

FIG. 1

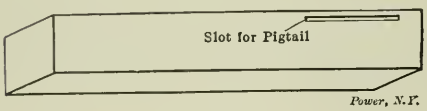

FIG. 2

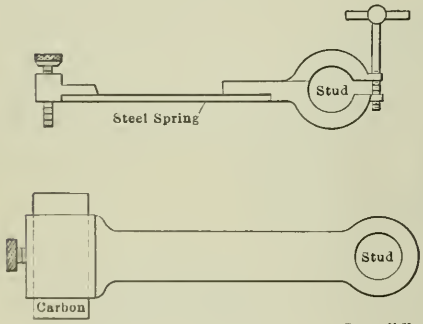

FIG. 3

holder has been improved. We found that the "pigtails" were secured to the brush by small brass bolts put through the copper webbing pigtail and a ¼-inch hole in each carbon brush. This made insufficient contact. The bolt made no contact with the brush inside the hole because it had to "clear." The point where the pigtail was squeezed against the carbon soon became overheated, carrying away the copper coating, adding to the resistance, starting the endless chain of more heat, more resistance, until it consumed either the brush or the holder.

Capping the Brushes

We made up a set of brushes like Fig. 1, which were copper-plated to insure good soldered contact. We then made caps of 1/32-inch sheet brass as represented in Fig. 2. A laminated copper pigtail was made up about ½ inch wide by ⅛-inch thick and passed through the slot at the top of the brass cap. The cap and pigtail were then soldered securely to the brush and the other end of the pigtail was fastened to a solid part of the brushholder. We have had no sparking nor overheating since. The brushes have lasted a year and are good yet; we have nearly doubled the load, and everybody is happy. This scheme of capping brushes has been carried out on about 25 motors ranging from 1 to 50 horsepower and is being applied wherever trouble comes up.

In capping brushes, no attempt should be made to solder caps to carbon without copper-plating, as only an indifferent contact will result, and while it may be inconvenient to buy brushes cut out at the top as needed it will pay to send them away for plating after cutting, if necessary.

That it is not always sufficient merely to carry out the instructions of the manufacturer can be clearly shown, although if these instructions were more generally followed much anxiety and expense would be saved. But there are cases where the man who designs a machine seldom or never sees it in regular operation, and certainly never has to "sweat blood" to keep a factory or a department of one running with a tricky motor.

We had a 40-horsepower motor running a positive blower two hours per day in a foundry. At the end of the run it was usually hot enough to fry eggs, and while running was so noisy as to be irritating. The brushholder was of the style shown in Fig. 3, where the brush is clamped to the holder for good contact, and the stud runs through a large hole in the other end of the holder, allowing the holder either to dance around like a dervish or require clamping the spring so tightly that it became practically jammed on the bars and squeeled like a pig.

In this case we made new brushholders of a different type and fitted them with capped brushes, and the machine now runs very coolly and quietly and is as good a motor as any we have.

One of the large manufacturers put out a 10-horsepower four-pole motor which has a commutator 3½ inches long, and is fitted with brushes 1¼ inches wide. The holders are attached to two wooden blocks, a pair on each block, and the blocks are fastened to the usual brushholder ring. All four of these brushes run in the middle of the commutator, making a track 1¼ inches wide. Trouble with one brush means trouble with four in a very short time. We took the wood blocks off and cut a notch ⅝ inch deep where each block fits the brush yoke. The two top holders were blocked in ⅝ inch and the two lower ones blocked out. This puts a positive and a negative brush in each track, which is no small advantage.

WE PAY FOR USEFUL IDEAS

How the Steaming of a Boiler Was Improved

I have charge of a plant in which there are two 150-horsepower boilers and one 100-horsepower. The 100-horsepower boiler is represented in the accompanying Figs. 1 and 2. Fig. 1 shows how the boiler was arranged when I took charge of the plant. The boiler did not steam good at all and did not seem to have very much draft, although there was a good-sized stack.

I fixed some of the brickwork that was loose, thinking that was the trouble, but it did not help very much. When the boiler was cut out the next time I decided to change some of the brickwork, as shown in Fig. 2. The back wall *A* was removed and an extra wall *B* was built behind the boiler and filled in with earth between the two walls *C* and *B*, cutting the space down from 48 inches to 18 inches. Since the change was made the boiler steams good, burns less coal, has a splendid draft and is better every way. It seems that the arrangement shown in Fig. 1 gave a space so wide that the flames and gases just whirled around in the large arch before passing out through the flues.

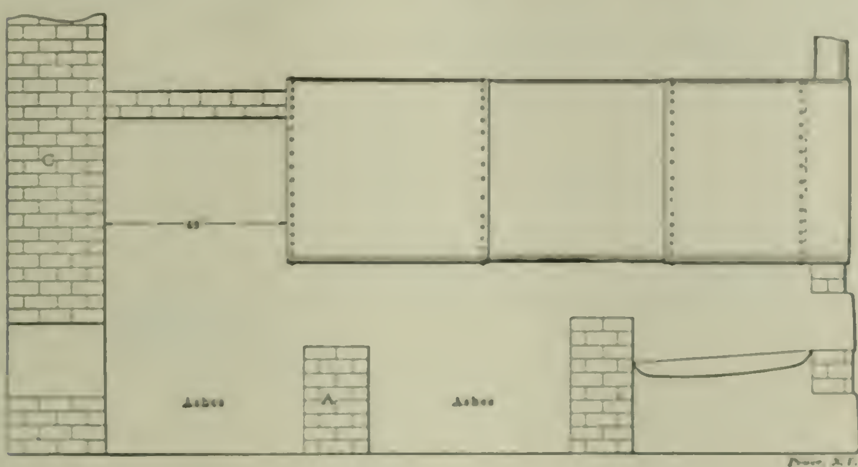

FIG. 1. BEFORE THE CHANGE

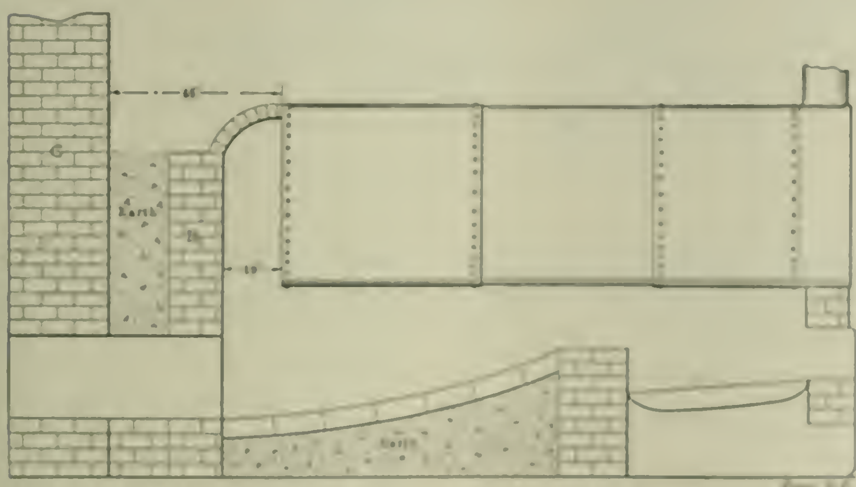

FIG. 2. AFTER THE CHANGE

Safety Cams

On page 730 of the April 20 number appeared a letter regarding safety cams, in which the writer states that the eccentric is set about 135 degrees ahead of the crank. This position gives the eccentric an angle of advance of about 45 degrees, which is excessive. He states that in this position the indicator diagram will show a square corner at the closure of the exhaust, or in other words no compression and late release. This is entirely wrong.

It would be impossible to get release and compression late on a Corliss engine with the eccentric set 135 degrees ahead of the crank. As a matter of fact, either one or both of these events must be very early. It would be possible to get both release and compression early, or it would be possible to get proper release or compression, while the other event in each case would be very much too early. The only way to get both events late, as Mr. Tryon states, would be to have the eccentric not set far enough ahead of the crank.

Suppose with the eccentric at 135 degrees advance we adjust the exhaust-valve reach rod, so as to get proper exhaust. The compression would be too high, and we would have to shift the eccentric back, then adjust the exhaust-valve reach rod to bring the exhaust right again, after which the compression will be seen to be reduced. If not enough, the eccentric and rod will have to be changed more in this same manner until both exhaust and compression are satisfactory.

Changing the eccentric in this way will have made the admission late, and to bring the admission right, the steam-valve reach rod must be shortened and the dashpot rod lengthened. The steam-valve reach rod is shortened to make the admission earlier, and the dashpot rod is lengthened to reduce the lap of the valve and allow the hook to catch on when in its lowest position.

These changes bring us to the trip collar, on which are mounted the safety cams and cam for tripping the hook by the action of the governor.

To set these trip collars it must be remembered that the block must always unhook and allow the valve to be closed by the action of the dashpot. The valve must never be allowed to be opened and closed by the hook. To set these trip collars, I unhook the hook and the eccentric placed with the safety stop in position for starting the engine; I then start the engine and have it run as slowly as possible until I get the trip collars set. At this speed the governor will remain on the safety stop and in this position the steam valves should close at the latest possible point of the piston stroke. To get this result the reach rod connecting the trip collar with the governor must be lengthened or shortened as the case requires, until the hook is tripped at the very latest point possible of its stroke upward.

When the trip collar is set in this position the safety cam should very nearly touch the end of the hook when the hook is in its lowest point, and if the governor is let down off the safety stop the engine should stop, because the safety cams should hold the hook off so that it cannot open the valve and admit the steam. If the safety cam does not hold off the valve hook when the governor is down and the valve gear is correctly adjusted otherwise, the safety cam should be set up on the trip collar until it is close enough to hold the hook off, and secured in this position.

Cleveland, O.

Faulty Engine Adjustment

On page 686 of the April 13 number, E. O. Brown presents two engine cards typical for badly adjusted old-style Fitchburg engines.

Two faults in adjustment may be detected: The change in lead of the head end at different loads points to a wrong position of the governor on the shaft. The excessive variation in cutoff of the head end compared to the crank end proves that the eccentric rod is too short, on account of which the rocker pin does not travel an equal distance on either side of the plumb line through the rocker-arm fulcrum.

The governor should be adjusted by trying to get the smallest movement in the valves, when swinging the governor weights in and out; the engine being put alternately on each dead center. Taking out the springs will convenience this operation greatly. If the governor is in the correct position a countersunk hole will likely be found on the shaft under the tap of the set screw in the hub of the governor wheel, which is generally drilled in by the manufacturers before shipment of the engine.

Before starting to change the length of the eccentric rod, mark the position of the crank end valve at the dead center, as its lead is correct and should not be changed. Then shorten the eccentric rod by turning the hook until the rocker pin swings an equal distance on either side past the plumb line through the center of the rocker-arm fulcrum. Put the engine at the farthest dead center and clamp the crank-end valve stem on its reach rod with the valve in the marked position. With this valve now in the correct position, the head-end valve should be adjusted by shifting its clamp until the indicator card shows the same lead at both ends of the cylinder at all loads.

Motor Controller Troubles

A short time ago the starting lever of a direct-current stationary-motor controller was broken, as shown in Fig. 1; it was impossible to get a new lever at once, so the old one was repaired with a patch. The repair took one hour, including the time spent in removing the lever and replacing it.

The break was due to one of the segments being loose and raised a little higher than the others. When the operator moved the starting lever the copper brush on the lever could not pass over the high segments, so force was used, with the result that the lever was broken and some of the segments were bent.

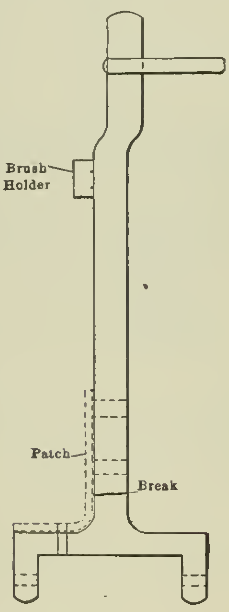

FIG. 1

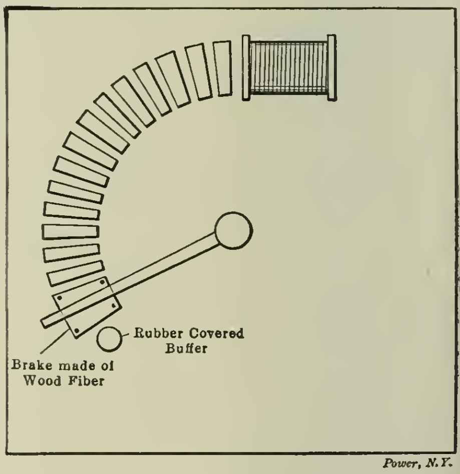

FIG. 2

Most motor controllers used in shop and factory work have rubber-covered buffers next to the brake (Fig. 2), in order to stop the starting lever when it is released by the magnet when the switch is thrown out. In time these buffers will wear out or break and, if not renewed in time, when the starting lever is released by the magnet it will strike against the pins which held the buffers on. These starting levers are made of cast iron, are very light and break easily.

Some makers of motor controllers use slate for the brake, which I think is bad practice, because when the copper brush on the starting lever becomes a little rough it will scratch the slate and dust gets under the copper brush, causing sparking at the segments when the lever is moved to the starting position. I had a controller of this type. I made a brake of wood fiber and had no more trouble.

A controller on one of our cranes used to spark badly. I found that the segments were all burned black. They were cleaned with sandpaper, but in a short time they were burned black again, when it was found that the carbon brush on the starting lever did not make good contact with the segments at the toe. After the brush was ground to a good fit with sandpaper there was no more trouble.

Synchronizing Trouble

I think C. L. Greer's synchronizing trouble was caused by the pulsating unidirectional electromotive force which exists between any commutator brush and any collector ring of the converter. Since the three-phase alternating-current electromotive force is 400 volts, the direct-current voltage will be about 650 volts. The instantaneous values of the pulsating electromotive force vary from 0 to 650 volts, giving an effective voltage of about 460 volts.

If the voltmeter plug is placed in *A*, the positive brush is connected to the positive busbar through the middle voltmeter lead. In synchronizing with the voltmeter plug in *A* and one of the synchronizing plug switches closed, the effective electromotive force impressed upon the lamps varies from 0, when the machines are in phase, to about 460 volts when in opposition. Therefore, the lamps receive about 460 volts instead of 400 volts. The plug *A* burned because the voltages were not equal, or because they were not exactly in phase when the switch was closed.

A Gas Engine Signal System

In dealing with the minor difficulties incident to gas-engine operation, the signal system represented by the accompanying diagram is a great convenience. It is preferable to have the signal control on the panel of the generator driven by the engine for which it is intended. This will avoid any confusion of machine numbers. In cases where the wiring on the panel does not permit of any additional wiring, a separate signal board may be used, as shown in the figure. A set of signals must be arranged between the gas engine and switchboard operators. A red and green lamp are placed over each engine at some convenient spot where they can be seen by the engineer from any part of his engine. These are indicated in the diagram by R and G and corresponding pilot lights R' and G' are placed on the signal panel for the guidance of the switchboard operator. By means of the small push-button switches A and B the lights are controlled. The lamps R and R', and G and G' are in series, respectively, across a 220-volt supply circuit, or one of some other convenient voltage. A large gong is placed near the center of the power house and rung by the switch C to call the attention of the engineers to their signal lights. The simpler the code of signals, the more effective it will be. The following code of signals for paralleling generators is very easily understood: Red lights to slow down, green to increase the speed, and red and green to balance the mixture in the cylinders. This code is also applicable for readjusting the load during parallel operation. For example, suppose that the load carried by three 2000-kilowatt alternators becomes unequally divided so that No. 1 generator carries 2000 kilowatts, No. 2 generator, 2000 kilowatts and No. 3 generator 1000 kilowatts. With these conditions there will be a decided hunting action between the units. To readjust the load it is necessary to look at the frequency meter to see if the speed is correct. If so, the gong is sounded, the red lamp is lighted over engine No. 1, both lamps are dark over No. 2 and the green lamp is lighted over No. 3. When the load has been divided equally among the three generators the lamps are extinguished, of course.

The governor switch is used in most cases, where mixtures are adjusted by hand, only to synchronize the machines. After the generators have been synchronized and the load becomes unbalanced, the engineer advances or retards the spark and adjusts the supply of gas alone until the proper conditions are restored.

SIGNAL-SYSTEM CONNECTIONS

Trouble in a Pumping Plant

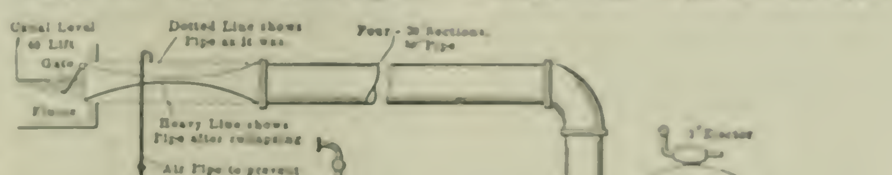
The article in a recent issue about "Pethlyn P. D." was very interesting, and I am sorry that I did not know the "P. D." some four years ago when I was engaged as chief engineer in an irrigation pumping plant, where on several occasions a very peculiar thing took place.

The 20-inch centrifugal pump, running at 240 revolutions per minute, pulled by nine wraps of 1¼-inch rope, was guaranteed to throw 25,000 gallons of water per minute, and after several tests was found to throw some 30,000 gallons. One morning I found a bearing hot on one side, which was something unusual. I noticed that the engine acted as if the load was light. I climbed up to the flume and found that only about one-half the usual amount of water was being delivered by the pump. I thought I had solved the mystery and that the suction was stopped up. As the suction pipe was not equipped with a foot valve, the water was raised by a 2-inch ejector. I got a long pole and ran it down along the suction pipe in the water, thinking perhaps that one of the floor planks in the intake had got loose and obstructed the flow in the pipe, but nothing was found wrong. I was in somewhat of a bad fix, 500 miles from home, 19 miles from a railroad, and 90 miles from a machine shop and if I had known of "P. D." I would gladly have given half of the hardest part of my past life. The water was badly needed, as some 3000 acres was planted with rice, and water had to be had. I shut down the engine and started the ejector, and I could feel the water in both suction pipes, and starting and running the engine and pump up to speed, the hot box was something of the past.

This same thing happened several times, and I never found the cause, and will give "P. D." a chance to solve the problem. The accompanying illustration shows details of the installation.

On one occasion, having plenty of water in the canal, we had stopped the engine to change the suction pipe in the fuel-oil tank, and to pack the boiler-feed pump. While we were working on the pump, the engine started, stopped and again started. The fireman had shut down the plant and was sure he had closed the main engine throttle. Looking at the receiver gage, it showed a pressure of 180 pounds. One can imagine my thoughts as the receiver was made of cast iron, and we never had more than 90 pounds in it.

During the installation, I had a be-



TROUBLE IN A PUMPING PLANT

pass put in between the receiver and trap, so that in case the trap should fail, it could be removed and repaired, and the bypass used for draining the condensation in the receiver, and not have water passing into the low-pressure cylinder. I opened the bypass, which was the only time it was used. We afterward found a globe valve partly open, on a pipe leading from the steam main to the receiver. We maintained a receiver pressure of 12 pounds by cracking the valve, and found the engine worked without any undue noise with this pressure for the low-pressure cylinder and 180 pounds for high-pressure cylinder.

When running night and day, we usually stopped at 6 a.m. and 6 p.m. to fill the grease cup on the crank pin. One morning the night engineer stopped as usual and, while filling the grease cup, heard the water from the flume rushing back to the river through the pump. He then knew that he had forgotten to drop the flap door on the end of the discharge pipe. He loosened the rope, dropped the door, and the result was that the velocity of the water and the sudden vacuum created in the discharge pipe caused one 20-foot length to collapse. This caused a shutdown for one week until a new section could be made. When this was put in I tapped a 1-inch pipe on top of the discharge pipe, with a globe valve at the bottom within reach. This valve was opened when shutting down the plant, and permitted air to go into the discharge pipe as the water went back through the pump after the flap door was closed.

C. WILHELMSEN.

Kentwood, La.

Explosion of a Fire Hoe

Engineers are all more or less familiar with boiler and flywheel explosions, but the explosion of a fire hoe is probably a new "wrinkle."

The photograph shows the handle of a

FIRE HOE AFTER EXPLOSION

fire hoe which exploded while the fireman was cleaning fires. The handle was made of ¾ inch steam pipe. Slack was used as fuel, and the coal pile was so near the boilers that in pulling out the ashes the handle had been jammed full of slack. Repeated heatings had baked the slack so that it tightly plugged the end of the handle.

On the occasion of the explosion the fires were very hot and very dirty, so that the handle got hot enough to ignite the gas formed on the inside of it by the coal.

RAY L. RAYBURN.

Decatur, Ill.

A Peculiar Pump Trouble

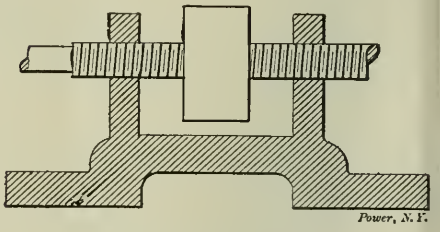
In the course of a somewhat varied and lengthy experience, the writer has come across some curious pump troubles and their remedies, but the following is the only one of its kind that he ever saw or heard of:

The incident happened in a pumping plant, consisting of a 14x24x14x18-inch compound condensing pump, and a 7½x7x12-inch independent air pump and condenser. The main pump was operated at 15 revolutions per minute and the air pump would form a vacuum of 26½ or 27 inches, with the steam valve one-third of a turn open. The boiler pressure was 65 pounds.

Upon starting the pump one day it was noticed that the air pump did not pull down the vacuum as usual, so the steam valve was at once examined to see if it was open its customary one-third turn, and was found to be so. The steam was at full pressure. The water valve to the condenser was never changed, so we looked for leaks, but could discover none, so the steam valve was opened a little more.

This condition continued for some time and we were compelled gradually to open the steam valve until it was wide open, and we were just about able to hold the 26½ inches of vacuum, but with the valve wide open there was no increase in the speed of the pump. The writer had suggested several times that the pump be examined internally, but was gently sat upon, until the vacuum began to disappear. Then it was decided that something must be done and the pump was shut down and opened up. The water end was thoroughly examined as a starter, everything being found as it should be. Next the steam cylinders were examined, but everything was found all right. The valve covers were then taken off, which in the writer's opinion should have been done first, and the valves appeared to be all right; the pump was then traveled to test them and they worked correctly. Then the valves were cocked up on one side to allow the ports and bridges to be seen. While the edges of the ports showed some little erosion, there was nothing to account for the extra amount of steam to operate the pump or the falling away of the vacuum.

Again the writer ventured a suggestion, this time to the effect that the trouble must be in the valves or ports, and advised that the valves be taken out altogether to enable a thorough examination of ports and valves. He was told to go ahead and do as he liked, and was immediately left alone. Upon removing both valves, which were of the ordinary D type, with two lugs on the top, between which was a rectangular block about ¾ inch



A PECULIAR PUMP TROUBLE

square, with a hole in the center, through which the valve stem passed and moved the valve, instead of locknuts, everything looked all right. It began to look like a case of "stumped," when upon turning the valve over again, the block upon the top moved over to the other lug, and the trouble was found.

In the top of the valve on one side, where the block rested as it moved back and forth, it had worn a hole through the valve, and when the valve was turned over, with the block held on top of it, it was hardly perceptible, yet upon taking the block out it seemed as though a blind man ought to have seen it, although five of us were unable to discover it.

A new valve was immediately procured and when the pump started again it went on the job with one-third turn on the steam valve as usual.

Brooklyn, N. Y.

What Would Happen if the Belt Came Off

In answer to H. B. Adcock, in the April 20 number, I will say that in case one of the exciter belts breaks he will have to look out for fireworks at that exciter's commutator.

The generator, running without a field, would draw excessive current from the busbars and if fused would probably blow the fuses. It would act as a sort of transformer, taking current from the busbars and pumping it into the exciter, probably burning the commutator badly.

If the other alternator could supply the current, the speed would increase, as the heavy lagging current would react upon the fields to demagnetize them and drop the load, although the current would be a great deal above normal full-load current.

CHARLES O. RANKIN.

Craftonville, Cal.

In reply to H. B. Adcock's question in the April 20 issue, I will say that the alternator whose exciter belt is thrown can be considered practically a transformer with its secondary circuit completed by a moderately high impedance. I venture to say that with some characteristics of design the alternator would continue to run somewhat as an induction motor, while upon the other hand it may draw such an excessive current from the other machine as to make it necessary to take it off the line at once. I am of the opinion, however, that no serious results would occur.

L. Earle Brown.

Ensley, Ala.

Replying to H. B. Adcock's inquiry in the April 20 number, as to what will happen if the belt driving an exciter should break, there would be no current flowing through the field circuit, but the generator would run as an unexcited synchronous motor, taking a very heavy lagging current from the busbars.

If both machines were operating at near their rated capacity when the belt broke, it would put quite a load on the one machine and I believe there would be some fireworks in a short time. It would be a good investment to install fuses between the generators and busbars, especially in this case, where the exciters do not operate in parallel and no auto-switches are provided.

Louis B. Carl.

Marshfield, Wis.

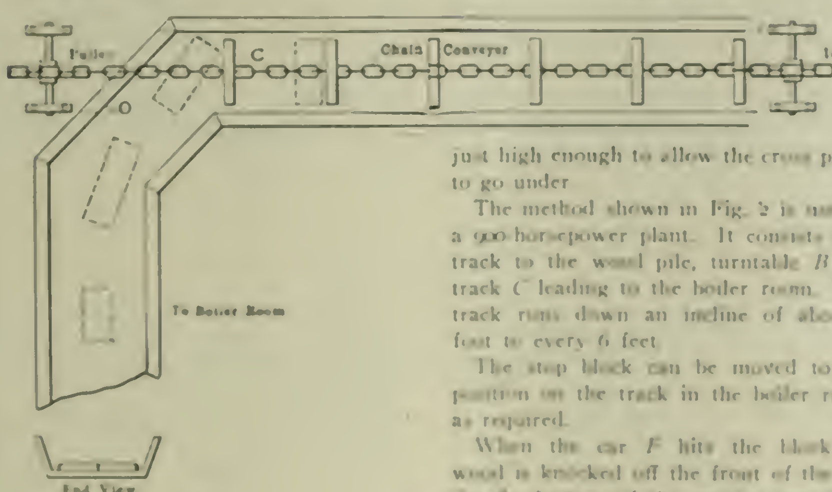

FIG. 1

I think the alternator would continue to run and carry the load. This would be because of its field being magnetized by an induced current from the other alternator, and if there were no fuses or breakers in the exciter circuit the exciter would probably continue running as a motor. Of course, the voltage and power factor of the system would be very much below normal.

Harry J. Bremer.

Schenectady, N. Y.

Handling Wood Economically

On page 121 of the January 12 number, I. B. Sutton wishes to know of a way to handle wood economically. The accompanying illustrations show two ways of handling wood which work successfully.

The system shown in Fig. 1 is located in a 3000-horsepower plant, and consists of a chute C which leads to the boiler room, having several openings which are opened and closed by a rope leading to any convenient place.

The conveyer is a common endless-chain conveyer with the cross pieces about 15 inches apart. The turning board is just high enough to allow the cross pieces to go under.

The method shown in Fig. 2 is used in a 900-horsepower plant. It consists of a track to the wood pile, turntable *B* and track *C* leading to the boiler room. This track runs down an incline of about 1 foot to every 6 feet.

The stop block can be moved to any position on the track in the boiler room, as required.

When the car *F* hits the block the wood is knocked off the front of the car. On the bottom of the car are two strips of iron to keep the wood from sticking. The car is built of heavy timber to withstand the jolt of stopping.

When wood is required in the boiler room, one of the firemen rings a bell to let the wood handler know. He in turn rings a bell and lets the car go and applies enough pressure on the brake of the engine to keep the cable tight and stop the engine when the car stops. When the car hits and unloads it is hauled up and loaded for the next call.

In Mr. Sutton's case, I should think power could be taken from the main engine, if the cable was returned to the boiler room, or the hoisting engine done away with by using two cars and make a double track part of the way at least.

Albin Sears.

Elberton, Wash.

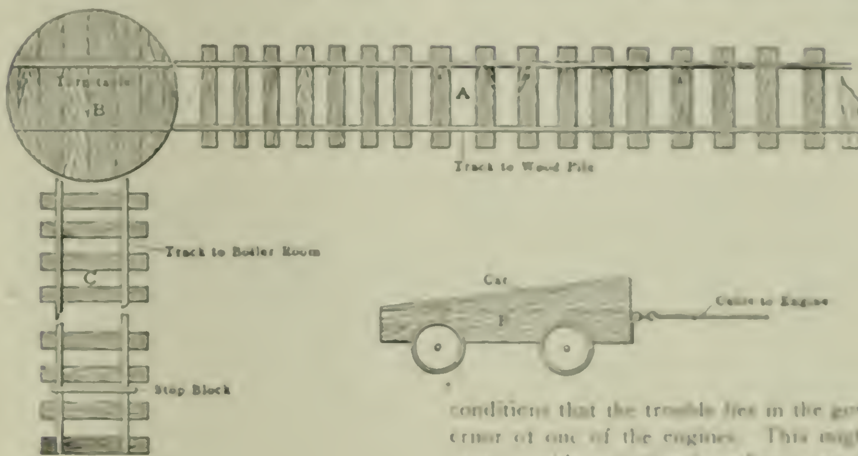

FIG. 2

Reversing Polarity

Referring to the letter in the April 20 number, by H. F. West, in regard to trouble in operating two direct-current machines in parallel, the fact that one machine is larger than the other should not interfere with their proper operation.

I take it that these machines are separately driven. It is possible under such conditions that the trouble lies in the governor of one of the engines. This might cause a wide variation in voltage, especially if one machine had a rising characteristic and the other not.

The compounding of his machine may not be correct for satisfactory parallel operation and if he can determine which machine has a tendency to produce the highest voltage at the busbars he could improve the conditions by inserting a coil of wire into the leads from this machine so as to give a greater drop in the leads between machine and busbar and, therefore, bring the voltage down. This coil need be only a large coil of the same wire as the leads and connected into the lead on the positive side.

T. A. Lees.

Quincy, Mass.

In answering H. F. West in regard to one of his direct-current machines reversing the other one at times, I will give my experience.

Taking it for granted that his machines are connected with an equalizer, I find that it is possible to run compound machines of greatly varying sizes together if they are wound for the same voltage, but it is sometimes necessary to put an extra shunt in the shunt field circuit on the machine which tries to take the load in grabbing heavy loads. Sometimes one machine will be found to be considerably quicker than the other and by increasing the size of the shunt he can obviate this, and I would advise him to try it. He can easily make the shunt out of german-silver wire and insulate it with tape; put the shunt on the machine which reverses the other one.

South Oil City, Penn.

Hydraulic Information

In a recent issue, under the head of "Hydraulic Information Wanted," William E. Pipe gives a certain stream flow, and states that by going back 500 feet from the proposed location of the plant a fall of 140 feet can be obtained. He inquires as to the size and grade of pipe, class and size of wheel most applicable to the case in hand, and the number of 16-candlepower lamps that could be carried.

His letter of inquiry does not contain sufficient information to enable one to make a very definite or reliable reply, and on the basis of incomplete and general information a reply must necessarily be considered equally incomplete and general. It may be of interest, however, to consider the matter in the light of the data furnished.

By a stream of water delivering 360 inches under a 12-inch pressure, doubtless a discharge of 360 miner's inches under a head of 1 foot is meant. Such being the case, a continuous discharge of this amount would mean approximately 12.45 cubic feet per second.

The selection of the proper size of pipe or penstock is in itself quite a problem, increasing in importance with the plants in which the cost of the pipe line is a large percentage of the total cost. The chief factors on which the proper solution of this problem depends are quantity of flow through the pipe, static head, probable total cost of development per horsepower, and the cost per pound of the penstock erected. Based on the above, expressions of considerable value have been worked out for the most economical diameter to install in any particular case. Since the friction in a pipe line for a fixed quantity flowing decreases with an increase in the size of pipe, it follows that the annual saving in the value of power occasioned by a reduction in the frictional resistance must be considered in connection with the increased yearly interest and depreciation on the first cost of the larger pipe. For example, if the reduced friction head in a 26-inch pipe line is such as to increase the available power 0.2 horsepower over that obtainable with a 24-inch penstock and power is worth $75 per horsepower per year, the annual saving would amount to $15. If the increased cost of the larger pipe erected is $200, with interest and depreciation figured at 8 per cent. per annum, the change would not be warranted. Briefly stated, then, that size of penstock would seem most economical for which the yearly interest and depreciation on the first cost of the pipe plus the value of the power lost in the pipe line per year are minimum. The accompanying table shows what diameter of pipe seems most economical.

The table was first prepared to include pipes of smaller diameter, as well as a 36-inch pipe, but as the proper size aupeared to be within the limits of a 22- to 30-inch pipe, only that section of the table is included. The value of power per year, the cost of the pipe line per pound, and the interest and depreciation figures are only approximate and cannot be expected to fit exactly the case in hand.

1 Pipe Diam. Inches.	2 Velocity per Feet Second.	3 Friction, Feet.	4 Power Lost. Horse-power.	5 Yearly Loss.	6 Cost of Pipe.	7 Yearly Interest and Depreciation.	8 Sum of Columns 5 and 7.
22	4 72	2.50	3.54	$177.00	$1100.00	$110.00	$287.00
24	3.97	1.70	2.41	120.50	1600.00	160.00	280.50
26	3 38	1 20	1.70	85.00	1775.00	177.50	262.50
28	3 02	0 90	1 27	63.50	1900.00	190.00	253.50
30	2 54	0 60	0 85	42 50	2240 00	224 00	266.50

Power at $50 per horsepower year. Interest and depreciation at 10 per cent. Pipe at $0.10 per pound.

From a consideration of the data contained in this table the 28-inch pipe appears to be the proper one. The friction losses are taken from tables for sheet-steel riveted pipe, as this grade of pipe is considered the proper one to use.

Based on the flow given and the effective head of practically 139 feet the power to be delivered by a turbine of 80 per cent. efficiency would be equal to

$$\frac{12.45 \times 139 \times 0.80 \times 62.5}{550} = 157.30$$

horsepower. Under the conditions of head and flow a high-pressure turbine would seem the most advisable. Figured on catalog conditions for this type of wheel the proper relation of power and diameter would call for a 20- to 25-inch wheel. The standard 22-inch wheel of one of the reliable companies is rated at 176 horsepower at 495 revolutions per minute, and a discharge of 13.9 cubic feet per second, and would appear to be the nearest fitted for the case in hand.

Assuming the combined generator and wire efficiency to be 80 per cent., the power delivered for lighting would be equivalent to

$$157.5 \times 0.08 \times 746 = 93{,}877$$

watts. The average power required to carry one 16-candlepower lamp is

$$16 \times 3.3 = 52.8$$

watts. The number of lamps that could be carried, therefore, would be

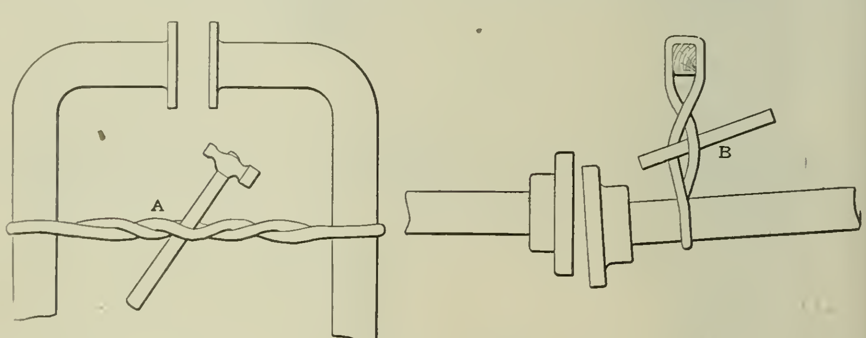
$$93{,}877 \div 52.8 = 1778.$$

B. R. McBride.

Madison, Wis.

The Spanish Windlass

The origin of the term "Spanish Windlass" is somewhat obscure, and as far as I have been able to ascertain it is not Spanish, and it is not a windlass, but of its utility as an improvised tackle there is not the slightest doubt. Among sea-going engineers it is a great favorite, as most of the machinery, etc, under their control is put together with a view to economizing space and is consequently not amenable to shop methods.



THE SPANISH WINDLASS

The accompanying line cuts show how it is applied at *A* for bringing two pipes together for jointing and at *B* for raising one end of a length of shafting to bring it into line for coupling. It will be seen that it does the duty of turn-buckle, screw, pulley blocks, or crowbar. The travel, or rather the length of pull exerted in proportion to the power applied to the "tommy" is enormous, being limited only by the strength of the rope itself. I have used it hundreds of times, and for as many different purposes, and I always regard it as one of the simplest and most useful emergency tackles. Many a time when working in cramped or otherwise inconvenient places such as the bilges of a ship, where it was not possible to use pinch-bar or pulleys, I have easily got over a difficulty by using a Spanish windlass on it, and frequently when I have been sent out into the country to overhaul engines, etc., I have been able to save considerable time by its use, particularly in some out-of-the-way places where the only available tools were a coal hammer and a monkey wrench with a loose jaw.

S. J. Bean.

London, England.

Three Engine Room Kinks

A main stop-gate valve on a boiler leaked so badly that it could not be entered for cleaning as steam leaked through from the other boilers. This was remedied by tapping a hole between the

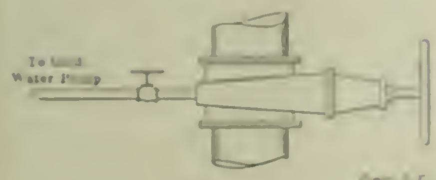


FIG. 1

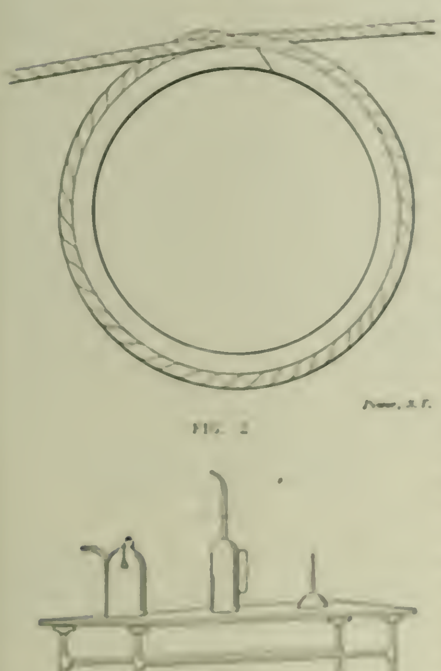

FIG. 2

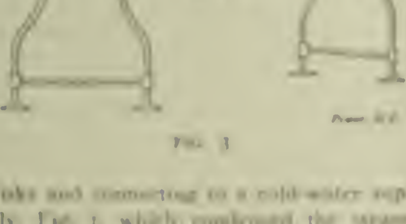

FIG. 3

disks and connecting to a cold-water supply, Fig. 1, which condensed the steam, and allowed the boiler to be entered.

A good way to enter small piston rings in a cylinder is to tie a string around them which compresses them and allows an easy entering to the cylinder. See Fig. 2.

A table for oil cans, etc., which I made for my engine room, is shown in Fig. 3. When painted or bronzed it makes a showy affair.

Milton Hiller.

Cincinnati, O.

Cleaning Fires

It is interesting to note the different way firemen go about cleaning fires. One man will make it a job to be dreaded, while another will do it so easily that it is apparently very little trouble.

To a large extent, it is a matter of good judgment. The man who uses judgment will begin about an hour before cleaning time to get his water level, fire and steam pressure in proper condition. He will then clean the fires with very little loss of pressure, and a minimum of discomfort and work. The man who uses no judgment and makes no preparations in advance will have several bushels of half-burned coal raked out with the clinkers, which makes it so hot as to be almost impossible to stand in front of it, fills the room with smoke and soot, and by the time he is done his own temperature and temper, also, are about as high as that of the boiler, and he will have to fight his fires for an hour to get the steam pressure up again.

The amount of coal wasted by carelessness in cleaning fires is very large in most cases. If the boilers are being forced, or a cheap grade of coal is used, it is impossible to clean the fires without raking out a pile of red-hot clinkers. The usual practice in this case is to have an assistant stand by and play a hose on them to quench the heat. This is a bad thing to do, however, as it makes it impossible to keep the boiler fronts in good condition, besides raising a stifling gas which must be breathed by the man doing the cleaning.

A better method is, before beginning to clean, to rake out several shovelfuls of ashes from the pit, and have the assistant throw a shovelful on the clinkers from time to time. This effectually kills the heat and causes no discomfort to the one cleaning the fire.

About an hour before time to clean the fires, the feed pumps should be speeded up, and the water level raised as high as is safe to avoid priming. The poker should be run over the grates frequently to sift all fine ashes through, being careful not to raise it up, or to get the clinkers up into the burning coal. This allows a free draft, burns all unconsumed coal that might be among the clinkers and leaves them dead and comparatively cool.

About five or ten minutes before beginning to clean, throw in a fire on the opposite side of the grates from the side to be cleaned, and slow down or stop the feed pumps. Then shove the live coals back against the bridgewall with the hoe, draw all clinkers out, draw the live coals forward and rake the clinkers from the back end of the grates out over the fire. Then level the fire over the cleaned grates and cover moderately thick with fresh coal, using lump coal broken medium fine, if available.

If there is not enough live coal remaining to start the fresh coal well, use the hoe to draw some over from the other side of the grates, and then throw in a light fire on this side also. As soon as the fire is up to an even thickness on the side cleaned, the other side can be allowed to burn down, and be cleaned in the same manner. If properly managed, fires can be cleaned in this way with little or no loss of steam pressure, with a decided saving in fuel over most methods, and with a minimum amount of labor and discomfort on the part of the fireman.

One of the hardest possible methods, and one very commonly used, is that of letting ashes and clinkers collect so thick on the grates up to the time to clean that a heavy fire is necessary to hold the steam, then using the slice bar to pry the fire over to each side while raking out the clinkers.

It is necessary to use both the slice bar and hoe in cleaning this way, and there is sure to be a large amount of partly burned coal raked out with the clinkers.

S. Kiron.

New York City.

Hot Bearings

In an article on "Hot Bearings; Some Causes and Remedies," page 678, April 6 issue, H. S. Brown mentions his experience with locomotive rod brasses, and suggests cutting away the brass at the sides so that only an end or crown bearing remains. In his Fig. 4 only about two-fifths of the projected area of the bearing remains. A modification of this which is sometimes used when it is desired to sacrifice as little as possible of the projected area is to relieve the brass slightly with a file for about ½ inch at the edges. This prevents binding at this point and provides a small oil pocket while the brass is coming down to a bearing on the crown.

Another method of preventing this pinching action consists essentially in placing a very thin liner between the two halves of the brass and then boring larger, the excess diameter being equal to the thickness of the liner. When there is no pinching this method gives theoretically only a line bearing in the crown of the brass and should be used only when the service is such that the part may be broken in by careful running. Either of these methods, however, may often be used to advantage in places where a half bearing held in pedestals is used, and where strains due to changes in temperature may cause the bearing to close slightly at the edges.

The suggestion that it is a mistake to reduce the amount of metal by coring out at the back brings up the subject of bearings of other than rod brasses and the use of light brass liners for the bearing surfaces, and suggests the desirability, where the service is severe enough to warrant it, of using all brass boxes, or at least enough readily to conduct away the heat generated by friction to a radiating surface sufficient to get rid of it. This will be appreciated when it is remembered that the conductivity of copper alloys will range between 2 and 2½ that of cast iron.

As to open grain in the material and the desirability of having a dense surface, forging in dies close to the finished size while excellent for small parts is not always possible with heavy unwieldy parts, such as shafts. A good method in this case is to roll the journal with a roller somewhat similar to that mentioned for rolling babbitt, the roller being held in the toolpost of the lathe, after the finishing cut has been taken, and forced against the journal by the cross feed. This gives the journal a very dense and smooth outer surface, effectively closing all open grain.

An excellent method of cooling plain high-speed (not ring-oiling) babbitted bearings, which I have sometimes used with considerable success, and which has not received the publicity that I believe it deserves, is to feed beeswax, in strings of 3/32 inch or ⅛ inch diameter into the oil hole. The running journal, especially if warm, readily takes the wax. The preparation of the beeswax strings is a simple matter, the only apparatus required being a short piece of ¾-inch or 1-inch pipe, a pipe cap and a rod of the same diameter as the pipe and of equal length. The cap is screwed onto the end of the pipe, a hole a trifle smaller than the desired diameter of the beeswax string is drilled in the pipe close to the cap, the pipe is nearly filled with the wax and the rod forced in in a vise. The wax is forced out at the drilled hole in the form of a continuous string. Any hard grease may be put into this convenient form for feeding through an oil hole in the same way.

Mr. Brown's article brings to mind certain troubles with old wrought-iron journals and pins. In one case a bearing on which the load was always in the same direction, and not alternating as in a connecting rod, ran hot whenever it was allowed to heat up beyond a certain moderate temperature. It was perfectly free, there was no binding and examination showed that both the journal and bearing surfaces were smooth; there was no visible cutting due to grit or foreign matter, and changes of oil had little effect. The trouble was finally located in a seam which was almost invisible when the bearing was cool, but evidently opened up and acted as an oil wiper when warmed up. When once located the trouble was overcome by scraping down the sharp edge of the seam with the corner of a file properly ground.

A. S. Williamson.

Urbana, Ill.

A Whistle Repair

The stem of a whistle was broken as shown in Fig. 1 and was repaired by drilling a hole nearly the size of the stem.

The hole *C* is drilled about ½ inch from the top of the hole drilled through the center of the stem. I ground the two ends of the whistle stem smooth and placed them together. After closing the hole *C* and the bottom of hole *D*, I filled the hole in the stem with the best grade of babbitt through the hole *D*. The

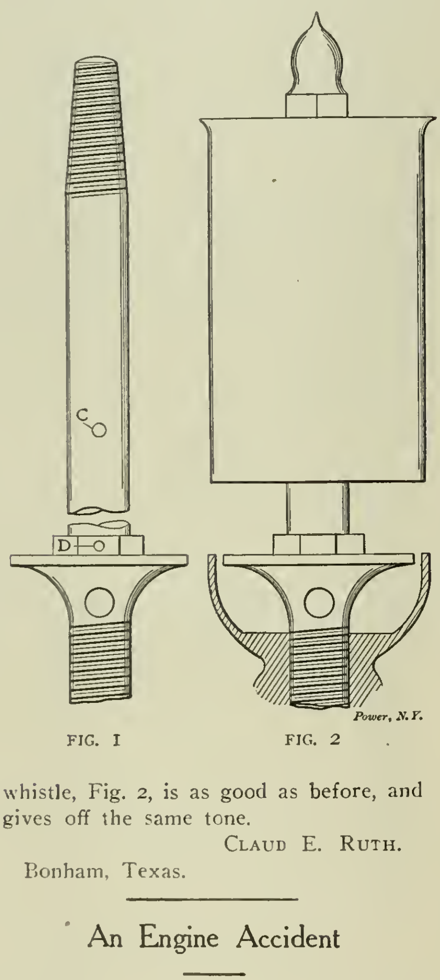

FIG. 1 FIG. 2

whistle, Fig. 2, is as good as before, and gives off the same tone.

Claud E. Ruth.

Bonham, Texas.

An Engine Accident

Referring to the letter in the issue of March 23, entitled "An Engine Accident," it appears that Mr. Sheehan, the writer, has been imposed upon. It seems incredible that an engine builder would attempt to shift the responsibility upon the operator for breaking a rod which had already cracked. It would not be any more unreasonable for a boiler manufacturer to claim that a defective tube would not have burst if the pressure had been reduced. It is doubtful that a reputable builder produced the engine in question.

It is true that the engine was unbalanced at the time the diagrams shown were taken, for the left-hand high-pressure diagram indicates 161.2 horsepower, while the right-hand low-pressure diagram indicates 147.4 horsepower. It does not appear, however, that the high- and low-pressure were taken under the same conditions; for upon reducing the former to the same pressure scale as the latter, the combination will show that the high-pressure exhausts at a lower pressure than the low-pressure cylinder receives and the diagrams will lap. Possibly the springs were inaccurate.

The unequal distribution of work should not have broken the rod, for a 3-inch rod transmitting the whole work of the engine (308.6 horsepower) would in the high-pressure cylinder, at 80 revolutions per minute, be subjected to a total load of 18,183 pounds; which is the product of the area of the high-pressure piston (198.5 square inches net) and the mean effective pressure necessary to develop 308.6 horsepower in the high-pressure cylinder alone (91.6 pounds).

The rod would then have been subjected to a unit stress of 18,183 divided by 7.07 (its cross-sectional area), or 2557 pounds per square inch; which, if the rod were not good for more than 50,000 pounds, ultimate, would represent a factor of safety of practically 20.

Assuming that Mr. Sheehan's statements are facts, this failure is clearly the fault of the builders, for it is clear from the above deduction that a 3-inch rod, even of wrought iron would, if sound, have carried the total load of the engine. That the rod showed an old break would indicate that excessive tension was not the cause of the trouble, but that bending, or some local weakness developed it.

Alfred Williamson.

New York City

Vibration and Tension

If an elevator rope, with the car three or four stories from the top, is pulled to one side and then released, it will vibrate slow enough to permit one to count the vibrations.

When two ropes of the same size are suspending the same car, if the tension in one is greater than in the other, the first will vibrate the faster; but I am not certain just what relation exists between the rate of vibration and the tension. If they are directly proportional, it certainly would afford an easy and accurate method of determining the relative tension in two or more ropes.

It seems quite evident that, if the ropes are of the same length, and weight, the rate of vibration depends only on the tension.

Who knows about this subject?

Some Useful Lessons of Limewater

The Chemistry of Sulphur and the Importance of Becoming Familiar with Its Varied Properties, Compounds and Affiliations

BY CHARLES S. PALMER

In starting out on the systematic study of sulphur and its compounds, theoretically one might reasonably ask for a table of the principal compounds, in their oxidized and reduced relations, just as we considered the tables of the compounds of carbon. All that will come in due season, but first let us ask for some tangible and practical illustrations of the compounds of sulphur, at least to show their great importance. One will not have to search long for such an illustration. We find it right at hand, in sulphuric acid, and in many substances which are directly dependent on sulphuric acid for their production and cheap abundance.

Of course, every worker in iron knows how commonly oil of vitriol, that is sulphuric acid, is used to eat off the scale formed on iron forgings; and likewise everyone thinks of the common production of effervescent sparkling waters which are aërated, that is, "airified," by carbonic-acid gas, which is itself set free from soda carbonates by means of this same oil of vitriol. But there are other illustrations of the importance of sulphuric acid, illustrations which are just as important and common but not quite so obvious, unless attention is called directly to them.

Thus, soda and its compounds until recently have been entirely dependent on sulphuric acid for their production; and when one mentions soda he is unconsciously suggesting the importance of such common things as glass and soap both of which are made from soda or its compounds. Moreover, many of the other acids are made by the use of sulphuric acid. Nitric acid is made by the action of sulphuric acid on certain nitrates, and hydrochloric acid is made by the action of sulphuric acid on common salt. Vast quantities of sulphuric acid are used in the purification of crude petroleum, and in manufacturing therefrom the various kinds and grades of burning, cleaning, illuminating and friction oils. Further, large quantities of the waste "sludge acid" from the purification of crude petroleum and also large quantities of fresh sulphuric acid are used in the treatment of crude phosphate rock in order to change into a soluble form the insoluble phosphoric acid so that it can be made soluble for use as fertilizer. These lessons are not primarily written for students of farming, but it is interesting to know that the three chief ingredients of fertilizers are phosphoric acid, potash and nitrogen in some form; and thus we see that one of the three, phosphoric acid as fertilizer, is dependent on sulphuric acid.

Importance of Sulphuric Acid

Indeed, the manufacture of sulphuric acid is so important that nothing else in the whole field of chemistry can be compared to it, except the manufacture of its opposite and contrasted mate, soda and its compounds, always excepting of course, the chemistry of fire and combustion.

There are immense quantities of sulphuric acid locked up in union with lime in the form of calcium sulphate, or gypsum; and yet, strange to say, we have not discovered any cheap and easy method for obtaining sulphuric acid from gypsum. Instead of this we are practically dependent for the manufacture of sulphuric acid on the burning of native sulphur or brimstone, or from the burning of sulphur contained in iron pyrites and copper pyrites. Formerly most of the sulphur used in the preparation of sulphuric acid was obtained from Sicily; but a few years ago it was discovered, accidentally, in boring for oil and water in Louisiana, that vast deposits of sulphur are to be found only a few hundred feet from the surface. Later on we will consider these sulphur deposits, but at present we will keep our attention fixed on the manufacture, the properties and the uses of the king of chemicals, sulphuric acid.

In the burning of pyrites, and particularly in the smelting of copper ores associated with pyrites, vast quantities of sulphur are burned off, and formerly the sulphur dioxide (two-oxide, SO_2) was wasted. In the far West, where the freight rates prohibit the manufacture and cheap shipping of such a common commodity as sulphuric acid, the sulphur fumes from the roasting of pyrites are wasted by the hundreds of tons every day. At the great smelters at Anaconda, Montana, where the low-grade copper ores are mixed with much iron pyrites, sulphur is thrown off into the air by immense chimney stacks in such quantities that it is safely estimated that enough of this material is wasted every day to make some two thousand or more tons of sulphuric acid; and yet this enormous waste goes on, in monotonous regularity, because it would not pay to save the sulphur for making sulphuric acid for which there would be no market. But in some of the works on or near the eastern coast pyrites are roasted in such a manner that the sulphur fume is saved for making sulphuric acid to be used in manufacturing fertilizer, or for any of the other common uses of sulphuric acid.

When the heaps of crude sulphur compounds of iron are allowed to stand exposed to the weather, there is formed much of common sulphate of iron, or "green vitriol," and when this green vitriol is collected and heated in closed stills, it gives off its water and sulphuric acid in the form of a very concentrated and caustic sulphuric acid, called "fuming" or "Nordhausen" sulphuric acid, from the name of a little German town where it was made over a hundred years ago. Afterward a method was discovered for making sulphuric acid from the sulphur fumes, or sulphur dioxide, by using the oxygen of the air in connection with nitric fumes. These nitric fumes are a mixture of several of the oxides of nitrogen, and in the presence of these nitric fumes, with the oxygen of the air, the sulphur dioxide goes over to the sulphur trioxide (SO_3, sulphur three-oxide), or sulphuric form. Later I will show just how the nitric fumes, "NO_2," help the oxygen of the air to make sulphuric acid out of water and the sulphur dioxide (sulphur two-oxide, SO_2).

When sulphur burns in the air, most of it goes to the SO_2, or sulphur two-oxide stage, only 1 or 2 per cent. of the whole going on to the sulphuric or SO_3 stage (sulphur three-oxide stage). In the presence of the nitric fumes, and with just the right amount of water or steam present, all of the sulphur goes over from the sulphurous or SO_2 stage to the sulphuric or SO_3 stage. The SO_3 or sulphuric stage is practically sulphuric acid, for sulphur three-oxide is the anhydride of sulphuric acid.

In this way sulphuric acid has been made so cheap for many years that in recent times the price of the crude acid is not far from a cent a pound. That means that the acid must be used near its place of manufacture, for such a cheap product will not stand the tax of distant and expensive carrying. Therefore, we will usually find a sulphuric-acid plant placed near the factory where it is to be used, in purifying crude petroleum, in making fertilizer, in making soda by the old Leblanc process, or in any of the other more important ways.

In this way it has come about, naturally, that chemical manufacture has built itself up and around the making of sulphuric acid. That is why we rightly call sulphuric acid the king of chemicals. Not to mention fertilizer and refined petroleum, or the other acids which are made from sulphuric acid, also note that the chemical opposite, soda and its compounds (the carbonate, the bicarbonate and caustic soda or sodium hydroxide), are the chemical opposites of and are made by the use of sulphuric acid. Noting all this, one is rightly glad to yield the leadership to sulphuric acid. Of course, in modern times the immense production of "sulphuric pulp," in making common paper from the softer woods, has come to be an industry which is almost incredibly great in its figures, and here we find that the sulphurous oxide, SO_2, or sulphur dioxide or two-oxide, is the active agent in softening the wood fiber; but great as this is, it is secondary to the larger use of sulphuric acid directly and indirectly.

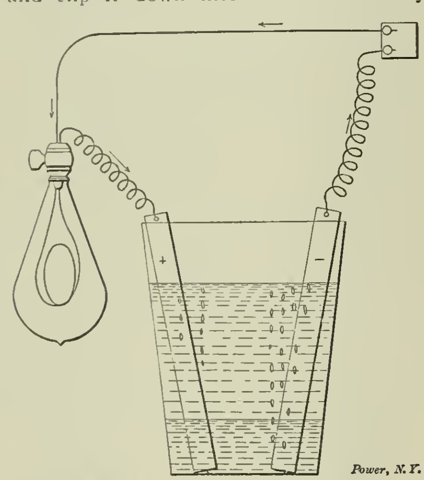
What Sulphuric Acid Is

But it is time to study sulphuric acid for itself. Note, first, that it is a heavy, oily liquid—"oil of vitriol," because it was first made by distilling green vitriol, or sulphate of iron. This sulphuric acid is a very harsh, corrosive liquid. One cannot touch it with anything which contains any water or the ingredients of water, without seeing the sulphuric acid take hold of it like a thirsty wild beast. Drop a little on common white pine or other soft white wood and you will note the inky spots where the acid takes the ingredients of water out of the wood.

Moreover, when the concentrated sulphuric acid takes hold of water, there is some sort of chemical union between the strong acid and the water; for much heat is developed. To show this, pour about an inch of water into a test tube, and then on this, carefully, about as much more of the strong acid. You can scarcely hold the tube, at the lower part, in the unprotected hand, such is the heat developed. Remember the rule which has been given several times as to mixing sulphuric acid and water, to the effect that the acid should always be poured into the water, never the water into the acid. If you stop and think of this, you will see the reason why this is so. Water boils at 212 degrees Fahrenheit (100 degrees Celsius or Centrigrade) and sulphuric acid boils at a much higher temperature, nearly up to the melting of common solder. Consequently, if the water is poured on the acid, so much heat is let loose by the first drops of water that the acid is warmed up at once, and the next drops are liable to be driven off into steam, as the acid gets at it; at any rate an explosive shooting-out of the water and acid occurs.

But if the acid is poured into the water, it mixes evenly with the water and, although the temperature rises quite high, the results act as though the water were a part of the acid, which is not far from the truth. This difference between strong or concentrated acid and dilute acid is so marked that the acid is often used in taking water out of things. Common alcohol can be turned into ether by distilling the two together, and the resulting ether is still popularly called "sulphuric ether;" not that ether contains any sulphuric acid, but simply that it is made from alcohol by the dehydrating or "water-subtracting" action of the strong acid. This difference between the concentrated and the dilute acid is so marked that it is now said, and quite truly, that sulphuric acid is not really an acid until it is diluted with water.

What is meant by this is shown best by an experiment. Take a strip of zinc, say half an inch wide and three inches long, and slip it down into a clean and dry



EXPERIMENT WITH DILUTE SULPHURIC ACID

test tube. Then pour over it about an inch of strong sulphuric acid. If you have never done this before you will be surprised to see but little action of the metal and acid on each other. But now, cautiously, break the rule just given (as to never pouring water on strong sulphuric acid) and you will note that, as you carefully pour on enough water to dilute the acid to, say, one part in four or five of water, the action between the metal and the acid will begin vigorously. You want to study this experiment and do some thinking with it. It used to be said that the first action of the acid on the metal is to make sulphate of zinc, and that then the action stops until some water is added to dissolve off this zinc sulphate so that more acid can get at the zinc. But that is hardly the way to look at it, for much more than this is happening.

Dilute Sulphuric Acid an Electrical Conductor

You will remember that it has been stated that acids are salts of hydrogen. Now the action of zinc on dilute sulphuric acid is to displace the hydrogen from the acid. But if the zinc cannot do this from the strong and concentrated acid, evidently the hydrogen is not ready to be set free from the concentrated acid as it is ready to be set free from the dilute acid. This is precisely what happens. The action of the water on the strong acid is to unlock, in some strange way, the hydrogen so that it is ready to be thrown off by the zinc. This difference between the locked and unlocked states of the hydrogen in the sulphuric acid is also shown by the fact that strong sulphuric acid is not a good conductor of electricity, while dilute sulphuric acid is an excellent conductor. This is shown by the following experiment:

I will suppose that you have a common electric light in your boiler room, with direct current. Arrange your tumbler electric battery cell, as shown in the illustration, but with both poles made of copper. Connect one pole to the leading wire from the current supply, and the other wire to a common lamp, using the lamp as a resistance. No more current can go through the tumbler electrolytic cell than can go through the lamp, so you are safe there. Having all ready, as shown in the illustration, pour about an inch of strong acid into the tumbler with the copper poles. You will note that but little current will flow and the proof is that the electric lamp will give out hardly any light. But replace the strong sulphuric acid by several inches of dilute acid and at once the electric lamp will light up, because the dilute acid is a good conductor of electricity. If you watch to see at which of the two copper poles the hydrogen comes off, you can tell which is the anode or in-going pole and which the cathode or out-going pole. Remember that hydrogen will come off from the cathode in the electrolytic cell, because the hydrogen, being the metallic element, goes with the positive current.

Some gas will come off from both poles, but the hydrogen is twice as great in volume as the oxygen; and so it is easy to decide which is the cathode or out-going pole of the current. In this way one can tell the direction of the direct current which is supplying his light. Of course one can use the small battery of the zinc-copper couple, described in a previous lesson; but that is rather a weak current with which to get satisfactory results. Still, one can do much good work even with weak currents.

Just why the concentrated sulphuric acid does not readily conduct electricity and why the dilute acid does conduct it are interesting questions. Broadly, it may be said that this difference between concentrated and dilute sulphuric acid is one of the main points in the modern theory of solution. It is evident that adding water to dilute the strong acid does something to the hydrogen so that it can be released from the sulphuric acid, either by the zinc, or by the electric current. This quality or condition of the dilute sulphuric acid, as contrasted with the concentrated acid, is called "dissociation," and that word means just what you have noted in the ready release of the hydrogen from the sulphuric acid by either the zinc or the electric current. The acid acts as though it were in some way separated or dissociated into its active parts. The two atoms of combining parts of hydrogen in sulphuric acid, H_2SO_4 make the parts on one side. To find what are the other parts of sulphuric acid, just write out the formulas of several of the sulphates or salts of sulphuric acid with several of the metals, and note what is common to all of the sulphates. You will find that the imaginary group, "sulphion," SO_4, is found both in sulphuric acid itself, and in each of its sulphates, thus: Sulphuric acid itself is $H_2—SO_4$; blue vitriol, or sulphate of copper, is $Cu—SO_4$; green vitriol, or sulphate of iron, is $Fe—SO_4$; white vitriol or zinc sulphate, is $Zn—SO_4$; gypsum, or calcium sulphate, is $Ca—SO_4$; glauber's salt, or sodium sulphate, is $Na_2—SO_4$; epsom salt, or magnesium sulphate, is $Mg—SO_4$, and so on.

Peculiar Action of Water

In all of these salts there is more or less of "water of crystallization;" but I have neglected that part of the formulas, to keep the attention fixed on the simple form of the salts in question, and you will note that in every case there is the imaginary group, SO_4, sulphion, which runs through all of the sulphates or salts of sulphuric acid. Evidently this sulphion group is the other part of sulphuric acid which remains when it is separated or dissociated into its active chemical or electrical parts by simple dilution with water. I shall have much more to say about this peculiar action of water from time to time; but it should be noted here that while the old chemistry used to say that when an acid and a base act upon each other a salt is formed, and water is the side product, modern chemistry says that when an acid and a base act upon each other water is formed and the respective salt is the side product. This is only one way of saying over again, what has already been noted, namely, that we live under the conditions of a water chemistry. It is water that acts upon common chemicals, waking them up to life and quick response to mutual exchange. We shall find that dilute solutions of acids, bases and salts make the common field of active chemical reaction and of quick electrical conductivity.

But we are studying the chemistry of sulphur in particular; and before closing this chapter, let us look for a moment at the accompanying plain oxidation table of sulphur. Note that on the left-hand, or reduced end, comes hydrogen sulphide, then sulphur itself, then sulphur dioxide, SO_2 (sulphur two-oxide, or sulphurous anhydride, because it is the anhydride of sulphurous acid); and, lastly, sulphur trioxide, SO_3 (sulphur three-oxide), the anhydride of sulphuric acid and sulphuric acid itself, H_2SO_4.

Here it is well for us to note that salts are usually named from the acid which makes them, giving the salt the ending "ate" if the name of the acid ends in "ic," and giving the salt the ending "ite" if the name of the acid ends in "ous." Thus sulphuric acid forms *sulphates*; from nitric acid comes a *nitrate*; from phosphoric acid comes a *phosphate*; from oxalic acid comes an *oxalate*, from acetic acid comes an *acetate*; from silicic acid comes a silicate, and so on. Similarly from the "ous" acids, come the salts ending in "ite." Thus sulphur*ous* acid makes the sulph*ites*; nitr*ous* acid, the nitr*ites*; phosphor*ous* acid, the phosph*ites*; and so on. It will be easily remembered that the "ous" acids and their salts, the "ites," are in a relatively lower state of oxidation than the "ic" acids, and their salts, the "ates." Sulphurous acid and the sulphites are in a lower state of oxidation than the sulphates and sulphuric acid.

If there were such a thing as "carbonous" acid, it would form the "carbonites," just as the more highly oxidized carbonic acid makes carbonates. As a matter of fact, real "carbonous" acid is well known, only it happens to be called formic acid, and makes the formates, as you will find by looking at the oxidation tables of carbon in a previous lesson. All this naming of acids and salts is a part of what is called chemical nomenclature, the long-name-ology of chemistry, and it will repay one to master the simple rules here given in naming common salts, for it is part of the system in general use. The only common exception to the naming of salts from acids is found in the names of such a thing as common salt, NaCl, which is made from common hydrochloric acid or muriatic acid. Common salt, NaCl, sodium chloride and hydrochloric acid, HCl or hydrogen chloride, are so-called because they are made up of two things, and two-thing compounds (or binary compounds) are given names which end in "ide," as the chlorides, the oxides, the sulphides, the nitrides, and so on. Thus, hydrobromic acid, HBr, hydrogen bromide, makes the bromides, as potassium bromide, KBr (kalium is the chemical Latin for potassium, the alkali metal). This careful use of names is only giving one many delicate mental forceps for picking up and handling neatly many valuable chemical facts. One handles potatoes with a potato digger, but one picks up diamonds with fine pincers; so you are assembling your kit of chemical tools for much good work which will be to your later and practical advantage. But just put in a few minutes with this table of sulphur compounds; it will be needed in treating this wonderful subject of sulphur, which is only a part of chemistry, the finest subject in the world.

TABLE OF SULPHUR COMPOUNDS

Reduced End			Oxidized End
H_2S Hydrogen Sulphide. The sulphides	S, or S_2 Elemental Sulphur. Lower Amorphous Crystalline	SO_2 Dioxide Sulphurous Anhydride	SO_3 Trioxide Sulphuric Anhydride
		H_2SO_3 Sulphurous acid	H_2SO_4 Sulphuric acid
		Sulphites	Sulphates

Fallacious Reasoning

By C. M. Ripley

Will one kind of coal with 13,000 B.t.u. per pound evaporate 30 per cent. more water than another kind of coal containing 10,000 B.t.u. per pound? At first glance many of us might be inclined to say yes to this question. But it is a fallacy to reason that as it takes heat to evaporate water and the B.t.u. is a measure of heat, therefore the more B.t.u. per pound of coal the more water will be evaporated proportionally.

Where the Fallacy Is

The weak point in the argument is that while the B.t.u. is an exact measure of the heat in the coal, it is not an exact measure, by any means, of the heat that can be put into the water. Obviously, the difference between total heat and useful heat is boiler efficiency. And right here comes in a question that is not often asked: "Does the efficiency of any certain boiler change as the type of fuel is changed?"

The answer to this question is that the efficiency of a boiler does change and can be 20 per cent. different in the same day, with the same wind prevailing and the same conditions existing in the draft, dampers, door openings, depth and care of fire, etc.

Why Boiler Efficiencies Change

The heating value which goes up the stack consists partly of unconsumed gases. Bituminous coal has a much larger percentage of volatile matter than any other solid fuel in common use. This volatile matter, called the "volatile hydrocarbons," is from 20 to 40 per cent. of the weight of the coal. As soon as coal is fired, the volatile matter begins to separate itself from the coal and start toward the stack. Since anthracite has on the average from one-sixth to one-tenth as much volatile matter as bituminous coal, it at once becomes apparent that the chance of unconsumed gases going up the stack from bituminous coal is six to ten times greater than if anthracite were used.

It is for this reason that it is difficult to get more than 80 or 85 per cent. boiler efficiency with bituminous coal, although anthracite carefully fired can easily give from 70 to 80 per cent. boiler efficiency.

The fixed carbon in both cases has little tendency to do anything besides stay on the grate bars until perfectly consumed. We can see therefore one of the great advantages in burning coke, since coke has no volatile matter and runs about 92 per cent. fixed carbon. The following analyses of different fuels will show the variations in the combinations between fixed carbon and the volatile hydrocarbon of four different fuels, and also their B.t.u. per pound:

CHEMICAL ANALYSES OF DIFFERENT FUELS.

	Bituminous.	Anthracite.	Buckwheat.	Coke.
Fixed car	60%	80.87%	76.92%	92.38%
Vol. H.C.	32%	3.98%	1.05%	
Ash.....	8 to 10%	11.23%	16.62%	7.21%
Heat units, B.t.u..	11,000 to 14,500	12,000	11,000	13,500

It would not necessarily be true for a fuel salesman to say: "I am selling a low-grade fuel which costs only a little more than half as much as buckwheat, and but little more than a third as much as a larger size anthracite. You get in my fuel 20 per cent. more B.t.u. for a dollar than in the kind of fuel you are now burning. Therefore you can expect a reduction of 20 per cent. in your fuel bill."

The shrewd engineer, before accepting this statement as true, will inquire: "What are the percentages of fixed carbon, volatile matter and ash in this fuel?" This is a very pointed question, and when we realize that the losses up the stack increase rapidly as the volatile matter in the fuel increases over 20 per cent., we can see readily that the heat units in a fuel are not a true measure of the usefulness of that fuel.

The error of this method of judging fuel can be corrected approximately by estimating what the efficiency of the boiler would probably be. The foregoing figures regarding boiler efficiency show a possible error, which can be stated as follows: Bituminous coal with 32 per cent. volatile matter, as compared with anthracite containing 4 per cent. volatile matter, gives approximately 20 per cent. lower boiler efficiency.

The advocates of elaborate tests of the B.t.u. in samples of coal should bear in mind that the item of boiler efficiency is to be reckoned with. In the same general types of coal the B.t.u. value is a fair judge of the evaporating value of the coal. But in comparing fuels of an entirely different nature, the discussion of the heat unit per pound is valuable only when taken in conjunction with boiler efficiency and proportion of volatile matter, ash, etc.

In a recent interview on this subject, Percival Robert Moses, consulting engineer, said:

"I have appreciated this fact for some years, and in the capacity of advisory engineer have recommended the use of those fuels which are low in the percentage of volatile hydrocarbons. The extent to which high boiler efficiency shows up on the cost record is amazing. We have frequently, working in conjunction with the chief engineer of a power plant, replaced a fuel costing $4.10 per ton with a different fuel costing $2.08 per ton. The surprising part is that with a theoretical difference of 2000 B.t.u. per pound in favor of the more expensive fuel, the month's consumption of the lower-grade fuel would show the same number of tons as when the expensive fuel was used. Since cheap steam is the foundation of power-plant economy, the savings effected have sometimes been remarkable."

Two Interesting Boiler Accidents

While inspecting and applying hydrostatic pressure to several small vertical boilers connected to hoisting engines operating on Devonshire street, Boston, Mass., the inspector's attention was called to a leak at one of the rivets in the lap seam of one of the boilers which had not been examined. Apparently the rivet had been calked several times without stopping the leak.

The working pressure carried was irregular, varying from that which would operate the engine under light loads to 90 pounds, at which point the safety valve prevented farther rise of pressure. Hydrostatic pressure was applied and at 93 pounds pressure, with a light snap, a crack about 2 feet long appeared in the overlapping sheet along the edge of the row of rivet heads. See Fig. 1.

This form of crack is exactly what would be expected if two sheets of metal were joined with a lap-riveted seam and then subjected to repeated bendings back and forth, until one of the sheets cracked. In the nature of the case it would not fail anywhere else.

A course in a boiler with a lap seam cannot be round and the pressure of steam tends to make it round. When the pressure is lowered or removed, the course tends to return to its original shape, and it is this bending, or breathing as it is sometimes called, that makes the lap seam an unsafe joint in boiler construction.

In the boiler room of the American Wringer Company, Woonsocket, R. I., on Sunday, September 27, 1908, at about 6 p.m., while steam was being raised in a boiler which had been out of service for some days for cleaning and minor repairs, the attention of the engineer was called to escaping steam near the rear end. Examination showed that it was coming from the longitudinal seam in the end course.

Pressure on the boiler, which had reached 85 pounds, was reduced as rapidly as possible and an examination made. This point was of butt double-strap treble-riveted construction and failed by cracking through the outer row of rivet holes, and it is believed to be the only failure of this nature that ever occurred in a butt and strap seam.

Inspection showed that the cause of the failure was not difficult to locate and could with certainty have been predicted from the beginning had the conditions been known. The boiler was not round and at the joint the curvature of the sheet departed 5/16 of an inch from the circle to which it should have conformed.

The boiler was of the horizontal tubular type, 17 feet 4 inches long. The inside diameter of the outside course was $72\frac{5}{16}$ inches; thickness of shell plates, 0.45 inch; thickness of heads, 0.5 inch. There were 132 three-inch tubes, 16 feet long, and six $1\frac{1}{2}$-inch through stays of iron upset to $1\frac{3}{4}$ inches where threaded, passing through channel-iron bars on the heads with nuts inside and out. Stamps found on the rear course in which the crack developed gave the name of the manufacturer and stated that the firebox had a tensile strength of 60,000 pounds. The type of longitudinal joint was butt and double strap, the inside strap being wider than the outside strap. The riveting was triple, the pitch of rivets on the rear and middle courses being $3\frac{3}{8}$ and $6\frac{3}{4}$ inches; on the front course it was $3\frac{1}{4}$ and $6\frac{1}{2}$ inches. The size of the rivet holes was 15/16 inch. The efficiency of the joint was 85.5 per cent. on the front course and 86.1 per cent. on the other courses. The safe working pressure, using a factor of safety of 4.5 and a tensile strength of 60,000 pounds would have been 141.8 pounds. Using 55,100 pounds, the actual tensile strength, the safe working pressure would have been 130 pounds.

The result of physical tests and chemical analysis made on test specimens cut from the shell plate in the immediate vicinity of the cracked section and in a girth-wise direction showed a tensile strength of 55,100 pounds, the elastic limit being 35,300 pounds per square inch. The elongation in 8 inches was 23 per cent. The appearance of the fracture of the test piece after breaking was silky. The chemical analysis was as follows: Manganese 0.65 per cent.; sulphur 0.045 per cent.; phosphorus 0.033 per cent.

A strip bent cold closed down upon itself without fracture on the outside of the bent portion, but developed two cracks on the inside. A strip heated cherry red and quenched in water was bent down upon itself and developed no fractures inside or out. A templet sawed to a radius of $35\frac{19}{32}$ inches, placed on the rear course of the boiler, developed the fact that the boiler departed 5/16 of an inch from a circle at the joint. A templet was sawed to fit the actual curve of the boiler. The templets nailed together giving a graphical representation of the difference between what the curvature of the boiler should have been and what the curvature was. An examination of the rivet holes in the rear course of the boiler developed the fact that the holes had been punched nearly full size, the slight amount of metal, taken out by reaming not being sufficient to leave the full size holes fair, this being shown by the rivets which were taken out of the boiler not being of uniform diameter. The burs at the edges of the rivet holes had not been entirely removed. The distance from the center of the rivet holes to the edge of the plate was not 1½ times the diameter of the rivet hole.

Internal inspection disclosed the fact that the shell plate on the lower half of the joint was cracked on the outside row of rivet holes, which were pitched 6⅛ inches apart as stated elsewhere, this crack starting at a point 1⅛ inches to the right of the second rivet hole from the rear girth seam and extending through seven consecutive rivet holes to a point 1½ inches from the seventh hole, or a total distance of 43⅝ inches. Internal inspection also disclosed the fact that the shell plate on the upper half of the joint, on the outside row of 6⅛ inches pitch, was also cracked. These cracks, however, were not continuous, and were confined to the region of the rivet holes, extending about 1 inch each side of three consecutive rivet holes, then skipping a hole. The next rivet hole was cracked on one side for about 1 inch, the rear end of the crack starting at a point between the third and fourth rivet holes, counting from the rivet holes in the rear-head flange, after skipping one hole, counting from the rivet holes in the rear girth seam, ending at a point between the second and third rivet holes, counting from the rear girth seam.

The crack on the lower half of the joint extended on the outside of the plate a distance of 29½ inches through five consecutive rivet holes, starting at a point 1⅛ inches to the left of the fourth rivet hole in the outside row, continuing from the rear girth seam and extending to a point 1¼ inches to the right of the first rivet hole in the outside row counting from the rivet holes in the rear-head flange. The third rivet hole, however, counting from the rear girth seam had two cracks extending from it a distance of 1¼ inches to the right of the hole and a crack 1 inch to the left of the hole. Adding the length of these two cracks to the continuous crack of 29½ inches would make 31¾ inches, the length of the entire cracked portion as seen from the outside of the boiler. Comparing this length of 31¾ inches with the length of the continuous crack of 43⅝ inches, as seen from the inside of the boiler, it will readily be seen that the crack started from the inside of the boiler and worked its way through to the outside. The crack as seen from either the inside or outside of the boiler resembles in no way the ordinary lap-joint crack. Ordinary lap-joint cracks extend in a more or less straight line through the solid plate along the edge of the rivet heads.

This boiler was sixteen years old and keeping in mind that it was exposed to excessive vibration for five years, that a cold-bending test resulted in two cracks on the inside of the bent portion, that the chemical analysis showed an excess of manganese, sulphur and phosphorus, and that the rear course of the boiler departed from a true circle 3-16 of an inch at the joint, and that the rivet holes had been punched almost full size, it would seem that the wonder is not that the boiler developed these cracks, but that it did not develop them before and that a disastrous explosion did not occur. Fig. 2 shows quite clearly the condition of the plate.

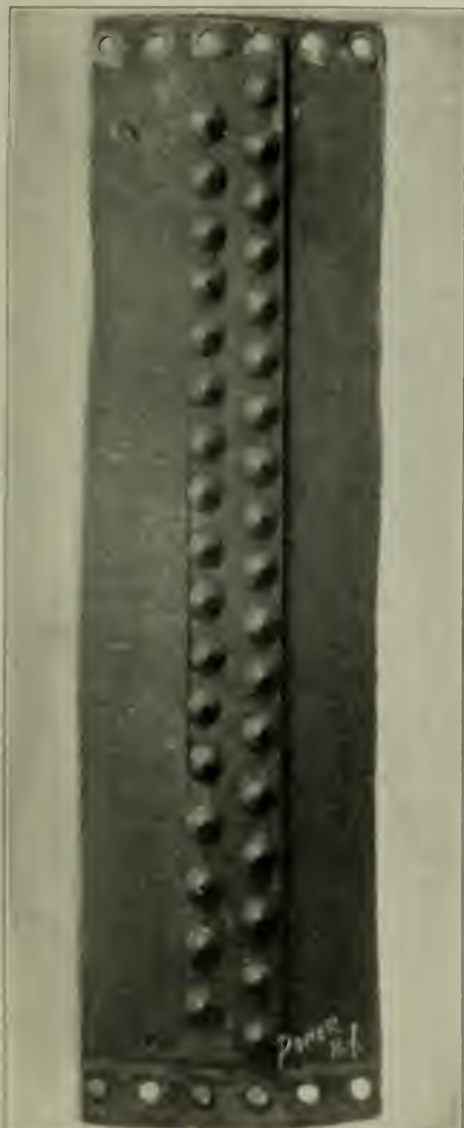


FIG. 1

FIG. 2

In transmitting a list of Nova Scotia firms handling steam pumps and machinery, which is on file at the Bureau of Manufactures, Consul-General David F. Wilber reports from Halifax as follows:

The sale of steam pumps in this district is largely by catalog, the same being in the hands of various machinists and general dealers in such lines. It is my opinion that if a competent agent were secured in that city and supplied with pumps for display in his salesrooms the chances for increased sales would be better than trying to sell by catalogs, as is done at present.

Consul-General Wilber further, in forwarding a list of firms at Halifax which might be interested in the sale of windmills and pumps, states that from his observations in Nova Scotia there is no single article which should be in demand among the farmers through that Canadian province so much as pumps and windmills.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 *copies of* POWER.

Our circulation for May, 1909, was (weekly and monthly) 152,000.

June 1 42,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Uniform Boiler Laws

Mr. Thomas Durban, of the Erie City Iron Works, in an address presented to the National Association of Manufacturers, at its meeting in New York recently, complained of the hardships to which the manufacturer of steam boilers is subjected by reason of the varying requirements of the boiler-inspection departments of different States, and even of different cities. "Various States in the Union," he says, "have enacted laws governing the matter of steam boilers, stating the quality of material to be used, the thickness of the material, and the manner in which it shall be put together, and in no two States are these laws similar, so that a general contractor or a general manufacturer who finds it necessary to locate branch factories in various States is confronted by the fact that he must have boilers built to conform with the various laws of the States, and a boiler that would fully comply with the requirements in New York State could not be used in Massachusetts, and one that could be used in Massachusetts could not be used in Pennsylvania, etc.

"The detriment of this can be readily realized when you take the case of a general contractor building buildings. A man may have a hoisting engine working on a job in New York. If he bids on a job in Boston, he is not allowed to use this engine in Boston; or he may have a contract in the City of Harrisburg, Penn., and cannot use the same equipment to complete a contract in the City of Philadelphia. In order to keep down the cost of production most manufacturers bring their goods through in duplicate and in quantities; in fact, the ability to do this distinguishes the manufacturer from the builder. This not only appertains to stationary boilers and portable boilers used in the construction of roads or buildings, but also portable boilers used by farmers in general farm work or in threshing. A manufacturer of threshing machines is compelled to build a different boiler for Massachusetts than he builds for Washington, and a different one for the State of Washington than the one built for Montana. So that the tendency is to localize business and to work against the manufacturer who is attempting to develop a large trade. This is not only detrimental to the manufacturer, but is equally detrimental to the user or the consumer, from the fact that he must pay an advanced price for his goods, and it greatly delays shipment."

The situation pointed out by Mr. Durban suggests the necessity of organization and uniformity of practice and requirements by the boiler inspectors. At present comparatively few States and cities have boiler-inspection departments, but the agitation is ripe and each season many bills for the creation of such departments are introduced. With their multiplication, and without substantial agreement among them, the situation of the boiler manufacturer might become very uncomfortable.

But the reputable boiler manufacturer does not want to build boilers that are not safe, and no board of inspectors wants to make rules that are unreasonable or unnecessarily severe. A boiler that is safe in one class of service in one State is as safe in the same class of service in another State. The laws of statics are not of political origin, and the capacity of material to resist rupture knows no geographical bounds. Such differences of opinion and of practice as exist between the various boards should be easily reconcilable and manufacturers would be unlikely to oppose whatever restrictions and regulations such boards might impose, provided they were imposed uniformly and all manufacturers and users were treated alike.

How Much Does It Cost to Clean Boilers?

How much better off would you be if you had absolutely pure feed water for your boilers, so pure that it would leave absolutely nothing behind it when it boiled away?

Our thought deals not so much with the decrease of efficiency by reason of the presence of scale, grease, etc., as with the cost of removing these deposits, and of making good the damage which they have caused, the loss of the use of the boiler during the cleaning and repairing process and the increased investment and standing charges created by the necessity for extra boilers.

The loss from scale while running is an indeterminate and widely variable factor. If one has plenty of boiler-heating surface, if the ratio of grate to heating surface is low and the rate of combustion moderate, the fouling of some of the surface to a considerable degree, or of all of it to a moderate degree, will have little effect upon the number of pounds of steam made per pound of coal. If, on the other hand, the heating surface is worked to its capacity and the number of pounds of coal burned per square foot of heating surface is large any deposition of scale upon that surface will have a much more serious effect upon the boiler efficiency. When, in addition, the influence of the density or porosity of the scale is taken into account the engineer is inclined to shrug his shoulders when he sees the frequently published statements of the percentage effect of various thicknesses of scale upon the coal consumption.

Some interesting figures could be made upon the other costs which have been mentioned, were the data available. How often must a boiler be cleaned? It depends, of course, upon the amount and character of foreign matter in solution or suspended in the feed water, but we need actual information for the general case, with such particulars as are available of the character of the feed and of the means which are resorted to to prevent scale. How much does it cost to clean a boiler of a given type and capacity? How long is it out of service? How often are tubes required to be renewed? How many fire sheets are burned or bulged by the presence of scale or grease? Practical information of this kind based upon records of experience would be especially desirable for our correspondence columns and we should be glad to have our contributors turn their attention in that direction.

Place the Blame for Boiler Accidents

In a sawmill out West the boiler exploded, killing six men and seriously injuring five others. It is stated that the sentiment of the coroner's jury in the case was expressed by the remark of one of them, who said: "They are dead, anyway, so what is the use of making a fuss?"

It is possible that the responsibility for a preventable calamity which either destroys or mars the life of eleven men, and adds to the burden carried by those directly connected to them by the various ties of human life, may not be placed at the door of the mill owners. But it should be placed, in a way that cannot be misunderstood, where it belongs. It may rest on the engineer, on the inspector or perhaps on the man who made the boiler. But blame there is, for every occurrence of this kind. These things happen because of the ignorance or cupidity, or perhaps both, of some man or some set of men, who bring about a condition which inevitably results in loss of life and the destruction of property.

That this state of affairs is not necessary is amply proved by the comparative immunity from disastrous boiler explosions enjoyed by Massachusetts and by the city of New York, where intelligent construction and inspection are compulsory. It is a fundamental principle in modern civilization that the individual has no rights which society is bound to respect and the privilege of manufacturing, installing and operating potentially dangerous apparatus has been allowed altogether too long. It may not be possible entirely to stop boiler explosions, but until that day comes when the use of high pressure steam for the transmission of power shall be unfashionable the manufacture and use of steam boilers should be regulated by society and not by individuals or groups of individuals with no interest beyond the profit arising from traffic and use.

State Boiler Inspection

In 1908 there were 470 explosions of stationary and portable boilers in the United States, a total almost identical with the record for 1907, and the number of persons killed by explosions was 281, as compared with 300 in 1907, 235 in 1906, 383 in 1905 and 220 in 1904. These figures were recently published by the Hartford Steam Boiler Inspection and Insurance Company. The company's records for the forty years from 1868 to 1907 show a total of 9550 boiler explosions, and the casualties resulting number 10,555 persons killed and 15,051 injured. This means a total of 25,606 persons maimed or killed in forty years, an average of 640 per annum, although in late years the annual number has been considerably in excess of this average, not to mention an enormous property loss.

These figures show plainly the menace to life and property of the high-pressure steam boiler, as it is now built and inspected, and indicates the urgent need of State legislation. With boilers properly built and carefully inspected, and the use of a reasonable amount of care in operation, there is little necessity for a single explosion, and no occasion whatever for the wholesale number now appearing in the annual reports. The lap-seam boiler has been the cause of many of these explosions, careless inspection has added its quota and inferior construction in boilers of the better class has augmented the total.

Bearing in mind that it is possible to operate a boiler with immunity, provided it is properly designed and constructed and is subject to a systematic and careful inspection, it is surprising that the subject of boiler explosions has not been given more general attention. Only five States have considered this annual destruction of life and property of enough importance to enact legislation providing for State inspection of boilers and regulation of their manufacture. Other States have given their municipalities the privilege of passing and enforcing ordinances, but legislation along this line is not uniform even in cities of the same State, and in most of the smaller towns it has been entirely neglected.

If this same number of people were killed and injured in one State there would undoubtedly be legislation, and if limited to one city such disaster would be deemed appalling. Its effect would be far reaching, and every State in the country would undoubtedly inspect the manufacture and operation of its boilers. When the matter is seriously considered, is there really any difference? The 300 lives are lost annually, and twice this number injured, and does it matter whether the unfortunates all live in one city or in one State, or are distributed throughout the country? In time of war, when 300 men are killed so many soldiers are lost to the country, and the loss is just as great and of as much importance whether the entire number come from New York State or are equally divided among the forty-six States of the Union. In a similar way should the annual loss of 300 lives from boiler explosions be regarded. Each State should assume its share of the responsibility and contribute to the general welfare of the country by preventing a needless waste of life and property within its borders.

Keeping Power Plant Records

One of the important factors in the cost of power-plant operation after fuel and labor expenses are figured, is the cost of maintenance. In order to know just what a plant is doing it is essential to keep an accurate record of the repair work. This is not difficult if the proper entries on the log sheet or in the engineer's notebook are made as soon as possible after the different jobs are finished. It often happens that the operating engineer is not informed what the different repairs cost. He is certainly entitled to know, if he is required to figure out the cost of power at regular intervals, but even if the actual costs are withheld through thoughtlessness or other cause, it is decidedly worth while to keep a record of the important repair items.

In one plant the cost of power production at the direct-current busbars per kilowatt-hour was 1.88 cents, for a recent month, as compared with 1.59 cents the previous month. The manager of the company naturally looked into the cause with the chief engineer. Incidentally, the cost had been figured in the company's offices by clerks out of touch with the operating condition. The chief engineer knew that he had used about one-tenth of a pound of coal per kilowatt-hour more in the second month, and also that the cost of coal per ton at the plant was 15 cents less than in the month when the total expense was lower. The labor cost was about 0.1 cent higher per kilowatt-hour in the second month, on account of a considerable reduction in the station load. The difference, as proved by the notes of the chief engineer, was largely due to an improvement at the station which had been charged up to operation by the bookkeeping department.

This improvement was the tearing out of all the wiring bearing on the lighting service and the replacement of the old system of incandescents by a higher-powered installation having much greater operating convenience. That the engineer was able to look over his notes of daily happenings made it easy for him to put his finger on the exact causes of cost variation, and clear himself.

MUST BE NEW OR INTERESTING

The New Class E American Stoker

The latest design of underfeed stoker is the "New American Stoker, Class E," of the American Stoker Company, 11 Broadway, New York City. It is so designed that no working part is in contact with fire, thereby eliminating the danger of burnt parts.

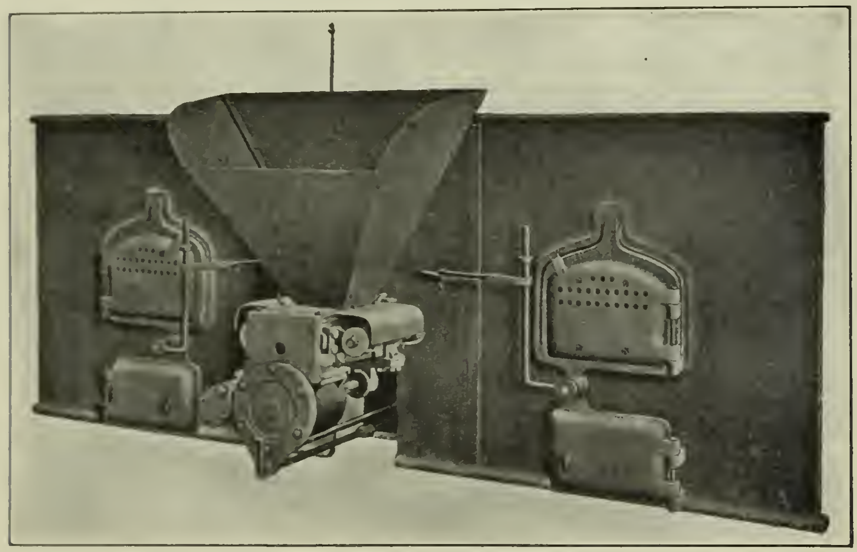

FIG. 1. FRONT VIEW OF "AMERICAN CLASS E" STOKER

This stoker is built on an oscillating-bottom principle, the feeding trough being in constant motion, gradually feeding coal to the fire above. While the coal is never allowed to settle in this trough, it cannot be driven in chunks or masses into the fire, even in the case of overloading.

The furnace doors, grate bars, etc., are air cooled, while the air for combustion is heated before its introduction to the combustion chamber. Every other grate bar is hollow, a current of air constantly passing through to the coal trough, at which point it is mixed with the gases which have been liberated from the coal, while between alternate bars there are spaces through which air is forced from the ashpit below.

The operation of the stoker is as follows: The fuel may be conveyed to the hopper either by coal-conveying machinery or by hand labor, and from the hopper it is carried under the fire by means of the reciprocating sliding bottom. As the coal rises from the trough, it is distributed to the sides of the furnace by the moving bars, shown in Fig. 2, which keep it constantly on the move toward the dumping trays along each side wall, where the clinkers and ashes are deposited. By means of levers on the outside these dumping trays can be actuated to discharge the ash and clinker automatically. The sliding bottom is actuated by a steam motor, shown in Fig. 1, the number of strokes of which may be varied from 1 in three minutes to 15 in one minute, and as each stoker is said to carry into the furnace about six pounds of coal, it will be seen that the rate of feed has a wide range of adjustment.

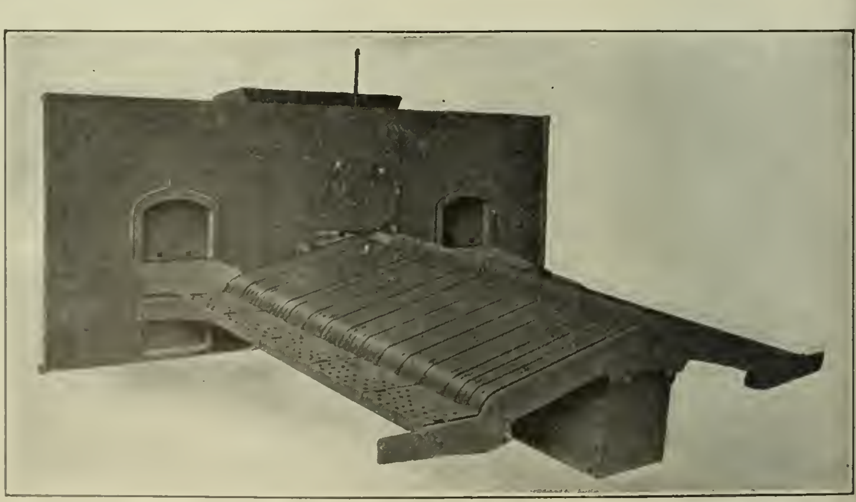

FIG. 2. SHOWING GRATE SETTING IN "AMERICAN CLASS E" STOKER

The movement of the piston of the cylinder *C*, Fig. 3, is transmitted directly through the piston rod to the crosshead *D*, which is bolted to the sliding bottom *E*. As the block *B* has the same movement as *D* and *E*, the coal is fed by it from the bottom of the hopper *A* onto the sliding bottom *E*, which not only carries it to the back end of the furnace but forces it to rise the full length of the trough. As the coal rises in the trough or coking retort, it is flooded onto the grate bars *F*, which are alternately moving and fixed bars, the moving bars working transversely to the retort, the extent of the movement being from ½ to 1 inch, depending upon the size of the furnace.

On the bottom of each moving bar are cast two lugs which engage with a bulb of the longitudinal rocking bars *H*, Fig. 4. These rocking bars in turn receive their movement through the agency of two spirals and nuts, which mechanism is entirely outside the furnace. The nuts are bolted to the crosshead *D* and reciprocate with the bottom *E*, the reciprocation of the nuts causing the spirals to rock to and fro.

The movement of the grate, in addition to carrying the burning fuel to the sides of the furnace, also conveys the clinker down and deposits it on the plates *K*, which are fastened to the hinge bars *L*. These hinge bars are actuated by levers conveniently placed outside of the furnace for dumping the accumulation of ash and clinker on the plates *K* when necessary.

One of the important features of the

stoker is the distribution of the air which enters the stoker through the aperture N, Fig. 3, which is covered by the wind gate O. This wind gate is adjustable by a crank P at the outer end of the furnace. The air upon entering the wind box Q passes upward along each side of the troughs or retorts and is discharged partly through the holes R into the retorts. The surplus air passes through the bar F

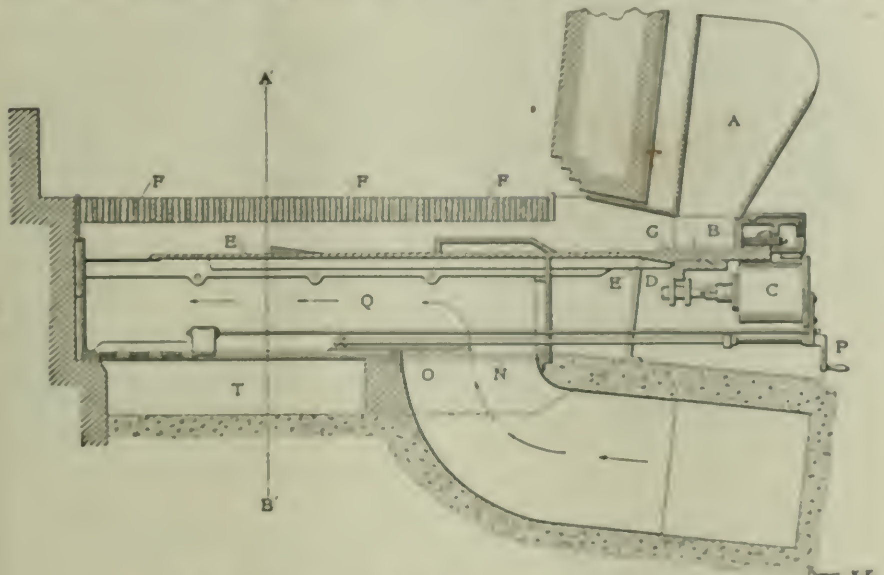

FIG. 3. SECTIONAL VIEW OF "AMERICAN CLASS E" STOKER

which is made hollow, but as the bar has no opening in its top surface, no air can find its way into the fire above it until it has passed through the aperture S at the bottom end of the bar, from which aperture it is discharged into the ash-pit. The air then rises and passes through the small spaces between the bars into the coked fuel.

The air passing through the bars keeps them cool and prevents their being burned

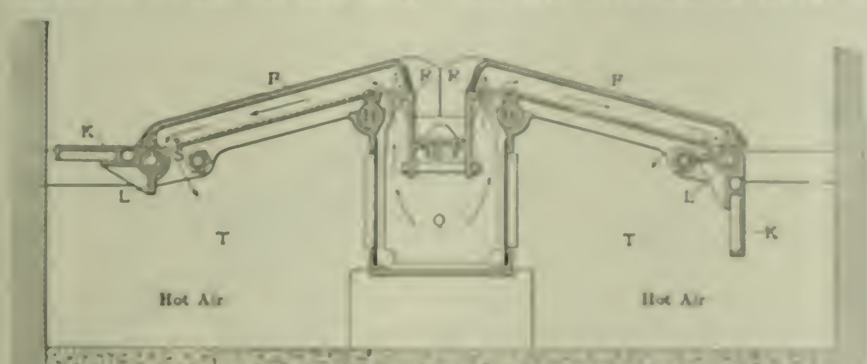

FIG. 4. SHOWING MECHANICAL OPERATING FEATURES

out. The heat taken from the bar in this way is said to raise the temperature of the air in the ashpit from 150 to 400 degrees Fahrenheit. The pressure of the air in the wind box Q is said to vary from ½ inch to 1¼ inches, and at T from 0 to ¼ inch.

When the dumping plates K are let down, air will find its way upward among the boiler tubes, but as the action of dumping and raising them takes but a moment, the loss from air passing upward into the boiler tubes is so slight that it is not necessary to close the wind gate O at such time.

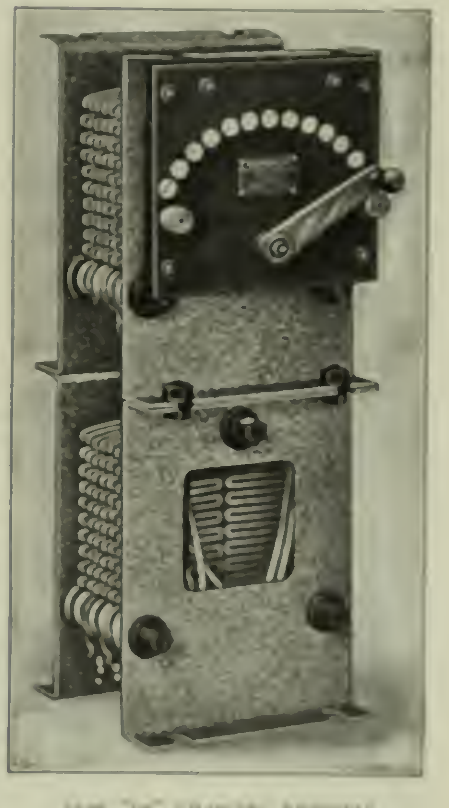
A test sheet was exhibited at the office of the company, showing that on coal of 10,400 B.t.u., showing over 10 per cent. of ash, an evaporation of 9 pounds of water from and at 212 degrees Fahrenheit was obtained. This coal was stated to be practically useless as hand-fired fuel, being a mine refuse. Another performance sheet was shown in which a coal of 10,816 B.t.u., with over 9 per cent. of ash, was made to produce an evaporation of 9.29 pounds of steam from and at 212 degrees Fahrenheit. Attention was called especially to the poor quality of coals used in these tests, which were the average for the plant at which stokers were installed. When it is considered that the average performance with good coal in the ordinary practice on flat grates is about 8 pounds of water to one pound of coal, the attractiveness of these results is readily apparent. Especially is this true when it is taken into consideration that the company claims to be able to evaporate as much water from the poorest slack coal as can ordinarily be obtained from coal costing 50 per cent. more per ton than slack coal.

The company has also perfected a marine stoker along very much the same lines, which it is to place on the market simultaneously with the "Class E."

Several governments, including the United States, England and Japan, are using the "American" stoker.

Rheostats for Charging Small Storage Batteries from Lighting Circuits

For use where a small storage battery is maintained, as in gas-engine power plants where only direct current at lighting voltage is available, the storage-battery rheostat herewith illustrated has been brought out by the Westinghouse Electric and Manufacturing Company, East Pittsburg, Penn. Some form of adjustable resistance must be employed, since the voltage at the beginning of the charge is less than that required when the batteries are fully charged, and the maximum voltage of the battery is lower than the voltage of the available charging current. The voltage applied to the battery should be increased gradually from the minimum value required at the beginning to about 2.7 volts per cell at the end of the charge.



TYPE "OB" CHARGING RHEOSTAT

The illustration shows a "Type OB" charging rheostat for 30 to 55 cells which is capable of carrying 50 amperes at any position of the regulating arm: this type of rheostat is also supplied, in the same current capacity, to charge 10 to 14 cells from a 110- to 120-volt circuit.

To select a charging rheostat for a given service, the circuit voltage, the minimum allowable battery voltage and the charging current in amperes must be known, and these should be specified when ordering such a rheostat or inquiring about one. The minimum battery voltage is the product of the number of cells in series and the volts per cell, usually 2 volts; in other words, twice the number of cells that are connected in series. Although these rheostats are rated as for 110 to 120 volts it is possible to use them on circuits of higher voltages, provided the difference between the minimum battery voltage and that of the supply circuit does not exceed that which would exist with the rated number of cells and rated circuit voltage.

These rheostats are finished in black marine on the face plate, the resistance conductors are coated with aluminum paint, and the supporting frames are galvanized. The resistance is of the grid type and is rigid, compact and substantial in construction. There are thirteen steps of resistance abjustment.

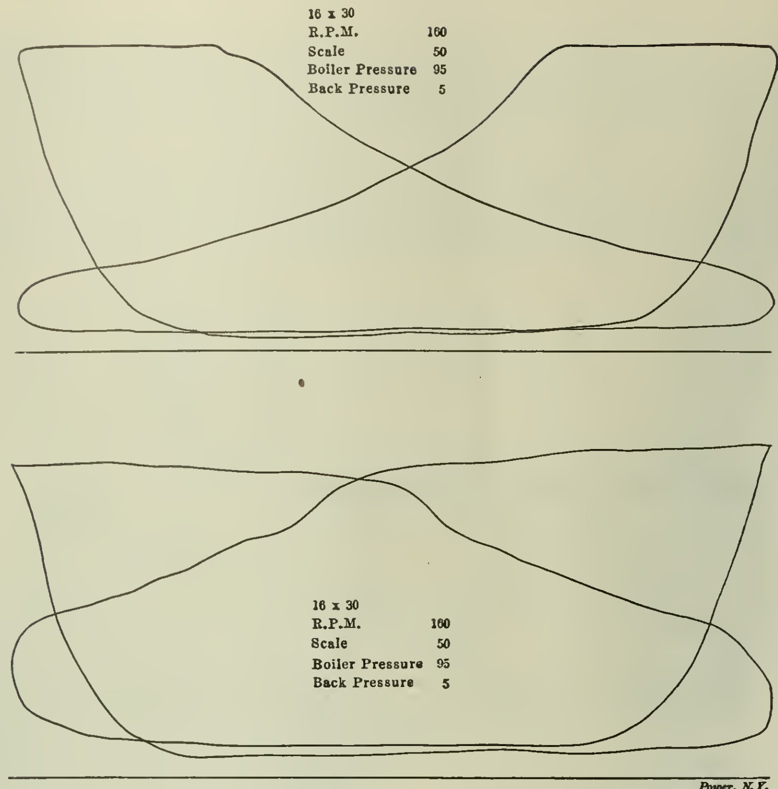


FIG. 2. DIAGRAMS FROM 16X30 HEWES & PHILLIPS ENGINE FITTED WITH FRANKLIN VALVE GEAR

The Franklin Valve Gear

The increasing demand for higher speeds in Corliss engines has led to the development by the Hewes & Phillips Engine Company, of Newark, N. J., of a new type of releasing gear which handles the valves quietly and effectively at speeds as high as two hundred revolutions per minute. Its construction will be apparent from the accompanying engravings.

The loose arm *A*, Fig. 1, is oscillated from the wristplate by the usual right-and-left connection and carries at its top a long bearing *B* for the liberating latch *C*. The length and stability of this bearing is well shown in the left-hand view of Fig. 1, and is one of the details which contributes most to the positive and smooth working of the device. The latch *C* is a bronze bar, practically straight, hollowed out for lightness and suspended in such a position that gravity enables it to function properly even at speeds as high as two hundred revolutions per minute without the aid of the light spring *E* with

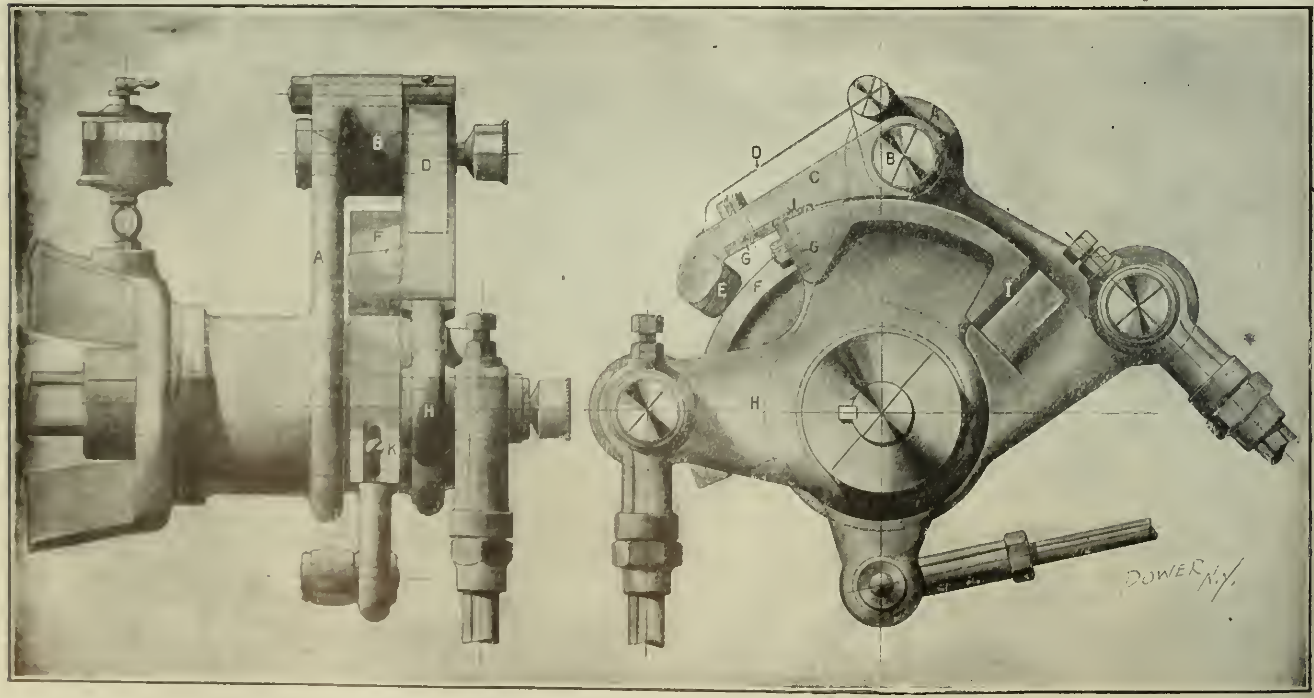

FIG. 1. DETAILS OF THE FRANKLIN VALVE GEAR

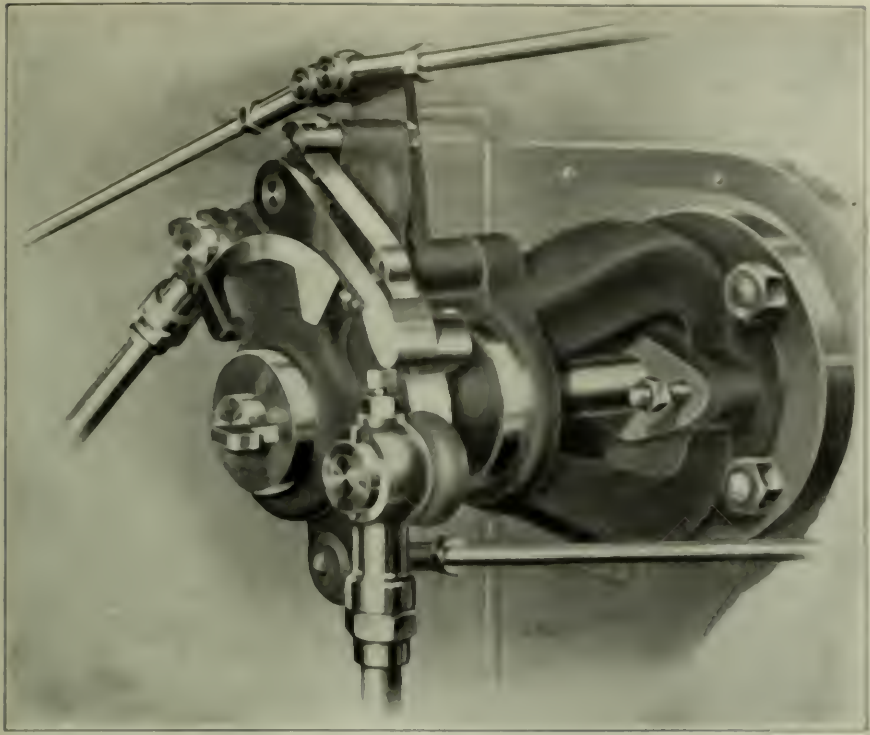

FIG. 3. THE FRANKLIN VALVE GEAR

which it is furnished for additional security.

The latch carries at its extremity the antifriction fiber block *E* which rests upon the face of the cutoff cam *F*, the position of which is determined by the governor. When this block rests on the low portion of the cam, as shown in Fig. 1, the latch blocks *G G* can come into engagement as shown and the member *H*, keyed to the valve stem, will be carried backward with the arm *A* opening the valve. When the fiber block *E* rides up on the high part of the cam, the blocks *G G* are drawn out of engagement and the valve is closed by the dashpot. If for any reason the valve should not close it will be pushed to by the fiber-faced block *I* upon the lever arm positively moved by the wristplate.

The sharpness with which the valve closes and the excellent manner in which the steam line holds up even with a late cutoff are shown by the accompanying diagrams taken from a 16x36 Hewes & Phillips engine fitted with this gear, running at 120 revolutions per minute and located at the plant of the *Newark Evening News*. The latch blocks *G G* are of hardened steel and square, presenting eight working edges each which may be used successively by reversing the position of the block. When the latch blocks engage, the contact of the latch arm takes place upon a fiber block *J* alongside the upper block *G*, avoiding even the clicking sound which usually accompanies the operation of a releasing gear. The construction of the latch enables an oil well of considerable capacity to be formed within it, provision being made by means of ducts to convey the oil stored in lamp-wicks, or other fibrous material, to the faces of the liberating latches, eliminating possibility of wear from lack of lubrication. The safety block *K* on the governor cam is so attached, as will be plain from the drawing, that no shearing off and destruction of the gear could occur from a loosening up of its attaching screw. The governor cam presents a considerable mass to receive the blow of the fiber block on the toe of the latch, and the thrust upon the governor is extremely slight, as may be experienced by handling the lever controlling the cutoff upon the shop apparatus upon which each gear is tested before being sent out. The success of the design has been attained, in fact, by using mass where it was needed and was either stationary or in motion at a very moderate velocity, in reducing the freely moving parts to the lightest possible weight and providing them with bearings which permit of the limited movement required while maintaining steadiness and freedom from vibration.

"Bestyet" Power Pump

The Lucas Pump Company, Dayton, O., recently redesigned its "Bestyet" power pump, the principal new feature being double gears in place of the single gear formerly used. The illustration shows a side view of the pump as now built. The main casting supports the two large gears, which have long hubs and run loose on shafts held in place by set screws. The crank pin connects the two gears and runs in a sliding bronze block in the link or crosshead. An oil pocket on top of the link distributes oil to the block and crank pin. The driving pinion is also double, to correspond with the gears. An outboard guide bearing is used on the piston rod, and an overhanging cylinder is provided, with an air chamber on the discharge side. The valves are easily accessible, by removing the valve-seat covers,

"BESTYET" POWER PUMP

without disturbing the suction or discharge connections.

These pumps, which are designed for pressures up to 110 pounds, and capacities of 1200, 2200 and 4200 gallons per hour, are fitted with rubber valves resting on brass seats, with brass stems and springs, the latter being wound in a peculiar manner for the purpose of maintaining an equal tension at all lifts. The pistons are of standard construction and fitted with square packing. Brass piston rods and cylinder linings are furnished when specified.

Casey-Hedges Boiler

The Casey-Hedges water-tube boiler, manufactured by the Casey-Hedges Company, Chattanooga, Tenn., is herewith illustrated. The chief features of this boiler are its simplicity of construction and the fact that the superheater may be installed without disturbing the setting.

The boiler consists of one or more steam and water drums, having two wrought-steel headers or water legs, one at each end, each header consisting of a handhole plate and a tube plate. The water legs are thoroughly braced with large, hollow staybolts. The construction of the legs is such as to form the strongest part of the boiler. The front water leg is 12 inches wide at the bottom, doing away with all restricted areas at this point, thus permitting free circulation of steam and water. The rear leg is 10 inches wide at the top, the lower portion being increased to meet the inclination of the lower bank of tubes at right angles, and forming a large settling chamber at this point.

Fig. 1 is a rear view of a Casey-Hedges tube boiler with the superheater connected through the header. It will be noticed that the superheater is in the direct path of the hottest gas and is so located that accumulated soot can be easily cleaned from it by steam jets blown through the hollow staybolts in the rear header.

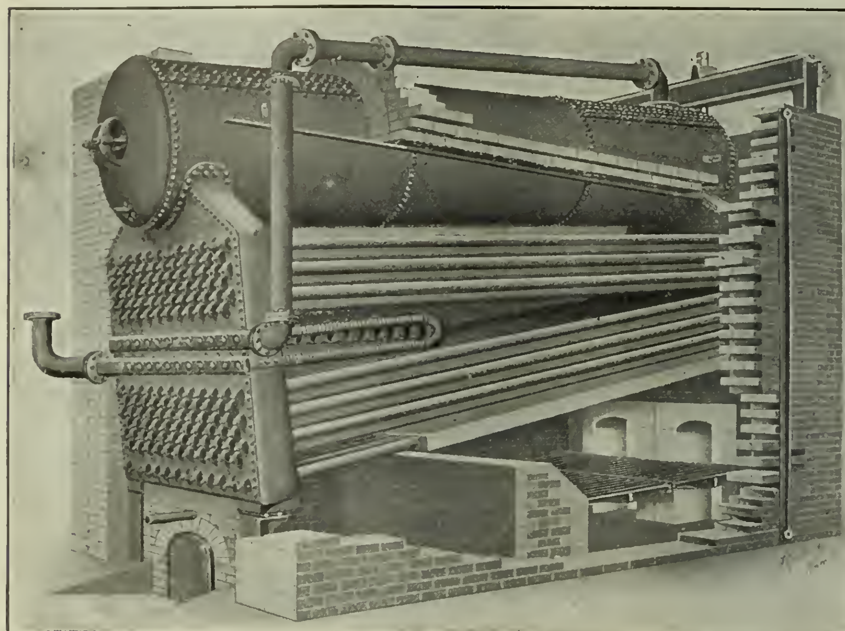

FIG. 1. REAR VIEW OF CASEY-HEDGES BOILER WITH SUPERHEATER ATTACHED

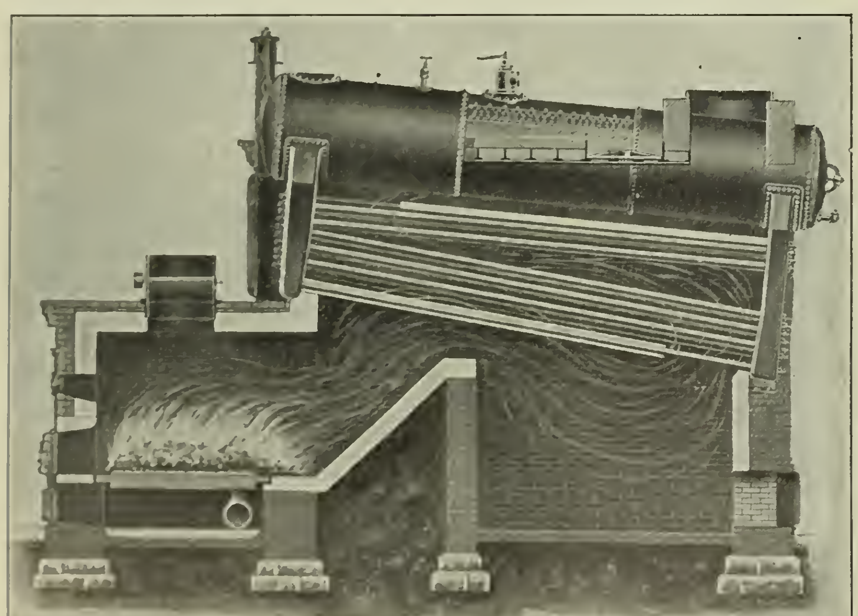

FIG. 2. CASEY-HEDGES BOILER WITH DUTCH OVEN ATTACHED

The tubes are divided into two banks, an upper and a lower, the upper bank and the drum being inclined 1 inch to the foot and the lower bank being inclined 2 inches to the foot. The lower tubes being the hottest, the inclination here is the greatest. This construction permits of a large area at the rear of the tubes, allowing for complete expansion of the gases at this point, the area decreasing as it reaches the front end, as the gases cool. The upper baffle consists of a special V-tile, the design of which is such that the passage for the gases may be decreased or increased to suit the fuel and draft conditions.

The circulation is an important feature with any boiler. In this type the double inclination of the tubes is a feature that allows for a rapid circulation of steam and water through the lower bank of tubes. The steam outlet is at the front end of the boiler and is provided with a dry pipe and a deflector or baffle plate which should insure dry steam, the steam outlet being about three-fourths the diameter of the drum away from the water level.

The downward circulation is through the rear leg which swells out to form a precipitating chamber for all solids that have not been deposited in the mud drum, the blowoff being tapped in the extreme bottom of the rear leg, which can be drained completely through the blowoff.

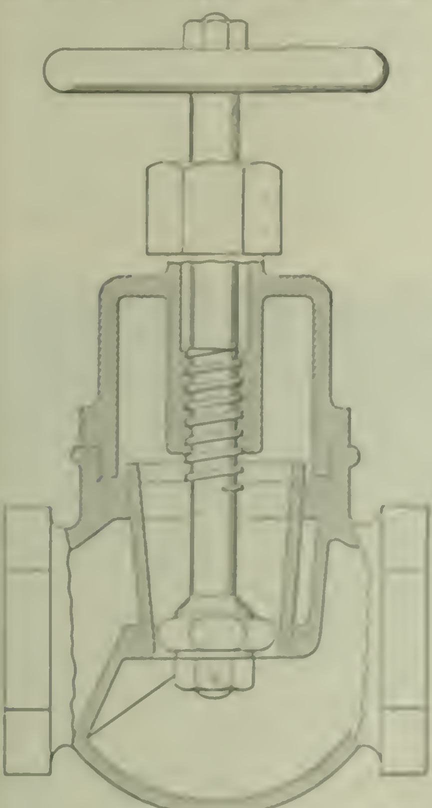
The boiler is constructed entirely of open-hearth steel, there being no cast-iron parts about the boiler proper. Each of the headers or water legs is stayed with hollow staybolts arranged so that a steam blower can be inserted through them and all soot that has collected on the tubes and tiling can be blown down into the combustion chamber. All cleaning may be done while the boiler is in operation, without admitting cold air to the fittings, which is an important feature. In order to clean the interior of the boiler there is provided, opposite the end of each tube water leg, a wrought-steel handhole plate that tightens under internal pressure, thus throwing no strain on the manhole bolts or arch. The handhole covers are easily removed and with a hose or tube scraper inserted the scale may be washed into the rear water leg, where it can be removed by taking off a few of the handhole plates in the bottom row. It is said that as many as five tubes can be cleaned with one handhole opening in the front end. A mud drum or sediment chamber, 8 inches in diameter, is provided with each boiler, located in the top drum. The feed water empties into the mud drum and all scale and impurities are deposited in it.

The blowoff extends from the rear of the sediment collector out through the rear of the drum, through which the sediment can be blown out at intervals. Owing to the construction of this boiler no cleaning aisles between batteries are necessary, and any number of boilers can be placed in a continuous row, which admits of a saving in brickwork.

In Fig. 2 is shown one of these water-tube boilers arranged with a dutch oven, which permits of burning out sawdust, bagasse, spent tan bark, etc.

Storle High Pressure Valve

The accompanying view illustrates the Storle high-pressure valve, manufactured by the O. O. Storle Valve Company,



STORLE HIGH-PRESSURE VALVE

Kewaunee, Wis. Its salient feature is that it can be opened and closed easily under pressure. The valve cone is swiveled on the stem, and when the valve is opened or closed it leaves or enters the seat without turning in it. This practically obviates leaks as a result of wear.

An additional safeguard against leaks is provided in the long cone used instead of a disk, which would sink deeper into the seat should it wear small and thereby continue tight. An accumulation of dirt or scale on the cone or the seat face is obviously improbable.

"Autoforce" Air Pump

A system for automatically ventilating engine and boiler rooms, workshops, or other places where the air may become

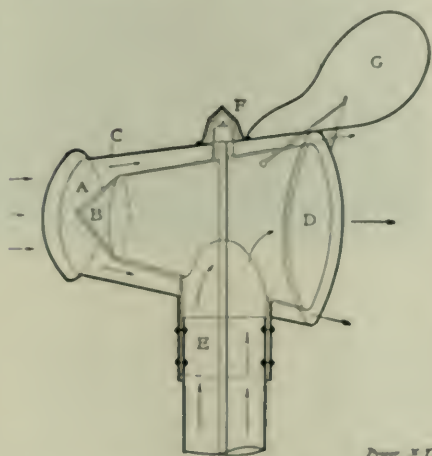


FIG. 1. SECTIONAL VIEW OF "AUTOFORCE" AIR-PUMP VENTILATOR

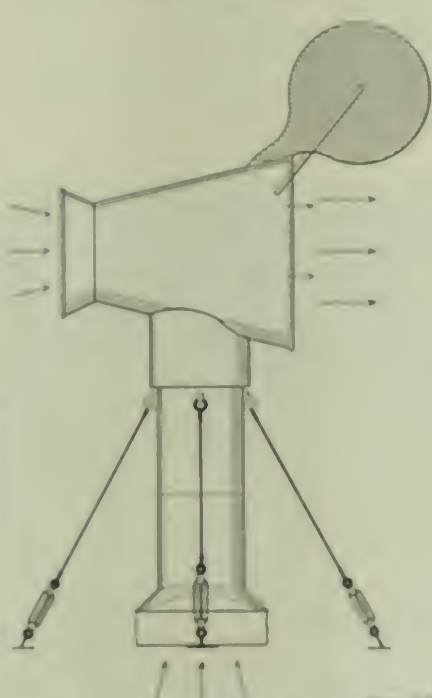

FIG. 2. EXTERIOR VIEW OF "AUTOFORCE" AIR-PUMP HOOD

foul is found in the "Autoforce" ventilating system, made by the Natural Automatic Ventilator Company, 53 Devonshire street, Boston, Mass.

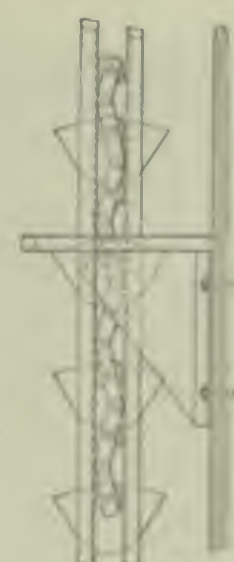
The so-called air pump is connected to common piping of suitable size, or properly installed air ducts, air shafts or chimney flues, and forms a natural system of ventilation, it is said. No machinery is required to operate it, and it requires no attention. Owing to its construction the "Autoforce" ventilator is said to create a constant unbroken suction flow of air upward each hour of the day, and also to prevent the possibility of its flowing downward. The operation is as follows:

The air enters at *A*, Fig. 1, and is spread by the point of the inner cone *B* into a conical form in the passage *C*. Upon reaching the outlet at *D*, the outward rush of air from between the inner and outer cones causes a partial vacuum in the interior of the inner cone, and as this partial vacuum must be occupied, it produces a continuous rush of air up the pipe *E*, as the pull of the air at *D* practically never ceases. The ventilating hood is pivoted at *F*, thus enabling the tail G to swing it, keeping the smaller end toward the wind, regardless of the direction from which it blows.

Fig. 2 is an exterior view of the hood as it would appear on the roof of a building.

Conveyer Safety Device

The accompanying sketch illustrates a conveyer safety device designed by Spencer & Co., Ltd., of Melksham, England, for the Greenwich generating station of the London County Council Tramways. At the south end of the boiler house,



CONVEYER SAFETY DEVICE

where the conveyer chains descend vertically, this arrangement was provided to prevent the chains and buckets from falling in event of breakage. Two continuous vertical runners are fixed the whole height of the building, and should the chain break it can fall only a few inches, as it would quickly jam in the runners.

Convention of Illinois State Association, N. A. S. E.

This was the fifth annual convention, held at Elgin, Ill., May 14 and 15, and was declared to be one of the most successful and enjoyable meetings ever held by the State organization. The time was well chosen, the place could not be improved upon and the result was satisfaction all round. Illinois, always famous for the relative number of ladies in attendance, did not disappoint in this regard, and all told, with delegates, members, friends and visitors, fully one hundred and twenty-five persons were gathered in Strauss hall when E. S. Purdy, president of Illinois No. 49, called the meeting to order. After prayer by Rev. W. H. Fuller, Mayor W. W. Fehrman spoke a few words of welcome in behalf of the city, followed by an eloquent address delivered by F. C. Joslyn, corporation counsel, of Elgin.

SUPPLYMEN AT ILLINOIS STATE CONVENTION, N. A. S. E., ELGIN, ILL., MAY 14-15, 1909

W. W. Brooker, of Joliet, president of the State association, responded to the address of Mr. Joslyn, following which R. I. White, superintendent of the Elgin schools, talked on "Education," in which it was shown how important a factor was knowledge in the development of this country. In responding, John W. Lane, editor of *National Engineer*, pointed out that while general knowledge was necessary to the country, the specific technical knowledge of power-plant operation was necessary to the engineer of today, especially so as the engineering-school graduate was beginning to compete with the operating engineer on his own stamping ground, and hard study was needed in order to meet this new competition.

Winding up the opening exercises was the address on "The Relation of the Engineering Experiment Station to the N. A. S. E." by K. G. Smith, assistant professor of mechanical engineering, University of Illinois, Urbana. This was listened to with much interest, as it touched upon points that have not been quite clear to engineers. It was shown that this institution could be of great benefit to men operating plants if they would take the pains to coöperate with it. Mutual confidence and helpfulness between the experiment station and the N. A. S. E. should exist, as both had education for their primary object, and while it was the function of the university to develop discoveries and new methods, it was up to the engineer to put them into practice. Furthermore, the operating engineer was in a position to gather data that the college could not possibly get, and working

DELEGATES AND VISITORS, ILLINOIS STATE CONVENTION, N. A. S. E., ELGIN, ILL., MAY 14-15, 1909 together should result in great benefit to all concerned. Professor Smith concluded by extending a cordial invitation to the State body to meet at the university, and promised that every facility necessary to a successful meeting would be placed at its disposal.

The afternoon session was consumed in discussing means for obtaining a State license law and for furthering the educational work of the association. Each of the fourteen delegates reporting was heard from on all topics discussed. In addition, many members who were not delegates participated in the meeting and offered a number of valuable suggestions.

In concluding the session, President Brooker spoke regretfully of the recent death of J. E. Boyle, No. 11, of Joliet, an active member of the association.

Election of officers resulted in the choosing of J. L. Randles, No. 6, of Peoria, as president; W. L. Parker, No. 49, of Elgin, vice-president; and W. E. Hill, No. 17, Moline (reelected), secretary and treasurer. Installation of officers was by F. W. Raven, national secretary, of Chicago. The meeting was then adjourned subject to the call of the president.

Meanwhile the ladies returned from the automobile ride with which they had enjoyed the afternoon, and all gathered at Unity hall, where a chicken-pie supper was served by the ladies of the local committee.

In the evening the entertainment was somewhat novel. Assembled in Strauss hall, the visitors were treated to piano, violin and vocal selections by local talent, which was well received. Stereopticon pictures were shown and music was available for those who cared to dance. By way of refreshments, peanuts, popcorn, apples and lemonade were served and everybody was instructed to talk to his neighbor and enjoy himself. The success of the arrangement proved it to be one of the leading features of the entertainment program.

D. K. Swartwout, president of the Ohio Blower Company, of Cleveland, presented a paper, which made a profound impression, at the joint meeting of the American Society of Machinery Manufacturers' Association with the National Supply and Machinery Dealers' Association at Pittsburg recently, dealing with the benefits of organization in the sales department. Mr. Swartwout was elected a vice-president of the association.

The May meeting of the Electric Power Association was held on the evening of May 27, at 8 o'clock, in the lecture room of the R. R. Y. M. C. A. building, corner Forty-fifth street and Madison avenue, New York City. C. W. E. Clarke, steam engineer for the New York Central, delivered a talk on "Efficiency Testing of Steam Apparatus."

Brooklyn Engineers' Club's New Home

The Brooklyn Engineers' Club recently purchased a building for a clubhouse at 117 Remsen street, Brooklyn, N. Y., into which it has removed, after having been located for nearly 13 years in the Montague street library building. The club's new home, which was one of the finest residences on what is known as "The Heights," has a brownstone exterior, and its interior design, decorations and appointments are very fine.

There is a reception room, 20x30 feet on the ground floor, with a small stage at one end—just the place for lectures, etc. The dining room is on this floor, also. On the second floor are the library, the secretary's office and smoking and retiring rooms. On the third floor are five bedrooms and a bathroom.

In a sense the Brooklyn Engineers' Club is an outgrowth of the Montague street library, for before that library became free to the public and a yearly subscription was collected from the readers, the trustees set aside certain shelves and alcoves for the use of people interested in engineering problems. Books on scientific subjects were gathered on the shelves in these alcoves and thus the Brooklyn engineers were thrown together in their search for information. That social intercourse led to the forming of a club, "the object of which is to promote social and professional intercourse among its members, to advance engineering knowledge and practice, and to maintain a high professional standard within all branches of engineering."

When the club was incorporated on December 29, 1896, the membership was fifty. The next year it had grown to 131, in 1902 it was 204, in 1904, 246, and at the present time it is 350.

The officers for the present year are: President, James C. Meem; vice-president, Winifred H. Roberts; secretary, Joseph Strachan; treasurer, William T. Donnelly; librarian, Frank J. Coelon. Board of directors: James C. Meem, Joseph Strachan, James W. Nelson, Winifred H. Roberts, William T. Donnelly, Charles M. Spofford, George C. Whipple. Standing committees: Library, James B. Van Vleck, Frederick C. Noble, George A. Orrok; membership, John M. Steinmetz, John W. Goodridge, Willard P. Hough; entertainment, C. A. Sonnet, Frank W. Coun, Harry P. Morse. Special committee: excursions, Frank C. Schmitz, Harry B. Snell, Francis W. Perry.

The annual convention of the Canadian Electrical Association will be held at Quebec on Wednesday, Thursday and Friday, June 16, 17 and 18. The headquarters will be at the Chateau Frontenac. T. S. Young, Confederation Life building, Toronto, is the secretary.

Engineers' Blue Club Banquet

The third annual banquet and reunion of the Engineers' Blue Club, of Boston, Mass., was held on Saturday evening, May 22, at the Century building. There was a reception from 6 to 7 o'clock in Sewall hall, the banquet, at 7 o'clock, being held in Howe hall, followed by an entertainment in Potter hall, the three halls being in the same building. Fully five hundred members and guests were seated at the table. When the coffee stage was reached, Albion H. Parker, president, closed his crisp speech of welcome by introducing Albert C. Ashton, of the Ashton Valve Company, as toastmaster, and the duties of this important office were disposed of in a most creditable manner. Those who made addresses were: Thomas Hawley, of the Hawley School of Engineering; Andrew J. Savage, United States Local Inspector of Vessels; Prof. Edward Miller, of the Massachusetts Institute of Technology; Dr. Louis C. Loewenstein, of the General Electric Company; Hon. William P. White, mayor of Lawrence, Mass.; Walter Lamont, manager of the Wood Worsted Mills, Lawrence; W. G. Smith, general manager, Fall River Ship and Engineering Building Company; Joseph H. McNeil, Massachusetts deputy chief boiler inspector; William J. Ranton, of Rochester, N. Y., grand worthy chief Universal Craftsman, Council of Engineers; Herbert E. Stone, New York, of the Dearborn Drug and Chemical Works. At close of the banquet an enjoyable vaudeville performance was given, during which John W. Armour, of Power, entertained. The committee in charge of this successful event comprised R. K. Neptune, H. H. Ashton and Harry H. Atkinson.

Wisconsin N. A. S. E. Convention

The ninth annual convention of the Wisconsin State Association of the N. A. S. E. will be held at La Crosse, June 18 to 20. An elaborate program has been prepared.

Personal

Lieut.-Commander Hutch I. Cone, U. S. N., has been appointed chief of the Bureau of Steam Engineering, which position had been filled by Rear-Admiral Rae.

Obituary

Francis S. Pool, vice-president of the D. T. Williams Valve Company, of Cincinnati, died Saturday, May 8, in his fifty-eighth year.

Business Items

The Wipaco Packing Company has removed to new offices in the Engineering building, 114 and 116 Liberty street, New York City.

Woodward Wight & Co., of New Orleans, La., will represent the Homestead Valve Manufacturing Company, of Pittsburg, in the Louisiana territory, carrying a full line of Homestead valves.

The Minneapolis Steel and Machinery Company secured an order for a 125-horsepower Muenzel producer gas engine and gas-producer plant from the Sisseton Mill and Light Company, Sisseton, South Dakota. This engine will run both the flour mill and electric-light plant and will be in service 24 hours a day.

The Leon-Ferenbach Silk Company, Wilkes-Barre, Penn., has purchased a Hewes & Phillips heavy girder-frame Corliss engine, with heavy flywheel and shaft arranged for two engines, which will go in its new mill at Wilkes-Barre. Members of this company have been using several of the Hewes & Phillips engines. The Sanitary Can Company, Bridgeton, N. J., is installing a 12x30-inch, 100-horsepower Hewes & Phillips Corliss engine for the operation of its plant.

Norman C. Brize has been elected president of the Standard Steam Specialty Company in place of E. H. Roberts, who died recently. Mr. Brize has had an extensive steam-engineering experience, both with this company and the Babcock & Wilcox Co., with which he was formerly connected. Percy A. Pinder has also been elected secretary and treasurer of the company. Mr. Pinder has been connected with the Standard Steam Specialty Company since its incorporation and was instrumental with Mr. Roberts in bringing the "Utility" specialties made by this company to their present successful position in the power-plant field. The main offices of the company will be continued at 542 West Broadway, New York, and branch offices will be established in some of the other large cities.

The Charles A. Schieren Company, of New York, has received a letter from the Barrett Manufacturing Company, of Elizabeth, N. J., to the following effect: "In regard to the 48-inch three-ply 'Duxbak' waterproof leather belt which you put on for us May 2, 1907, we take pleasure in stating that the belt has been in service ever since, running 24 hours a day, 6 days a week, and has caused us no trouble whatever during that time. After the belt had been running for about six weeks it became a little slack, as all belts do, and we had it taken up on a Sunday and the following Monday morning it was doing its duties the same as usual. Since the time it was first put on our pulleys it has run true, and has required no dressing or other attention, and we could not ask better service of any belt under any conditions."

Among the direct-current generators recently sold by the Crocker-Wheeler Company, of Ampere, N. J., is one of 300 kilowatts capacity, 250 volts, purchased by Perry Fay Manufacturing Company, Elyria, Ohio. Another machine of this type, having a capacity of 200 kilowatts, 125 volts, was bought by the Cleveland Provision Company, Cleveland, O. There were many sales of smaller generators ranging in size from 35 to 100 kilowatts. A large order was placed with the Spanish American Iron Company, Felton, Nipe Bay, Cuba, for 230-volt direct-current motors aggregating 235 horsepower. Another sale of direct-current motors, which totaled 135 horsepower, was made to the Morgan Engineering Company, Alliance, Ohio. The International Silver Company, Meriden, Conn., has ordered six Crocker-Wheeler Form I machines, having a combined capacity of 131 horsepower. In addition to the above a large number of smaller orders for direct-current motors have been booked.

Henry Docker Jackson, consulting engineer, 88 Broad street, Boston, Mass., visited the works of the Westinghouse Electric and Manufacturing Company, at Pittsburg, recently, to make an acceptance test on a special 250-horsepower motor which is to be used to operate a ventilating fan in a coal mine in West Virginia. This is one of the largest electrically operated ventilating fans in the country. The motor is a specially designed one, the general scheme being suggested by Mr. Jackson, the design and details being worked out by the Westinghouse company, the idea being to get the starting characteristics of the best type of induction motor combined with the operating and line-regulating characteristics of the synchronous motor. The tests were eminently successful, both the starting characteristics and the regulating characteristics being remarkably good. The motor and fan are being installed in connection with other work at the mine, the consulting engineers on which are Timothy W. Sprague and Henry Docker Jackson.

The Ontario Hydro-Electric Power Commission, which is charged with the construction of the provincial government system for transmitting power from Niagara Falls to leading cities and towns of Western Ontario, has decided to install the protective system over the entire transmission line. In addition to giving protection against accidents it promises to reduce the chances of the dislocation of the time through electrical disturbances to a minimum. The system is operated by an arrangement of automatic cutouts working as soon as a break occurs in the transmission conduit. If a short-circuit occurs the wire is grounded, or should the wires break at any place, that section immediately becomes "dead," so that the broken wire can be handled by, or come into contact with, any one without danger. The estimated cost of the protective system is $106,000. The commission awarded contracts for the copper wire required for it to the Dominion Wire Manufacturing Company, Montreal, and for the porcelain insulators, intended as a safeguard against lightning, to the Ohio Brass Manufacturing Company, of Mansfield, Ohio.

A good example of the results obtained by a sales department and factory organization working in harmony is afforded by a recent contract handled by the Buffalo Forge Company, Buffalo, N. Y. In connection with cold-storage warehouses operated by the Pacific Fruit Express Company at Roseville and at Colton, Cal., eight large fans were required by the Pacific Engineering Company, San Francisco. Each fan was to deliver 44,500 cubic feet of cold air against a pressure of three ounces per square inch, and to be of the full housing type with bearings supported on concrete piers, with the blast wheels overhung on the shaft, and with stuffing boxes on the fan housings, to prevent leakage of air. Although special in several particulars the Buffalo Forge Company undertook to furnish these fans, each having 7-foot wheels running at 380 revolutions, making shipment of four in 10 days and the balance in 15 days afterward. As the entire shipment weighed 32,000 pounds, the advantage in freight on account of shipping in one car would be considerable, and when the order was received by wire at the factory on April 19 it was decided to make a special effort to complete the eight fans in the time promised for the first four. Shop drawings were not started until the receipt of the order, but preliminary notice was sent to the factory and by the time prints were received by the various departments on April 20 much of the material had been got ready. Friday, April 30, the tenth day after the order was received, shipping was begun, and by that night the eight fans, with shafts, pulley and outboard bearings were loaded on a 42-foot gondola.

New Equipment

Schram & Sons, Oshkosh, Wis., are putting in a new engine room.

The Rumford Falls (Me.) Power Company is building a new power house.

The Shore Electric Company, Red Bank, N. J., will build a new power plant.

The Brunswick (Me.) Electric Light and Power Company is building a new plant.

The West Hampton (L. I.) Ice Company is erecting a new building for its 15-ton ice plant.

The Grimes Milling Company, Salisbury, N. C., contemplates installing a new Corliss engine.

The City Councils, Harrisburg, Penn., have appointed a committee to learn if the city may legally erect a municipal ice plant.

The Milwaukee (Wis.) Linseed Oil Company is making improvements in power plant, including installation of new boiler.

The Merchants Association, Newburg, N. Y., is considering the formation of a company for the purpose of erecting a co-operative electric-light plant.

The Superior Ice Manufacturing Company, Columbus, Ohio, has been incorporated with $75,000 by William S. Nigh, E. W. Edwards, Chas, E. Klunk.

The Isthmian Canal Commission, Washington, D. C., will receive bids up to 10:30 a.m., June 14, for centrifugal pump and engine, gasolene motors, transformers, electric hoist, etc., as per Circular No. 512.

The Alpine Power Company, Alpine, Texas, has been organized with $35,000 capital by H. W. Townsend, J. H. Derrick, R. B. Slight, etc. Besides furnishing power the company will manufacture ice.

Sealed proposals will be received by the Board of Trustees of the Massillon State Hospital, Massillon, Ohio, for the installation of a new high pressure steam main and to make certain alterations in the boiler house.

New Catalogs

Foster Engineering Company, Newark, N. J. Folder. Pilot and emergency valves, pressure regulator, etc. Illustrated.

Murphy Iron Works, Detroit, Mich. Booklet. The Murphy Furnace in the Paper Mill. Illustrated, 48 pages, 4½x6 inches.

The Foos Gas Engine Company, Springfield, Ohio. Catalog No. 21. Horizontal engines. Illustrated, 56 pages, 7x9 inches.

The Kennedy Valve Manufacturing Company Elmira, N. Y. Catalog. Valves, hydrants, etc. Illustrated, 132 pages, 5x9 inches.

A 42-Inch Low Pressure Elevator Pump

Run on the Exhaust of Electric-Light Engines; Vacuum Produced by an Evaporative Condenser Condensing 1 lb. of Steam with 3-4 lb. of Water

In 1903, the L. S. Donaldson Company, a large retailer of Minneapolis, Minn., announced its intention to enlarge its already extensive building, together with its mechanical equipment. This magnificent building with its unique front of glass and iron attracts the attention of all visitors and justly deserves its popular name of the "Glass Block," as more than efficiency and adaptability to the purpose for which it was designed. Mr Donaldson's instructions when the design of the plant was under way were "The best that money can buy," and he has every reason to feel proud of the result. The engine-room floor is of white tile picked out with a figure not shown in the photographs. The walls are tiled to a hight of to electric generators. There is also a 2-ton Wolff refrigerating machine with a 12x36 Corliss cylinder attached, and an American blower capable of delivering 90,000 cubic feet of air per minute into the building for ventilating purposes.

But the unique feature of the installation is the method employed for running the pumping engine for the elevators,

FIG. 1. CONDENSER, WITH SPRAY OPERATING [illegible]

seventy-five per cent. of the façade is of plate glass. The structure therefore presents a striking appearance even in the daytime, but is still more impressive at night, when illuminated by 4000 incandescent lights on the exterior and [illegible] arc lights within.

The power plant, as may be judged from the illustrations presented herewith, is a model not only in appearance but in a feet and, together with the ceiling, are handsomely tinted above this line. All the columns and other trimmings, including a handsome switchboard, are of pink Tennessee marble. The engines are handsomely finished in a deep wine color.

The power plant consists of [illegible] and a [illegible] Corliss engines, all built by the Minneapolis Steel and Machinery Company and directly connected worked out by Joseph [illegible], designing engineer for the Minneapolis Steel and Machinery Company, along lines suggested by F. M. [illegible], chief engineer for the L. S. Donaldson Company. The pumping engine is of the horizontal flywheel Corliss type with a steam cylinder 42 inches in diameter directly connected to a water cylinder [illegible] inches in diameter, with a stroke com-

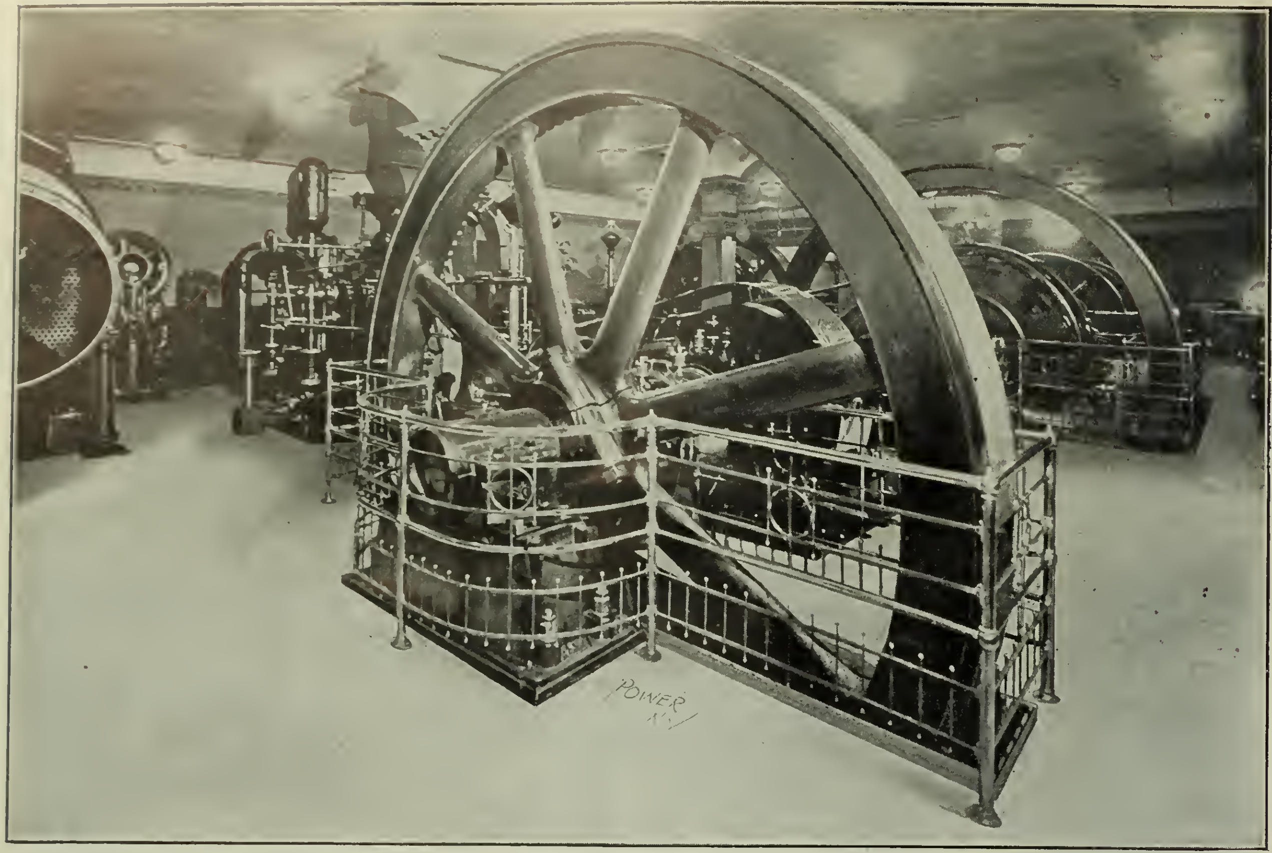

FIG. 2. PUMPING ENGINE, IN FOREGROUND, AND PARTS OF CONDENSER AND AIR PUMP

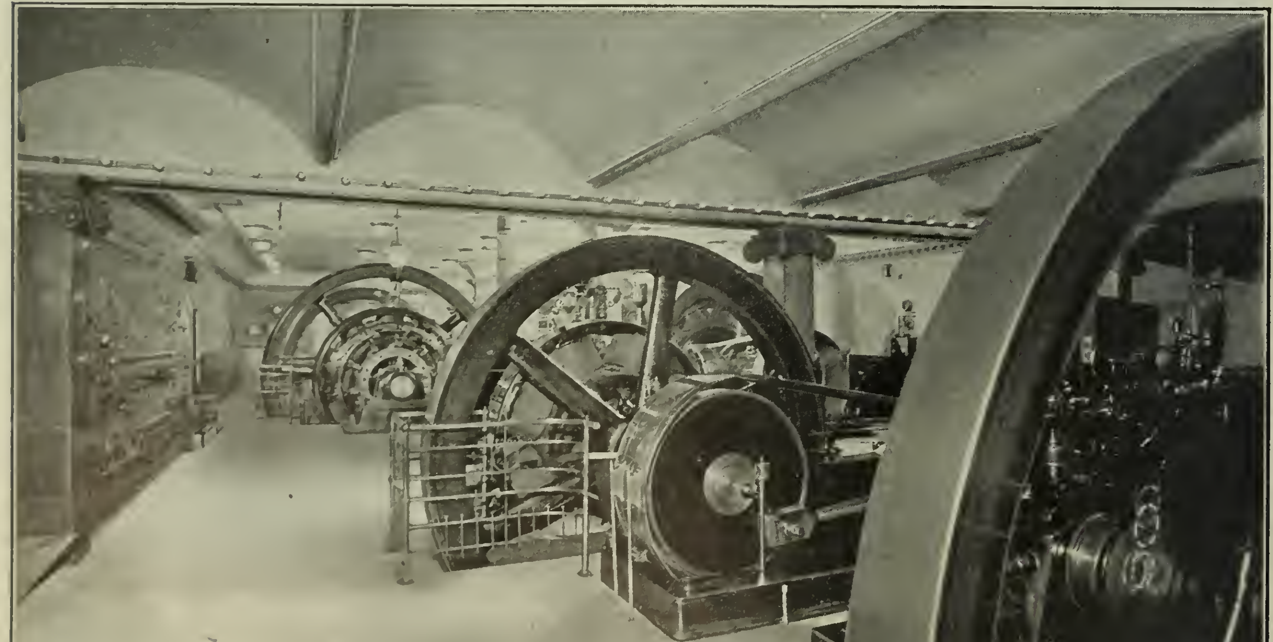

FIG. 3. VIEW IN ENGINE ROOM; SHOWING ALSO SECTION OF ICE MACHINE

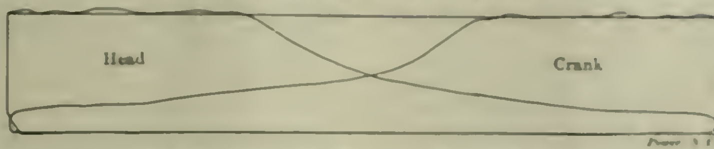
mon to both of 42 inches. The pumping head of 120 pounds per square inch is automatically maintained by placing the regulation of the engine under the control of the water pressure. The system has never once failed during the six years in which it has been in use.

Nothing very remarkable so far, but this pumping engine is run upon the exhaust steam of the other units, working it from about atmospheric pressure into a vacuum of 24 inches, as shown by the accompanying indicator diagrams, in the center of the retail district of Minneapolis, where it would appear to be as impracticable to run a condensing plant as it would be to keep cows on the Sahara. It is made possible thus to run this engine condensing, in a locality where condensing water is out of the question, by the use of an evaporative condenser, shown at the left in Fig. 1. This condenser consists of a cast-iron case containing 1260 one-inch brass tubes, 66 inches in length, disposed horizontally as shown. The exhaust steam from the pumping engine is introduced into the shell and surrounds the tubes. One end of the shell is extended and into this extension is introduced a 1½-inch pipe provided with a rose head which sprays the cooling water, taken from a hotwell at a temperature of 125 degrees Fahrenheit, into the tubes. Connected to an extension at the other end of the shell is a 90-inch ventilating fan which draws its air supply through the tubes of the condenser, incidentally ventilating the engine room which, although located in the basement and, as the photographs show, not lofty in its ceiling, is thus made perfectly comfortable even in midsummer. The water sprayed into the tubes is evaporated, each pound disposed of in this way abstracting the heat necessary to condense a pound of the steam, and enough additional heat being carried away by the air to condense one-quarter of the steam which comes to the condenser, so that for each pound of water produced in the condenser and made available for boiler supply, only three-quarters of a pound has to be furnished to the condenser. The spray is handled by a 2x4-inch duplex pump. The air pump is a 10x12-inch single-acting Edwards, shown against the back wall in Fig. 1, while at the right in the same illustration is seen the steam cylinder of the pumping engine. The fan and air pump are driven by an electric motor using 55 amperes at 110 volts.



INDICATOR DIAGRAMS FROM THE PUMPING ENGINE

Fig. 2 shows the pumping engine in its entirety, with the condenser still visible at the left and with the other units of the plant in the background, and Fig. 3 is a view from the other end of the room. Attention is called to the lighting scheme, the illumination being sufficient to have allowed the photographs from which our illustrations were made to be taken without the aid of other light than that habitually used. The entire responsibility of enlarging and remodeling the power and light plant fell upon Mr. Overholt and although the pump in question was designed and built by the Minneapolis Steel and Machinery Company, the scheme for operating it with the exhaust of the other engines in connection with the evaporative condenser was evolved by Mr. Overholt and he has been granted a patent upon the arrangement.

FIG. 4 ANOTHER VIEW OF THE ENGINE ROOM

A Course in Plant Management

Since 1906 the Teachers' College of Columbia University, New York City, has been giving a series of evening technical courses on a variety of subjects. These courses are open without examination to men or women who desire to obtain higher technical knowledge in their trades and professions, but no academic credit is given. For the school year 1909-10 it is proposed to introduce a course in plant management, which will be under the direction of J. C. Jurgensen, formerly chief engineer at the St. Regis hotel. The course will consist of forty sessions, held on Monday and Wednesday evenings, from 7.15 to 9.15 o'clock and will begin on October 25. This particular course is intended for operating engineers, engineers' assistants, building superintendents and others. A good knowledge of arithmetic and elementary physics is required of all who enter, and the following aspects of plant management will be studied from a practical standpoint:

Introduction—Machinery selection, layout and installation of the plant; schedules for identification and operation; common units for measuring plant economy; instruments and measurements.

Engine Room Accounting—Records of operation; compilation of operating data; billing of records for daily comparison and reference; purchase of coal, supplies and labor; storeroom and toolroom management; computation of total operating costs per unit output; plant depreciation, interest, depreciation annuities; computation of actual cost per unit output; arrangement of expense and plant deficiency reports to owner.

Cost Analysis and Expense Control—Method of determining standard unit costs; distribution of expense to various systems operated; leaks in direct expenses; leaks in operation and machinery; relation between plant efficiency and actual cost per unit.

Industrial Betterment Methods—Training and handling of men; apprenticeship and bonus systems for power plants; accidents and liability insurance; fire-underwriters' regulations; fire protection and appliances; fire-fighting organization for individual buildings.

This in brief is a summary of the course which should prove of value to engineers and those wishing to join their ranks.

From all accounts Mr. Jurgensen is the very man to conduct this course. Formerly, while at the St. Regis hotel, it was his custom to sign apprentices after the European fashion, compelling embryo engineers to work two years and at the end of that period to sign a contract for four years more as machinery operators. At the end of the fifth year those who proved efficient were given certificates as operating engineers and recommended to police headquarters for licenses. The certificates were based upon two years' continued service as apprentice engineers, with good-conduct marks for sobriety, truthful and manly conduct, punctuality in attendance, industry and faithfulness in giving employers a full day's work, and a strict and willing obedience to orders. The rules established by Mr. Jurgensen were brought to the attention of members of the governing board of Columbia, and the offer to him to conduct the course in plant management followed.

Efficiency Test of Three-Wire Balancing Dynamos

By J. W. Himmelsbach

The following test was made on two direct-current generators forming a balancing set on a three-wire 250-volt system. The rating of each generator was 250 kilowatts at 125 volts and 500 revolutions per minute. These two generators and their driving-motor, a 550-kilowatt three-phase synchronous machine, were built with a common shaft supported by four bearings. The object of the test was to determine whether or not the generator met the guarantees made for them, particularly in regard to efficiency. The generators were shunt-wound and each had eight poles and eight brushholder studs with eight brushes on each stud; the commutators had 288 bars each. Before the test was commenced, all brushes were refitted and the commutators turned true. As the test was made in a large substation supplying a 250-volt three-wire system, the load for the set was obtained directly from station busbars. The connections were as shown in Fig. 1.

The armature currents were measured by Weston shunt ammeters connected in the main generator leads. These ammeters were mounted on the switchboard. The field currents were measured by shunt ammeters in series with the field circuits. The armature voltage was measured across the machine terminals; the field voltage was measured directly across the field-winding terminals and therefore did not include the drop in the leads nor across the field rheostat. All instruments used in the test were given an accurate check with standard instruments before the test was commenced. For measuring temperature rise, glass mercury thermometers reading up to 100 degrees Centigrade, were used. As temperature rise by thermometer was the method decided upon, no cold resistances were taken.

Full-load Run

This test was of 24 hours duration, with both machines running at approximately full ampere load and 117 volts across machine terminals. Every 15 minutes readings were taken of the armature and field currents and armature and field voltages. At each reading the temperatures were taken of the air at each end of the set and of field coils, one on each machine. At the end of the run, the temperatures of the armature winding, field winding and commutator on each machine were taken at short intervals until the maximum was ascertained.

Hot Resistances

The hot resistances of the armature and field windings were taken immediately after the 24-hour full-load run. Just before load was taken off, the field resistances were taken by the fall of potential method, with full-load field current. The armature resistances were measured with all brushes down, using a small storage battery giving approximately 450 amperes. The drop was taken across 36 commutator bars beginning immediately under a brush, light readings being taken between the commutator segments under each positive and negative brushholder. The readings obtained were considered as showing too great a variation, due to the low current density, and on that account were not accepted. Another set of readings on armature resistance was taken after the 125-per cent. load run, at a temperature approximating the temperature of the armature at the end of the full-load run. These readings were obtained by blocking the armature and then forcing the full-load

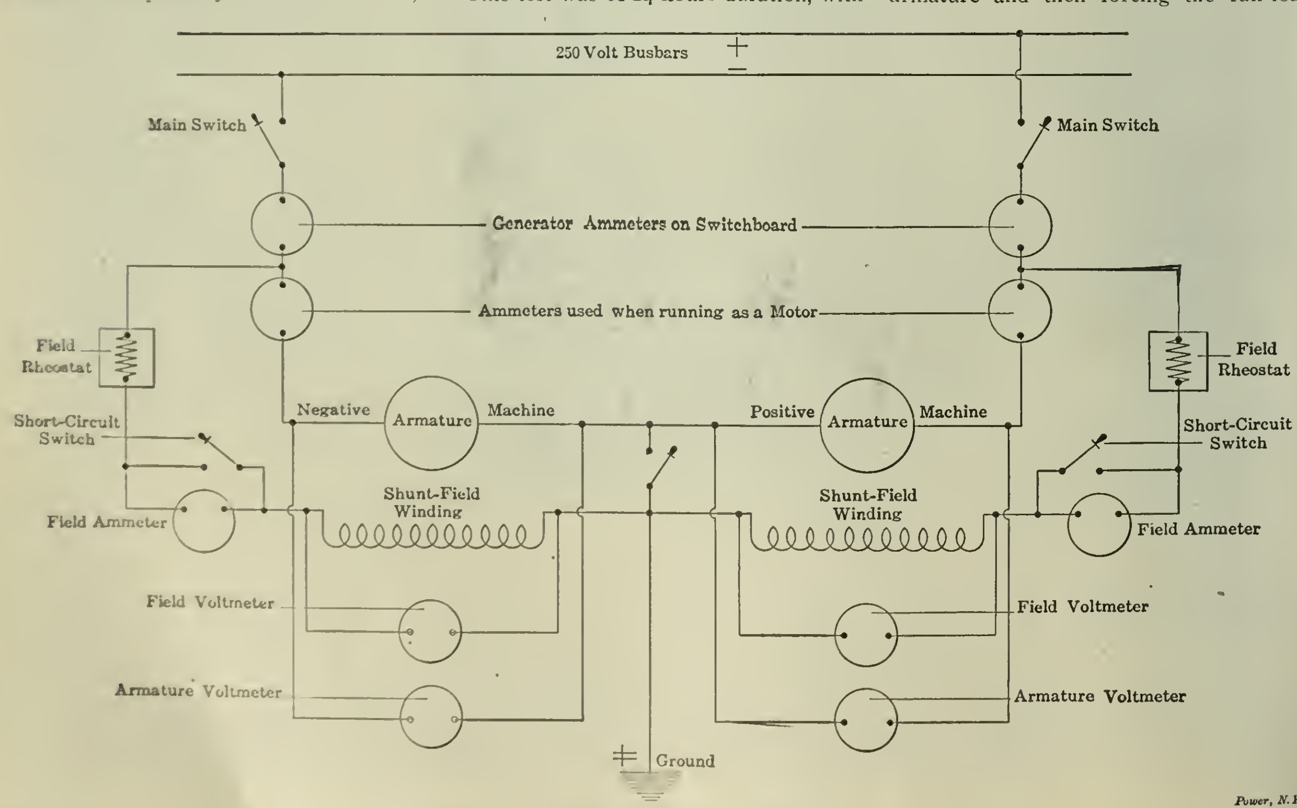


FIG. 1. DIAGRAM OF WIRING CONNECTIONS

current of 2000 amperes through the circuit. The drop was taken between adjacent brushholders as before, and the resulting resistance values checked fairly well.

Brush Contact Resistances

These measurements were taken at the end of the full-load run. Pilot brushes, consisting of two copper wires set in a wooden block fitted in the brushholders were employed, one brush being on a negative brushholder and the other on a positive brushholder. With full-load current on the machine the drop was measured between the negative pilot brush and negative machine terminal and between the positive pilot brush and positive machine terminal. From these readings the total resistances of brush contact, brushes and machine leads were obtained.

Overload Run

As soon as possible after the full-load run, a load of 2500 amperes (25 per cent. overload) was put on the set, which was run under these conditions for two hours. At the end of this time temperatures were taken of the armature windings, field windings and commutators. The air temperatures at each end of the set were also taken.

Windage, Friction and Iron Losses

These measurements were taken at the end of the run with 25 per cent. overload and were obtained by driving the set with one 125-volt generator running as a motor and measuring the input. The set of readings first taken included iron loss, brush friction, bearing friction and windage of both direct-current machines, and a negligible brush and armature resistance loss in the driving motor. These readings also included windage and the bearing friction of the synchronous motor. The machine run as a generator, on which measurements were being taken, was excited to give a terminal voltage equal to 125 volts plus the resistance drop in the armature winding, brushes, brush contact and machine leads. With the speed of the set held constant at 500 revolutions per minute, the power input to the motor was measured. Readings were also taken at several points on the saturation curve of the machine, but these do not enter into the calculations. As the driving motor was separately excited, the loss in its field winding cannot be included in these readings. Call this set of readings No. 1. The field circuit of the generator was then opened and the input to the driving motor again measured. Call this reading No. 2. The difference between No. 1 and No. 2 gave the net iron losses of the generator. All the brushes of the generator were then lifted and the

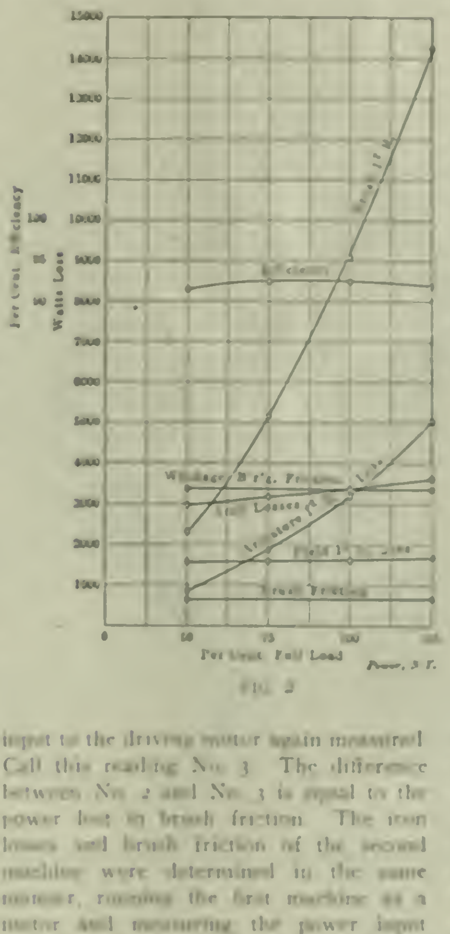

Fig. 2

input to the driving motor again measured. Call this reading No. 3. The difference between No. 2 and No. 3 is equal to the power lost in brush friction. The iron losses and brush friction of the second machine were determined in the same manner, running the first machine as a motor and measuring the power input as before. The readings designated as No. 3 include the windage and bearing friction of the whole set, and the net amount of this loss was obtained by subtracting from No. 3 the losses in the driving motor, consisting of brush friction, armature resistance loss, iron loss and brush contact resistance loss. The assumption was then made that the windage and bearing friction for each machine was proportional to its rated capacity. This assumption gives the loss for each 125-volt generator as being 25 per cent. of the net total loss as calculated from No. 3.

Efficiency Calculations

These calculations were based on hot resistances, the field-winding resistance as taken at the end of the full-load run and the armature resistance as taken at the end of the overload run after cooling to a temperature equal to that at the end of the full-load run; the brush contact resistance as taken at the end of the full-load run. Armature and brush contact resistance losses were calculated from the percentage of full-load current required. The iron losses for different loads were taken from a curve obtained from values of the terminal electromotive force corresponding to the load on the machines. The field-winding loss was obtained from values of field current corresponding to the original armature voltage used in obtaining the iron losses. Brush friction, bearing friction and windage were considered as being constant at all loads.

In the accompanying table are given the results of the test on one machine, and in Fig. 2 curves drawn from these tabulated values.

RESULTS OF THE TEST ON ONE MACHINE.

Load %	Arm. Current	Arm. I²R Loss	Field I²R Loss	Brush I²R Loss	Iron Loss	Brush Friction Loss	Windage and Bearing Friction Losses	Total Losses	Per Cent. Eff.
125	2,500	[illegible]	1,673	[illegible]	[illegible]	650	3,062	[illegible]	91.7
100	2,000	4,214	1,661	[illegible]	[illegible]	650	3,062	21,374	92.2
75	1,500	[illegible]	[illegible]	3,114	3,130	650	3,062	[illegible]	[illegible]
50	1,000	[illegible]	[illegible]	[illegible]	[illegible]	650	3,062	[illegible]	91.5

Note.—All losses given in watts.

Coal Consumption of Steam-Turbine Stations

By N. A. Carle

It is desirable to know the approximate number of tons of coal which should be consumed per day by a power station as a check on the actual figures. Sufficient information is usually available for approximating the desired result from data which has been obtained at various times by tests of the equipment. Records are on file showing the rate of evaporation of the boilers in pounds of water evaporated per pound of coal from and at 212 degrees Fahrenheit, the water-consumption rate in pounds per hour per kilowatt of the turbines and auxiliaries, and the load factor of the station. The installed capacity of the station is known and the factor of evaporation is calculated from the values of the temperature of the feed water, the steam pressure and the amount of superheat.

From the foregoing data the approximate coal consumption per day can be ascertained. The chart on page 1002 is designed to calculate the result graphically from this data.

Examples

(1) A power station with an installed capacity of [illegible] kilowatts has a load factor of [illegible] per cent. The turbines and auxiliaries require [illegible] pounds of water per hour per kilowatt and the evaporative efficiency of the boiler is [illegible] pounds of water evaporated per pound of coal from and at 212 degrees Fahrenheit.

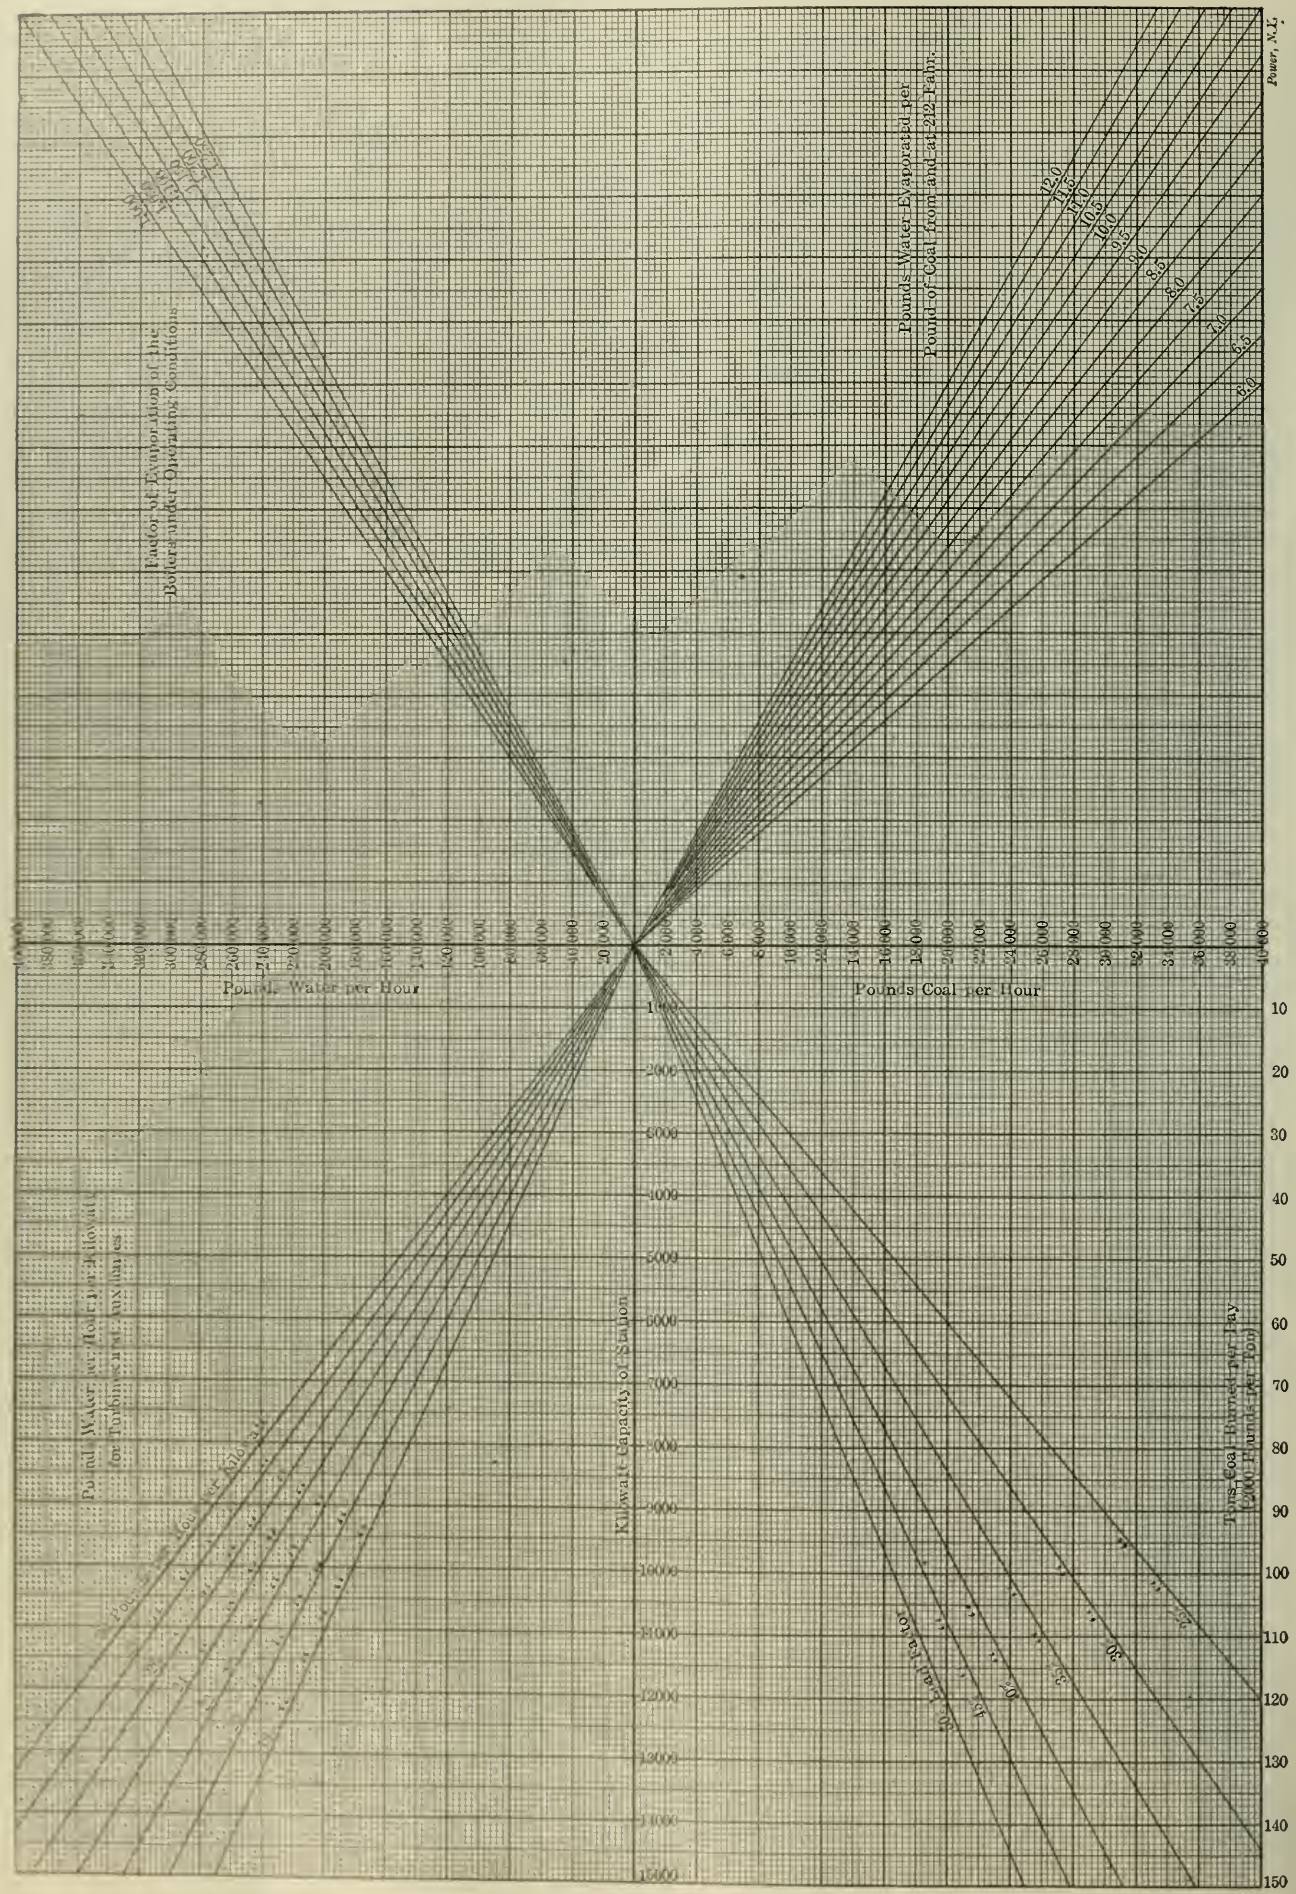

CHART FOR DETERMINING THE COAL CONSUMPTION OF STEAM TURBINE STATIONS

The temperature of the feed water is [illegible]05 degrees Fahrenheit, the steam pressure is 150 pounds per square inch, gage pressure, and the amount of superheat is [illegible]5 degrees Fahrenheit. What is the coal consumption per day?

The factor of evaporation for these conditions is approximately 1.100. Starting with 10,000 kilowatts, read up to 24 pounds of water per kilowatt-hour, then across to 1.100 factor of evaporation, then down to 10.0 pounds of water evaporated per pound of coal from and at 212 degrees Fahrenheit, then across to 35 per cent. load factor, and down to approximately 11 tons coal burned per day. This result is in short tons of 2000 pounds and can be reduced to long tons of 2240 pounds by multiplying by the constant .893. However, it will be sufficiently accurate to multiply by 0.9, as the result obtained is only approximate.

(2) A power station with an installed capacity of 12,000 kilowatts burns 150 short tons of coal per day. Tests show that the water consumption for the turbines and auxiliaries is 26 pounds per kilowatt-hour, and the evaporative efficiency of the boiler is 11.5 pounds water per pound of coal from and at 212 degrees Fahrenheit, under operating conditions which yield a factor of evaporation of 1.150. What is the load factor of the station?

Starting with 12,000 kilowatts read up to 26 pounds of water per hour per kilowatt, then over to 1.150 factor of evaporation, then down to 11.5 pounds of water evaporated per pound of coal from and at 212 degrees Fahrenheit and extend a horizontal line from this intersection to the left crossing the lines for load factor until it intersects a vertical line through 150 tons coal burned per day. The result gives a load factor of approximately [illegible] per cent.

The famous Wright brothers, the aeronauts, have been nominated "Doctor honoris causa" of the technical University of Munich, which is one of the largest and, perhaps the best in Germany. This is considered as a great honor.

Getting the Most Out of Gas Engines

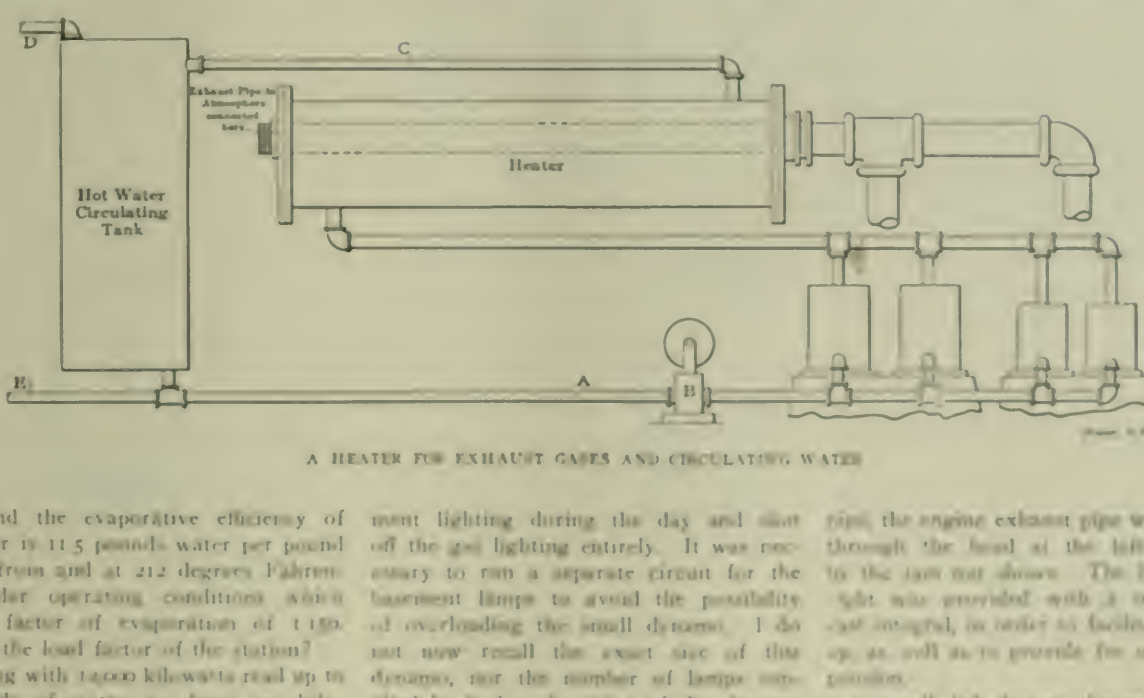
By E. G. Tilden

It was once my good fortune to be so placed that I could try some experiments on a gas-engine plant. The power outfit consisted of two vertical double-cylinder, four-stroke-cycle engines, one of 20 and the other of 40 horsepower and a direct-current generator for night lighting, belted direct from the larger engine, which also drove the machinery at night through shafting and belting. The 20-horsepower engine was used to drive the machinery during the day when lights were required only in the basement; this lighting was done with gas.

It was found by experiment that the smaller engine would almost pull the ordinary day load with one cylinder, showing that we had a large surplus of power. Consequently, we installed a second generator of proper size to handle the basement lighting during the day and shut off the gas lighting entirely. It was necessary to run a separate circuit for the basement lamps to avoid the possibility of overloading the small dynamo. I do not now recall the exact size of this dynamo, nor the number of lamps supplied by it, but the price of the dynamo was $125 and shutting off the basement gas meter, shut off a regular monthly gas bill of $60, while the amount of natural gas required for the engines for the month following the installation of the little generator was about 10 per cent. less than it was the previous month.

About the time the small generator was installed, experiments were being carried on with a view of finding the best timing of the igniters on the engines, and this was determined just after the installation of the extra machine. The apparent paradox of less gas consumption with more power was therefore due to the fact that the efficiency of the engines was improved by the ignition adjustment after the little generator in question had been put to work, and also by the larger load factor thereby obtained.

The plant equipment also included a boiler for furnishing hot water. In one part of the works we were buying water to cool the gas-engine cylinders, dumping the water, heat and all, into the sewer; while in another part of the building we were buying more water and burning "perfectly good" coal (that had to be paid for) to heat it up. A scheme for doing away with this double loss was finally developed. A heater, along the general lines shown herewith, was provided and connected up so that the exhaust gases from both engines passed through it, while the circulating water discharged from the engine jackets also passed through the heater and was heated for use in the hot-water system. The only loss was the hot water that was drawn off at the faucets, which was made up from the street main through the pipe A.



A HEATER FOR EXHAUST GASES AND CIRCULATING WATER

In making the heater, the body of which was a piece of ordinary 14-inch iron pipe, the engine exhaust pipe was screwed through the head at the left and held in the tank not shown. The head at the right was provided with a stuffing-box, cast integral, in order to facilitate making up, as well as to provide for unequal expansion.

A small belt-driven plunger pump B was used to insure proper circulation, its suction being connected to the pipe A and drawing the cooler water from the circulating tank. The discharge from the engine-cylinder jackets passed through the heater in contrary direction to that of the exhaust gases, back to the tank through the pipe C. The pipes D and E are the leads to and from the circulating system from which the hot water was drawn in the shops. The boiler was disconnected and permanently retired.

The cost of the heater, pump and piping was about $200, while the saving in cost of water and coal was just about that amount per year, to say nothing of the work and bother got rid of.

Some Useful Lessons of Limewater

An Interesting Chapter on the Chemistry of Sulphur; How to Make Hydrogen Sulphide; What It Will Do; Different Sulphur Forms

BY CHARLES S. PALMER

There are several matters connected with the chemistry of sulphur which we will take up, in order to get familiar with this common and useful substance and its compounds. The first thing is that innocent-looking compound, hydrogen sulphide, H_2S, or sulphureted hydrogen, as it used to be called. You may have heard of its bad-egg odor, but it is not really so unpleasant if it is handled right. The easiest way to make this gas (note that it is a gas) is first to make some iron sulphide, by heating together in an old iron pot some iron turnings and common brimstone. The iron and sulphur will unite with considerable heat; and when the operation is over, you can turn out the fused mass on the brick floor to let it cool. Break it into lumps, and you will note the dark bronze color of this iron sulphide, FeS. Fe stands for *ferrum*, the Latin for iron. When this iron sulphide is treated with dilute sulphuric acid, about one part of sulphuric acid to four or five of water, the action is like that shown in the following equation:

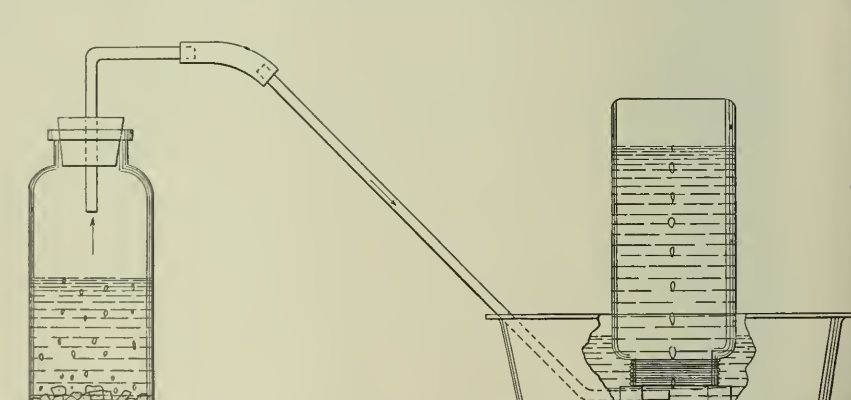
$$\underset{\text{Iron Sulphide}}{FeS} + \underset{\text{Sulphuric Acid}}{H_2SO_4} = \underset{\text{Ferrous Sulphate (Iron)}}{FeSO_4} + \underset{\text{Hydrogen Sulphide}}{H_2S}$$

Making Hydrogen Sulphide

This experiment of making the hydrogen sulphide is done in a common pickle jar, with a delivery tube, a common pneumatic trough and one or two fruit jars, as shown in the accompanying sketch. When you have collected several jars, take them out of the trough and set them mouth upward, covering them with cardboard covers. You will burn this gas, hydrogen sulphide, H_2S, and you will note that it burns readily, with a distinct and peculiar flame. The gas burns in the air, and the taper is extinguished when thrust up into the jar. You will not fail to note that as the gas burns it gives off the same kind of sulphur fumes, and with the same smell, as when you burn the common sulphur eight day match. You can see how all this happens by one glance at the oxidation table of sulphur given in a previous lesson; and here you will note the great advantage of having the compounds of each element given in order, from reduced, or hydrogen compounds, to oxidized or oxygen compounds.

Just why the burning sulphur stops at sulphur dioxide, or two-oxide, SO_2, instead of going over to the full oxidation form, SO_3, sulphur trioxide or three-oxide, is a curious matter, and one which has everything to do with the making of sulphuric acid, as we will see later. But you will miss half the game in studying this hydrogen sulphide, H_2S, the bad-smelling gas, unless you go on to some interesting experiments in analysis. So we will make several solutions of the common metals; such as sugar of lead (lead acetate), green vitriol (iron sulphate), blue vitriol (copper sulphate), white vitriol (zinc sulphate); and also some arsenic solution (common white arsenic dissolved in hydrochloric or muriatic acid), and some antimony solution (made by dissolving the metal in a mixture of hydrochloric and nitric acids (aqua-regia, or royal water, because this mixture of nitric and hydrochloric acids will dissolve gold). This solution of antimony you must not mix with much water because water will throw it out of solution. You will also want to add a few drops of ammonia to the solutions of iron and zinc; the rest will act best if left slightly acid.

You might almost mix these up, without labels, and even if the solutions were of the same color, the hydrogen sulphide would* pick each of them out for you. If you put some of each of these solutions of the various metals, each in a separate small jar, and lead in some of this gas, hydrogen sulphide, with the delivery tube, cleaning the delivery tube after using it in any solution, you will get this marvelous result: This same gas will throw down a black precipitate in the lead and the iron, but the lead solution is neutral or slightly acid; the gas hydrogen sulphide will throw down a yellow precipitate in the arsenic solution; it will throw down an orange precipitate from the antimony, a dark brown or black from the copper, and a white precipitate from the zinc solution. All this will take place right under your eyes, with the same gas, a colorless gas, hydrogen sulphide, H_2S, just as described: lead, black; copper, dark brown; antimony, orange; arsenic, yellow; iron, black; zinc, white. You can see that all this would be very convenient in telling what metal one had in solution. This set of tests is so useful and so remarkable that it will repay you to make some effort to collect the material for the tests and go through with them. It will give you much food for thought; and it will begin to show you how anyone can learn to test and analyze the common solutions of the common metals.



MAKING HYDROGEN SULPHIDE

At first one should begin with one metal in a solution, but after a time you can handle several metals, taking out each in its place and proving it up as you go along. Sometimes chemists speak of analyzing a solution of all the metals, but that is not quite correct, because it is not possible to have all of the metals in solution at the same time and in the same solution; but one may easily have as many as ten or fifteen of the common metals in the same solution; and one can learn to find each in its place, with the help of this gas, hydrogen sulphide. You will also note that it makes a difference in using this gas, hydrogen sulphide, to precipitate the metals, whether one sends it into a solution which is alkaline or acid in reaction. Thus, some of the metals will precipitate only in alkaline solution; others will precipitate in both acid and alkaline solutions.

Hydrogen Sulphide in Mineral Waters

This gas, hydrogen sulphide, occurs in many natural mineral waters. Some of the most famed of the health resorts owe their fame to the supposedly curative powers of the hydrogen-sulphide waters. The hydrogen sulphide is not the only substance in the waters, but as a rule there are several other ingredients, some salty in a broad and general sense, and some gaseous, like carbonic-acid gas. You can find out much about these waters by applying to the United States Geological Survey for a pamphlet called "Geo-Chemistry," by Prof. F. W. Clarke (Bulletin No. 330, Washington, D. C., U. S. Geol. Survey). It should be noted that this same gas, hydrogen sulphide, is what is called a reducer, that is, it can take oxygen, or its equivalent, out of bodies, bringing them down to a lower state of oxidation. Thus, if you lead some of the hydrogen sulphide into a dilute solution of nitric acid, you will note a yellowish or perhaps a milky white precipitate come down in the solution. This is only sulphur, which comes from the hydrogen sulphide, as it reduces the nitric acid to some lower form of nitrogen oxide. The gas, hydrogen sulphide, is quite soluble in water, and such a solution is often called "sulphydric acid," after the analogy of hydrochloric acid, although the old name, "sulphureted hydrogen," is still used also.

If sulphur is mixed with soda and fused for some time, peculiar dark-brown substances are formed, called "livers of sulphur," which are nothing more than sulphides of sodium. When these are treated with such acids as the sulphuric or muriatic, the same gas, hydrogen sulphide, is given off, and although you will always detect it by the nose, which is a perfectly legitimate reagent, it is handy to remember that a bit of filter paper moistened with any soluble salt of lead, such as lead nitrate, or lead acetate (sugar of lead), makes an excellent and easy test for the gas, the paper becoming dark brown or stove-polish black. One reason why good white lead paint often turns dark in the vicinity of drains is that the lead in the paint is colored dark by this same test; that is, by the foul gas, hydrogen sulphide, escaping from the refuse of the drain.

Different Forms of Sulphur

The next subject to study is sulphur itself. This comes into the market in several forms: First, as roll sulphur or common brimstone ("burnstone"). This is simply pure sulphur which has been melted and cast into thick sticks. When this roll sulphur, or brimstone, is crushed to a powder, it is called "flour" of sulphur. "Flowers" of sulphur is something quite different, however. It is made by condensing the vapor or fumes of distilled sulphur over water, or in a cool chamber, where it falls down as a soft fine powder, which is sulphur in a different condition from merely powdered brimstone. The "flowers" of sulphur is more than half in what is called the "amorphous" or gummy condition, while the powdered or "flour" of sulphur is mostly in the crystalline condition. We will see in a moment what these mean.

Take an ounce or two of brimstone and break it up so that it will slip down into a common test tube. The test tube must be held by a handle, either of wood or wire, as shown in a previous lesson, or at least with a loop of thick paper. Heat the sulphur carefully over a common flame or alcohol lamp. You will note that the sulphur melts to a clear thin liquid, of a magnificent yellow color. Pour some of this into a tumbler of water, and it will form hard yellow shot, which are made up of one of the two principal crystalline forms of sulphur. Now save most of the melted sulphur in the same test tube, and go on heating it. You will note that shortly it begins to get orange in color, then much darker, and soon it is so thick that you can hold the test tube upside down without its flowing out of the mouth of the test tube. Go on heating it, and in a short time, while still dark in color, it will get somewhat thinner, not as thin as it was when first melted, but thin enough to pour from the test tube.

This hot sulphur will also boil, and if you let the vapors that escape from the test tube fall quietly onto the surface of some water in a tumbler, you will note the beautiful light yellow skin or "pellicle" of "flowers" of sulphur. You can pick this up like a thin piece of sheet rubber, for its elasticity is remarkable. But while the test tube of dark-colored sulphur is still hot, pour it out in a thin slow stream into a tumbler of water, noting that it falls down much like so much molten rubber. You will get a little pile of this rubber-like sulphur at the bottom of the tumbler of water; and as soon as it is cool enough to handle, pick it up in the fingers and handle it. It is precisely like softened rubber. You can draw it out, noting its elasticity. But set it aside for some minutes, and you will see that it soon becomes brittle, and also somewhat lighter in color. This elastic form of sulphur is called "amorphous" sulphur; that is, elastic, gummy, noncrystalline. As it hardens and gets stiff it becomes crystalline and somewhat lighter in color.

Making Sulphur Crystals

Now look at the sulphur which is still left on the sides of the test tube. Even with the unaided eye you can see that it is largely made up of needle-like crystals. These are of what is called the monoclinic form. Take enough sulphur to fill a small cup, melt it and let it cool until it has just crusted over; then, breaking the crust, you will see the inside filled with a radiating nest of these needle-like crystals. They will show better if you pour off the still molten and not yet solidified sulphur. These crystals are of a beautiful golden yellow, but in a few hours, almost always after standing over night, they will lose their clearness, becoming opaque, and somewhat lighter in color. This change is due to a change in crystalline form, not in the outside form of the crystal, but in the inside of the crystals. The new form is called the ortho-rhombic, and it is the form in which natural sulphur crystals occur.

One can easily get some of these by making a solution of sulphur, as by dissolving it in the foul-smelling liquid called carbon disulphide. This carbon disulphide is frequently used as an exterminator of insects about flour mills and grain elevators. It can be obtained from any druggist, and if you work with it you must remember to keep it away from a flame as it is exceedingly inflammable. If you should get some of this, you could easily make a solution of sulphur, afterward pouring it out into a saucer and letting it evaporate, when the small orthorhombic crystals are seen to collect as the solution of sulphur in carbon disulphide, CS_2, evaporates. If you ever take the trouble to go up to some mineral cabinet you will see quite large crystals of this natural ortho-rhombic sulphur.

In summing up, we will notice that sulphur has several forms in the liquid state, and also several different forms in the solid state. In the liquid state there are three forms: First the thin, light, watery form, then the thick, dark-colored tarry form, and lastly the still dark but fairly liquid form which, poured into water, gave the amorphous form. In the solid state we found three forms, also: the two crystalline forms and the amorphous or rubber-like form. It is interesting to notice that sulphur carries out this tendency to exist in several forms, even into the gaseous state, as the vapor which we poured over the water is a very heavy gas, having the formula S_6, and if this is heated still higher it falls into a thinner vapor having the formula S_2.

This tendency for a substance to exist in several forms is called allotropism, and the different forms are called allotropic forms. There is no common element which can rival sulphur in the variety and perfection of these forms, nor in the ease with which they are made; although carbon can exist in the common form of coal, and also in the two crystalline forms of the diamond and of graphite, or lead-pencil ore, and common iron can exist in several forms. When we come to the chemistry of iron and steel you will hear much of the so-called "alpha" and "beta" forms (these words alpha and beta are the old Greek names of the letters A and B). Common oxygen also can exist in the form of common oxygen, O_2, and also of ozone, O_3. Similarly we shall find that some of the oxides of nitrogen have allotropic forms, as also does common carbonate of lime, in the forms of calcite and aragonite.

The next subject to consider is the first oxidized form beyond sulphur, namely, sulphur dioxide; but this is so closely connected with sulphur trioxide and the making of sulphuric acid that we will leave the subject to another lesson. Meanwhile just a word about the occurrence of sulphur. Until recent years most of the sulphur of commerce was obtained from the little island of Sicily in the Mediterranean sea, but some years ago, when boring for oil and gas in Louisiana, immense deposits of sulphur were found at a depth of only a few hundred feet. These deposits of Louisiana sulphur (which seem to be almost inexhaustible) occur in connection with a lime compound, gypsum or calcium sulphate; but the awkward thing about it was that the deposits were almost inaccessible from the fact that they were covered by thick and obstinate quicksands. All attempts of mining engineering to penetrate these quicksands and to reach the sulphur deposits by shafts failed, until Dr. Frasch invented a method of sinking several large tubes in series, one within the other. Through the outer tubes steam and hot water are forced down at a temperature and pressure sufficient to melt the sulphur in the gypsum beds, and this molten sulphur was then forced up to the surface in a liquid stream where it is allowed to flow into large tanks and harden naturally. As it cools, it is broken up and shipped without further treatment. This curious method of mining sulphur accidentally happens to result in furnishing a very pure and a very refined form of sulphur; in fact, over 99 per cent. pure; and this article has practically replaced foreign sulphur in the home market.

Steel Bands versus Leather Belts

By E. Hoffmeister

Successful trials have been made to replace leather belts by steel bands. Because they have nearly no thickness, they avoid the main evil—the slip—nearly perfectly (less than 1/10 per cent.) and have therefore an efficiency of more than 99 per cent. An especial friction layer is fastened on the pulleys in order to produce the necessary friction between the band and the circumference of the pulley. The length of the band is practically constant. The distance of the shafts may be small. The air resistance, which is very considerable at high speeds, plays no rôle with steel bands.

Band drive is exceptionally qualified for big drives and is very efficient, as well in regard to effect as to speed (to 330 feet a second). It is superior to rope drive by about 15 per cent., and is excellent for dynamos and motors and gas engines. The efficiency is nearly incredible. For example, at a trial a 1/8x3/128-inch steel ribbon ran at a speed of 190 feet a second, transmitting 146 horsepower.

To transmit 100 horsepower at 200 revolutions a minute, with 40-inch pulleys, the cost per year, everything included (interest and amortization), would be $700 with ropes, $400 with leather belts and $82 with steel bands.

National Gas and Gasolene Engine Trades Association

The National Gas and Gasolene Engine Trades Association will meet on June 22, 23 and 24, at South Bend, Ind., with headquarters at the Oliver hotel.

This association was organized some months ago to advance the interests of the gas- and gasolene-engine trade, and promote a profitable acquaintanceship among the various lines of trade interested in the internal-combustion engine. Anyone who is interested in this type of engine, whether manufacturer, dealer or user, is eligible to membership.

The program has not as yet been fully completed, but will include, among others, the following papers:

"The Suction Gas Producer for Small Power Plants," by C. J. Atkinson, Watertown, Wis.

"Storage Batteries for Ignition Purposes," by G. L. Chambers, Cleveland, O.

"A Running Test of a Gas Engine, with Data," by J. C. Miller, Chicago, assisted by others.

"Water, Its Uses and Abuses in Relation to Gas Engines," by H. W. Jones, Chicago, Ill.

"Some Accessory Items," by E. H. Campbell, Detroit, Mich.

"Compression Couplings," by William S. Noyes, Chicago, Ill.

"Advantages and Disadvantages of Selling Gas Engines Through the Jobbers and Dealers."

An invitation has been extended to the American Gas Power Society and the National Gas and Gasolene Engine Manufacturers' Association to attend this meeting.

By way of entertainment there will be a trolley ride from South Bend to St. Joseph, Mich., furnished by courtesy of Gas Power. The local Chamber of Commerce has also arranged for an automobile ride and inspection of the large and interesting factories of the Studebaker Manufacturing Company and the South Bend Watch Company. Everyone who is interested in the line of work of the association is invited to attend these meetings, whether members of the association or not.

Coal Analysis *

Coal-bearing rocks underlie three-fourths of Illinois, including 85 of its 102 counties. The coal area is estimated at from 36,000 to 42,000 square miles—the largest area of bituminous coal within any single State. There are approximately 1000 mines in the State of which over 400 are railway shipping mines. The work of the State Geological Survey is therefore very largely devoted to coal and the problems of the coalfields.

Illinois ranks second among the States in the production of coal. In 1907, 51,317,146 tons, having a total value of $54,687,382 were mined. The figures for 1908 are not complete but preliminary estimates indicate that Illinois was almost alone among the States in holding its production. While in the country as a whole the amount mined fell off from 15 to 20 per cent., Illinois mines produced as much as or possibly more than in 1907, a record year. Despite this gratifying fact it remains true that our mines are not working to anything like their capacity. In 1907 the average number of days worked was 218. It would probably be fair to assume 300 working days a year as possible. On this basis there was a loss of 30 per cent. of loss in our State. The reasons for this are complex. In part they lie in the nature of the coal, which prevents its storage without spontaneous combustion; in part, in the general ignorance as to correct methods of firing and the real value of the coal; and finally in part, in the present organization of the industry with excessive competition in selling. The net results are bad for the industry and therefore for the State as a whole. Cheap coal reduces manufacturing costs but allows wasteful burning. It also entails wasteful mining and even prevents the introduction of methods of safeguarding the men in the mines. It is a serious question whether we are not paying, in loss of life in the mines, in loss of efficiency in our plants, and in loss of interest and capital invested in the industry, more than the cheapness of the coal is worth.

The study of the coal and coalfields of the State has been carried on both in the field and office. The work has been directed toward:

(1) The solving of problems of stratigraphy, such as the distribution and correlation of various coal beds, together with the collection of all data relating to the origin and the mode of deposition of the coal and accompanying beds.

(2) A study of the composition and uses of coals.

(3) A study of the mode of occurrence of coal as relates to the methods and costs of mining.

*Delivered as an address before the Illinois Fuel Conference at the University of Illinois, Urbana, Ill., by Dr. H. Foster Bain, director Illinois State Geological Survey, March 13, 1909.

(4) A study of the preparation of the coal for the market, its transportation, its normal markets and the competitions which it meets.

The first step in the solution of the problems of stratigraphy is the making of accurate detailed maps and the compilation of drill records. This is now being done and considerable areas near Peoria, Springfield, Belleville and in the Saline and Williamson county fields have been surveyed in coöperation with the United States Geological Survey. These maps show the thickness and lay of the coal beds and from them it will be possible to tell quite exactly how much coal is present and to plan its economical working. At present it is possible only to guess at the original content of the field and these guesses vary from 136 billion to 240 billion tons. Either is perhaps sufficiently large for our comfort.

The study of the composition of the coal is directed especially toward the determination of its availability and the best means of using it. Samples are taken by uniform methods in the mine and in the market and in connection with the Engineering Experiment Station elaborate experiments are being made of the methods of storage, of handling the coal, and of burning it. We hope soon to take up the matter of gas production and coke making and have had under way for sometime certain preliminary experiments.

The mode of occurrence as relates to mining methods and costs has been barely touched. In my judgment it would be well if the State made separate provision for this work. In the absence of special provision we are attempting to gather such notes as we can in the course of our regular work. "It has been found impracticable at the present time, mainly owing to limitations of funds, to undertake certain highly desirable studies of the technology of the mining industry and of the geographical distribution of markets for Illinois coals. It is believed that much good would result from investigations along these lines and that certain portions of the work are well within the proper field of the State Geological Survey. It is now well known that there is, under present commercial conditions, an enormous waste in the mining of Illinois coal. In individual districts it has been estimated to amount to as much as 60 per cent., though of course such losses are not general. It would, however, probably be safe to say that in very many places 50 per cent. of the coal in the ground is left unmined or is ruined in the process of mining. In addition, the methods of mining introduced in recent years have greatly increased the production of fine sizes and have also, seemingly, increased the danger to life and property in the mines. The causes for all these losses are complex, and it is not to be supposed that either operators or miners willingly submit to them. Neither is it to be expected that the losses of life and property can be entirely done away with. At the same time experience has abundantly proved that careful and impartial investigations of such conditions will point the way to the remedying of some at least of the abuses, and in view of the enormous importance of the subject to the State and the public at large, such studies are believed to be amply warranted.

There has been no opportunity as yet seriously to take up the study of markets. The expansion of markets for Illinois coal is a matter of vital importance to the coal industry and indirectly to the people of the entire State. One of the most important means of promoting this expansion is by removing certain misapprehensions as to the quality of the coal and the pointing out of better means of burning, so as to increase its efficiency and decrease the smoke produced. This work has been taken up vigorously by the Engineering Experiment Station, which has published excellent bulletins on "How to Burn Illinois Coal Without Smoke," and other similar subjects. In addition to this valuable work, there should be investigations of the actual markets for the different grades of coal and of possible enlargements of these markets. There are large areas to the northwest within which Illinois washed coals might profitably supplant Eastern coals now being sold. There are other areas to the south and west where, with proper organization of transportation agencies, even in advance of improvement of the rivers, trade territory would be gained. Any widening of the market would be of large benefit to the local industry, particularly if the summer market could be increased. For this reason the studies now under way relating to weathering of coal and coal storage are especially important.

The Easton Gas and Electric Company's Plant

By Edward T. [illegible]

The Easton Gas and Electric Company's generating plant is situated in South Easton, Penn., on a strip of land between the canal of the Lehigh Coal and Navigation Company and the Lehigh river. This was originally a water-power plant receiving water from the canal and discharging into the river, the working head being about 20 feet. Up to 1905 the plant was operated in conjunction with a

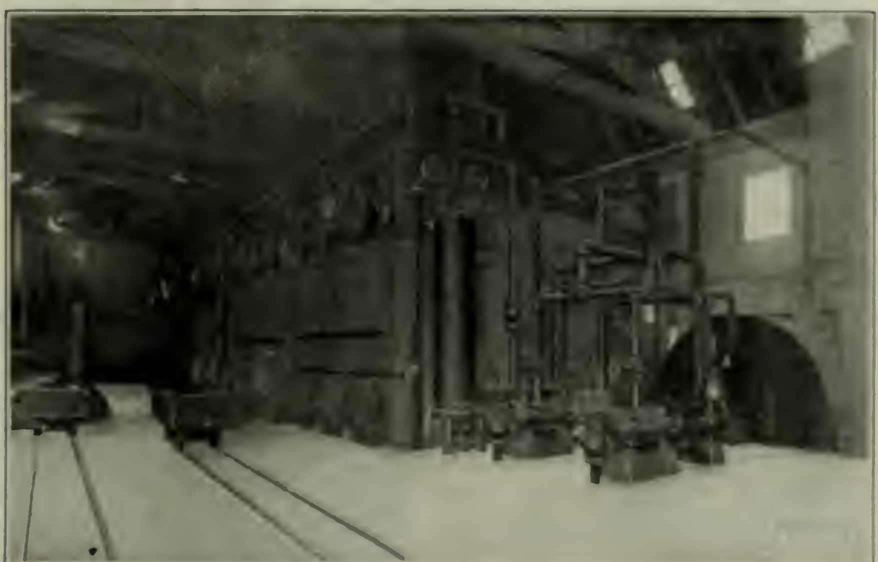


FIG. 1. THE BOILER ROOM

steam plant situated on Ferry street in Easton about 1½ miles away. In that year it was found advisable to abandon the steam plant and build a new one in the same building with the water-power plant in South Easton.

The New Steam Plant

In 1907 this new steam plant was enlarged 100 per cent. and the water-power completely remodeled. The present equipment consists of four prime units of a combined capacity of [illegible] kilowatts, capable of carrying continuously [illegible] kilowatts, and three water-power units rated at [illegible] and capable of carrying [illegible] kilowatts when there is sufficient water. The steam installation consists of four [illegible]-horsepower Babcock and Wilcox water-tube boilers and two [illegible]-kilowatt 60-cycle two-phase [illegible]-volt Curtis turbo-generating units running at [illegible] revolutions per minute. The boilers have selfficient capacity to carry 50 per cent. overload on the turbines. Each boiler is equipped with 180 four-inch tubes and with 80 square feet of Treadkill shaking grates. They are built for 200 pounds working pressure and have superheaters to give 100 degrees superheat. A low

FIG. 2. UNLOADING COAL FROM THE CANAL

grade of coal is used, forced draft being supplied by two 7-foot A B C blowers. Two steel stacks, 100x6 feet, furnish sufficient draft to carry half load on the boilers. Both the feed-water pumps and forced-draft equipment are controlled by automatic regulators.

Coal is received from canal boats and unloaded by clam-shell buckets. It is then carried and dumped in the storage yard by means of a Hunt automatic railway. Sufficient coal is stored in the summer months to last through the winter. A bucket elevator carries the coal from this yard to an overhead tank from which it is dumped by gravity into one-ton charging cars. These cars pass over scales before reaching the boilers, which are fired by hand directly from the cars. The ashes fall from the grates into the boiler ashpits, which have sloping bottoms, are loaded by gravity into ash cars and dumped on the low land back of the plant.

The turbines are equipped with Alberger surface condensers of the counterflow type, with automatic hotwells from which the water of condensation is delivered to a storage tank. From this tank the boiler-feed pumps obtain their water. Makeup water is added at the condenser by means of a bypass between the steam and water chambers. The cooling water is siphoned from the canal through the condenser and discharged into the river. The bypass used for the makeup water also keeps the siphon free from air.

The cooling water enters at one end and at the top of the condenser, and after traveling three times its length, is discharged at the bottom of the opposite end. Steam enters at the bottom and the dry-vacuum pump connection is made at the top. This arrangement insures that the air removed by the vacuum pump will be as dry and cool as possible and

FIG. 3. TURBO-GENERATING UNITS

that the hotwell water shall be at the highest possible temperature.

On the turbines, hydraulic valve gear and oil step bearings have been installed in preference to electric valve gear and water steps. The auxiliaries, including two-stage dry-vacuum pumps, hotwell pumps, step pumps, boiler-feed pumps and blower engines, are steam driven, and their exhaust is condensed in a closed feed-water heater. The 40-kilowatt exciters are motor driven and are controlled by a Tirrill regulator. A 35-kilowatt steam-turbine exciter is used to start the plant in case of a complete shutdown.

Foundations of both boilers and turbines consist of piers and reinforced-concrete girders. The fact that the plant had to be placed in an existing building through which passed penstocks and tail races, made the ordinary foundation impossible.

Hydraulic Installation

The hydraulic installation consists of two 1000-horsepower and one 180-horsepower units, each consisting of two runners on a horizontal shaft. The largest units have 48-inch runners and are direct-connected to 500-kilowatt two-phase 60-cycle 2400-volt generators running at 150 revolutions per minute, while the smaller machine has 24-inch runners and is belted to a 120-kilowatt 60-cycle two-phase 2400-volt generator. Lombard governors are used on the 1000-horsepower units.

On the electric end the steam and hydraulic plants are run in parallel, the object being to keep the hydraulic plant loaded at all times, and to handle any excess load with the steam plant. Power is distributed by eight sets of feeders. Three two-phase 2400-volt lines transmit power to the Ferry street plant which is used as a center of distribution for both alternating and direct current. By means of motor-generator sets power is converted to direct current for lighting and trolley service, a Gould storage battery with a booster being used to even up the trolley load. Six single-phase lighting lines with phase voltage regulators distribute power and light from this plant. Three two-phase 2400-volt lines transmit power and light directly from the generating plant to the adjacent portion of the city, and two 11,000-volt three-phase lines transmit power about eight miles to Nazareth and Bottown. At Nazareth it is stepped down to 2300 volts two-phase to supply power and light to the city, and at Bottown power is delivered to a synchronous converter for trolley service.

The company here is located in one of the best communities in the country for the development of light and power, especially the latter, as the city of Easton and surrounding territory are dotted with manufactories of various natures, prominent among them being a number of large silk mills which find electric drive particularly applicable to their work. During the past fall the company passed under the control of the Doherty Operating Company, of New York, and already, under Henry L. Doherty, it has gained a strong impetus and is rapidly forging ahead and will no doubt outgrow its present plant within the year. The combination of steam and water under which this plant operates, puts it in a particularly favorable position in competing for the power of the different industries in its territory, and an interesting development in this field is the use of electric motors in conjunction with water wheels in the numerous feed and flour mills, soapstone, paint and other mills which are located along the rivers and streams flowing into the Lehigh and Delaware rivers which unite here.

The power branch of the business has been developed to the point where a day load of 1400 kilowatts is carried on the plant continuously, and the field is only touched. In and around this company's territory is a possible development of over 7500 horsepower, which the company is making a strong effort to secure with exceptionally good success. The management of the company is invested in H. F. Cresson, formerly of the United Gas Improvement Company, of Philadelphia. His assistant, F. L. Franklin is to be credited with the unique and efficient equipment of the generating and distribution systems and the high standard of operating efficiency.

It is a case of leaping before looking when a boiler is immediately condemned because a certain horsepower is not being generated. The fault may lie in the engine rather than the boiler. Poorly adjusted valves are responsible for large consumption of steam by the engine and the engineer cannot always detect the cause of the increase without mechanical aid. It is good policy to make use of an indicator and learn from it the root of the trouble that is responsible for the undue consumption of steam.—*Engineering Journal of Canada.*

Inspection for New York's Low Pressure Boilers

By A. C. Rossary

In a previous article upon the supervision of the power of New York city exercised by the Sanitary Company, generally known as the Boiler Inspection Bureau of the Police Department, it was stated that only three times in 40 years had there been boiler explosions in the city. To those who glanced through the commissioner's report for 1908, this statement may seem to be in error, for a dozen accidents are reported as occurring to high-power boilers and a list of about 20 injured is given.

An analysis of the list of casualties shows that six of the twelve were caused by the blowing out of tubes. Of these, two were caused by defective metal, one by foreign matter found in the tube, and two were due directly to the crowding on of steam during the heavy traffic on the Brooklyn Rapid Transit in summer. Nine were injured severely, but none fatally, in these cases.

Of the remaining six explosions, one was caused by the bursting of a cap on an economizer and another by the blowing out of a defective gasket on a lower manhole plate. The gasket had been inspected after it had been twice repaired and passed by the insurance company. Seven cast-iron headers in the front of one boiler cracked for some unknown reason and caused an explosion, but no one was injured. One of the explosions reported was the breaking of a steam pipe in a dry dock caused by the raising of the dock with the tide; another casualty was due to the escape of steam on the second floor of a plant. The steamfitters making repairs disconnected the pipe before the steam had been shut off and were scalded.

Danger from Low-pressure Boilers

Having analyzed the use of the high-power plants, it will be interesting to consider those of the so-called low-power plants, particularly at this time, when an effort and a strong one, is to be made to bring them under the control of the Sanitary Company through an ordinance to be introduced before the board of aldermen.

It is contended by the Sanitary Company, that there are thousands of high-pressure boilers in New York, masquerading as low-pressure boilers, with the logical sequence of increasing the plants to incompetents, the discharge of licensed engineers and the incidental escape of the plant from the vigilance of the Sanitary Company.

In the Voss bill before the last session of the legislature, an attempt was made to define a low-pressure boiler as one not having more than 6 square feet of grate surface. At the rate of three horsepower to a square foot of grate surface, it practically permitted 18 horsepower instead of the 10 horsepower which the present law seemingly allows; only seemingly, observe, for it really allows any pressure the owner cares to put upon his boiler, as it is not subjected to test, inspection, compulsory employment of a licensed engineer or any kind of supervision, as long as the safety valve is set for 10 pounds.

There are low-pressure boilers in New York with 30 and more square feet of grate surface, absolutely immune from any kind of regulation by the fact that the valve is set for 10 pounds pressure. What happens when the safety valve sticks or some other dangerous factor arises is shown clearly in a tabulation drawn up for Deputy Commissioner Hanson to be presented to the board of aldermen as reasons for the passage of the ordinance bringing the low-pressure and portable low-pressure boilers under the care of the Sanitary Company. These casualties are only a few of those that occur yearly in New York. Others were not even reported to the bureau, being in many instances cases for the coroner. They are worthy of consideration by the authorities of every large city where low-pressure boilers are not subject to regulation.

October 22, 1908—Bernard Kolan, 23 years old, janitor, killed by low-pressure boiler exploding at 1075 Tinton avenue, the Bronx.

November 10, 1908—low-pressure boiler exploded, 203 Vanderbilt avenue, Brooklyn; no loss of life.

December 10, 1908—Fred Mundha, 37 years old, janitor, burns about the face and body. Removed to Swedish hospital. Mabel Mundha, four years old, fractured skull, removed to the Cumberland street hospital. Died in hospital. Elizabeth Mundha, five years old, lacerated chin and leg and general contusions. Removed to Cumberland street hospital. These were the net results of the explosion of one of those high-pressure boilers masquerading, legally too, as a low-pressure boiler in the basement at 110 Quincy street, Brooklyn.

April 29, 1909—Dr. William Niles, 45 years of age, 214 Lenox avenue. Killed in the basement of his residence by the explosion of a low-pressure boiler. He had forgotten to open the connections from the waterback, and the boiler naturally let go.

Only a few days before a similar low-pressure boiler gave way and killed a woman. When the case was before the coroner, it was discovered that the man who installed the plant had fled. It was not necessary for him to leave, for according to law he could not be punished. Was not the safety valve set for 10 pounds?

The Courts' Construction of Low-pressure Boilers

The courts of New York by their construction

struction of the word "and" in section 243 of the Greater New York charter, have effectually tied the hands of the police and granted immunity to owners or lessees who wish to run plants without engineers and beyond the jurisdiction of the inspectors. The word occurs in the clause exempting from the compulsory employment of licensed engineers on certain "boilers carrying not over 10 pounds of steam and not over 10 horsepower." According to the courts, the 10 pounds of steam and the 10 horsepower are interdependent, one hanging to the other.

Under this ruling, it is only necessary for the owner of a high-power plant to set the safety valve at 10 pounds to step out of the jurisdiction of the police, discharge his engineer and put a laborer in charge of a boiler which may have 35 square feet of grate surface and a capacity of, perhaps, 100 horsepower. The law, knowing nothing of the bearing of grate surface upon steam capacity, goes by the letter, and the result is that owing to the increasing use of electricity supplied by central stations, thousands of high-pressure boilers have been converted into so many menaces to the lives and property of the occupants and owners of buildings. There is as yet no means of heading off the danger.

A steamfitter tells an owner that if he has his safety valve set for 10 pounds, he can safely dispense with the service of his engineer and put on a laborer to handle the plant and take current for his motor and electric lights from an electrical company. That he need not have his boilers inspected and can refuse to make repairs. In addition, he will be freed from the trouble of sending in reports. Under the regulations of the Sanitary Company it was necessary to make twelve reports a year on the condition of the plant and the owner was forced to make repairs, the need of which he could not understand, not being an engineer. The proposition appeals to the owner. He keeps his boiler for heating purposes, connects all the radiators in the building and has the safety valve set for 10 pounds. Then he finds that his grate is too large and the safety valve is blowing all the time. The idea of selling the surplus steam to his neighbors is then conceived, and the result is three or four houses are heated by a single boiler; a boiler which, according to law is a low-pressure affair carrying only 10 pounds of steam and having a capacity of only 10 horsepower, when in reality this same boiler has a capacity much in excess of this figure.

Presently a warm day comes. The radiators in all the houses are shut off tight. The substitute for the licensed engineer is somewhere in the neighborhood. The indicator starts to spin and perhaps the safety valve sticks. Presently the substitute for a licensed engineer returns, looks at the meter, sees 150 pounds registered, wonders a little, but thinks it is all right because the valve has not gone off. There can be no danger; he opens the door and throws on a little more coal. Suddenly a tube gives, the substitute becomes a blistered parboiled object writhing on the floor in a cloud of steam. The owner is fortunate. The giving of the tube saved the building. He can get another tube and another substitute. No one is to blame, that is, criminally.

Hoisting-engine Menace

Another menace to life and property in the city that has developed and is growing rapidly, is furnished by the increased use of electricity for hoisting engines. Again the engineer's salary is an important element together with the dodging of repairs that should be made. The contractor does away with his boiler, sets up a motor, takes current from the street and a laborer is substituted for a licensed, skilled mechanic. It was just this penny wise and pound foolish policy that dropped one of the gigantic statues worth thousands of dollars as it was being swung into position on the front of the Hall of Records. It is liable to drop a ton of metal on the heads of pedestrians at any moment. And no one is to blame. The courts have held that there is no boiler and therefore no need for a licensed engineer, and the police department has no jurisdiction.

The ignorance of the average owner of the fact that the supervision of his plant is as much for his own good as for that of the general public is most appalling. Only recently a man came into town with a traveling crane. He demanded exemption from inspection of his boiler and the compulsory employment of an engineer, on the ground that his crane was a locomotive engine, because forsooth, it ran on rails. It took considerable time to convince him, first, that the bureau was not persecuting him, second that there was no graft in it, and third, that it was as much for his benefit as for that of the public that his plant be regulated. Then he was willing to obey the law.

The Voss Bill

This bill, known as Assembly No. 443, was an attempt on the part of the International Union of Steam Engineers, acting with the approval of Deputy Commissioner Hanson, to straighten out the kinks of the law and to do two important things. The first was to rip the mask of the law from the pseudo-low-pressure boilers, and the second was to obtain recognition for the ability of steam engineers to handle power other than steam. The increasing use of current from commercial electrical companies in large cities, particularly in hoisting plants, and the consequential discarding of boilers and discharge of licensed engineers and their substitution by laborers whose hands are untrained in the art of lifting, all combine to present a problem which engineers must solve with legislation. The Voss bill was an attempt to solve it so far as New York City was concerned.

The bill provided for the annual report of owners, agents, lessees, etc., and the inspection of every engine or engines, irrespective of motive power, in addition to the previously stated steam boiler or boilers, by the Sanitary Company. The company, as heretofore, to limit the pressure "or power to be applied to such engine or engines, irrespective of motive power." The certification of inspection to be precisely the same in all cases and the fee for inspection to be the same.

It will be noticed that these amendments would give the Sanitary Company practical supervision of the power in New York, as it states "irrespective of motive power," be it electrical, gas, gasolene, hot air, in addition to its present control of the high-pressure steam plants. The amendments are frankly directed at the control of hoisting engines where electricity is used.

In this connection, it might be pertinent to inquire the amount of expert knowledge the police department possesses of motive power other than steam. Its bureau of electrical service, consisting of 107 men, with 10 exceptions all patrolmen, operate 2000 miles of special police wires and make all repairs and maintain the electric light and power of the department.

It has even been said that there are inspectors in the Sanitary Company who are not practical engineers. A careful investigation failed to find one who had not a certificate as a licensed engineer, obtained before he entered the department, and the records of the bureau show that each man in touch with the practical work of the bureau passed an examination before the examiners on his ability as an inspector when he was drafted into the bureau. Further, each man has had his qualifications for the position certified to by three citizen engineers of good standing in New York.

It is in fact remarkable how many engineers, boilermakers and steamfitters are to be found among patrolmen. Recently ten were required to operate the harbor flotilla of gasolene launches. Thirty-five were drawn from the force and sent to the bureau for examination. A number were rejected as having no experience in that line of work, stationary men mainly, and 10 were sent to the harbor squad on probation. All of the 35 had certificates showing good standing as engineers, obtained, necessarily, before entering the department.

To continue with the bill, the amendments to section 343 exempted vehicles and chartered railway locomotives or boilers not carrying over 10 pounds of steam and "not having more than 6 square feet of grate surface," and here is where it hit those operating such plants, "or to operate any engine, irrespective of motive power, exceeding 10 horsepower," without a certificate. The remainder of the section ran as formerly, and at its conclusion the following addition, brought the crafts that ply around New York, under the supervision of the bureau, and in that way, under the engineers of the city:

"This section," it stated, "shall also apply to and include the operation and use of all boilers and engines in vessels used on the waters in the city of New York, not coming under the jurisdiction of the United States Government."

This refers to derricks, scows and non-passenger and nonfreight carrying boats, solely, for a later amendment eliminates motor boats, gasolene launches, etc., used privately.

New Ordinance under Way

The failure of this bill to win a favorable hearing at Albany, followed immediately afterward by the killing of Dr. Niles previously referred to, and the Schreyer decision were the motives for the drafting of a new ordinance for the regulation of low pressure boilers to be submitted to the board of aldermen. That the police department had no jurisdiction over boilers used for generating steam for heating purposes, regardless of the size of the boiler, had been the decision in the court of special sessions, April 29, 1909, in the case of John Schreyer, of 343 Central Park West.

At this address is a 20-family apartment house. The boiler is 12 feet long by 3 feet in diameter. Since 1902 it had been a licensed high-pressure boiler subject to annual test and inspection. But in 1908, Schreyer decided to run the boiler at low pressure. John Adams, found operating the plant without a license, was summoned to the West Side court and held for trial in the court of special sessions for violating section 343 of the charter. He was promptly discharged by that court, it being decided that the charter does not authorize the police department to examine boilers in private dwellings, although the danger of the 20 families arising from the combination of an unlicensed engineer running an unlicensed boiler was explained.

The ordinance as drafted by Lieutenant Breen and being considered by Deputy Commissioner Hanson for final draft and presentation, is as follows:

"All boilers used for generating steam for heating purposes in the city of New York are hereby placed under the jurisdiction of said police department which is hereby authorized and empowered to test said boilers. Such tests of boilers shall be conducted in accordance with the provisions of the Greater New York charter and laws of the State of New York as are applicable to boilers provided for in said charter and laws.

"The provisions of this ordinance shall not apply to the use of steam boilers for generating steam for heating purposes in any private dwelling which shall be intended or designed for, or used as, the home or residence of not more than two separate or distinct families or households. A violation of this ordinance is a misdemeanor."

It is expected that if passed the ordinance will be beneficial in two distinct ways. It will prevent the owners of large apartment houses from taking advantage of the Schreyer decision and run their boilers independent of engineers or inspections, and it may afford a chance to examine and bring under the system of the bureau the class of men now operating the low pressure plants, with the probable formation of a fourth-grade engineer authorized to run low-pressure plants only.

It is conceded by the bureau that to force an owner of a low-pressure plant, in a building where the rents are not high, to employ a licensed engineer of the third grade is a hardship. For the operation of these low-pressure plants a class of oilers, firemen and general assistants who have not completed their time for the third-grade certificate, might be secured, examined and attached to the bureau, and the same system of monthly reports and annual inspection be extended to them.

Cast Iron Fittings and Superheated Steam

By John Primrose

Articles have been appearing in engineering papers and manufacturers' publications in which superheated steam has been charged with being responsible for the failure of cast-iron fittings, and for trouble due to leaky valves in steam-pipe connections. In cases where there has not been time nor opportunity to investigate thoroughly, the result has been rather to militate against the use of superheat, and in many cases people have been afraid to avail themselves of the increased economy and other advantages of superheated steam. Statements to the effect that all cast-iron fittings and valves must be replaced by cast steel, if superheated steam is to be used safely, are most unfortunate at the present stage of development of superheated steam in this country, because the popular knowledge of the subject is such that the effect of such a statement is to picture untold troubles of all kinds with the steam equipment for which no possible increase in economy would be a recompense. It is a pity to block an advance in steam economy of such undoubted value unless, of course, there is some real danger in the way.

In a number of cases cast-iron fittings through which superheated steam was passing failed in various ways, and the conclusion arrived at was that superheated steam weakened the metal. The complete lack of a satisfactory theory or reason why superheated steam should weaken cast iron and make fittings and valves made of that material dangerous arouses suspicion of the correctness of the conclusion. Test bars were carefully cut from some of these fittings and the breaking strain compared with what it should be for an average run of iron. The metal of the broken fitting showed, in some cases, but half the tensile strength, and the conclusion arrived at was that superheated steam passing through a fitting reduced its tensile strength at least 50 per cent. The logic whereby the conclusion is obtained is not apparent. The fitting was evidently weak, otherwise it would not have failed; so that nothing has been learned by breaking test bars. Further, cast-iron fittings have been failing in saturated-steam lines since the metal was first used for the purpose, easily accounted for by the well known difficulty of making homogeneous castings and the difference in the tensile strength of castings from the same heat. It is not remarkable, then, that several cast-iron fittings have failed when passing superheated steam, and the cause is much more likely to be the original weakness of the metal rather than the effect of superheat. Cast-iron fittings carrying a fluid so far removed from superheated steam as water have been known to decrease in weight and fail in different ways. Certain it is that cast-iron fittings have failed in many ways before the advent of superheated steam in this country, and it seems unreasonable that a few subsequent failures should be considered proof that superheated steam is injurious to cast iron.

One manufacturer of cast-steel fittings has made elaborate tests, exposing cast-iron flanges to varying temperatures from 500 to 800 degrees Fahrenheit, for a number of weeks. The effect on a flange 12½ inches in diameter was to increase the diameter $\frac{1}{32}$ of an inch. Upon this is based a theory that a molecular change in the metal has resulted, the increased volume indicating loss in tensile strength, and that possibly the carbon silicon and phosphorus contents of the metal are so affected by the temperature that the strength is impaired. There are very many reasons why this latter is scarcely possible, but assuming for the sake of argument only that cast iron does "grow" and lose strength at these varying temperatures, why condemn superheated steam? If superheated steam were allowed to vary in temperature to any such extent as these tests, the damage to fittings and valves in the steam line would be quite inconsiderable compared with the difficulties in operating the engines or turbines.

Constant temperature is essential to economical operation whether saturated or superheated steam be used, and it is quite possible with properly designed superheaters to keep a temperature within 10 degrees either way of a determined point, or a maximum variation of 20 degrees. It is quite true that in some cases superheaters have been so designed that the temperature fluctuates and troubles have followed, but the troubles with the pipe-line fittings have been the least of these, and the cause has been not the temperature due to superheat, but the fluctuations in temperature due to the design of the superheater, in the same way that a fault in the design of a boiler, engine, or condenser is likely to be heard from.

So much has been charged against superheated steam that an investigation was started to find out what the people of most experience in the use of superheat in this country and abroad had found out concerning the effect of superheated steam on cast iron.

In Europe superheaters are always a part of a power plant of any importance and superheated steam has been in common use there for more than thirty years. If, in the few years during which superheated steam has been used in this country such destructive characteristics have developed, the Germans with their thirty years of experience ought to be in a position to tell us about it. A well-known German engineer was recently in this country, and the matter was brought to his attention. He was interested and surprised that he had not learned before of the effect of superheated steam on cast iron and promised to look the matter up on his return home. He has since written that he could not find anything in their engineering literature to bear out this contention, or anyone who believed that such a thing was possible This engineer's experience with superheated steam extends over twenty-five years or more and shows that highly superheated steam—600 degrees Fahrenheit—has no effect on cast iron. He uses fittings of gray-iron castings, except where the government specifications insist upon cast steel. The government insists upon cast steel at times, but with regard to the pressure of the steam rather than to the temperature, and is not influenced by the steam being saturated or superheated.

Investigations in England, where superheaters have been used for a much longer time than in this country have resulted in much the same information. A member of the engineering staff of one of the steam-users' associations corresponding to our insurance and inspection companies writes that he "has not found any reduction in strength of either cast iron or steel due to temperatures obtained in practice." As in Germany, cast steel is used for fittings above certain pressures, but it is because of the pressure and not at all because the steam is superheated. Different steam-users' associations in England have been consulted and they have all agreed that superheated steam does not weaken cast iron in their experience.

In this country there exist many proofs of the fallacy of the theory that superheated steam weakens cast iron. A number of superheaters built entirely of cast-iron pipes and headers were installed in 1901—eight years ago. These superheaters are located in the settings of Babcock & Wilcox boilers above the first pass of tubes, directly in the path of and surrounded by gases at 1000 to 1200 degrees Fahrenheit. These superheater tubes are, of course, cooled by the circulation of the steam at 175 pounds pressure, and superheated 150 degrees, but must be considerably hotter than the temperature of the steam, or than the usual temperature of cast-iron fittings, in steam lines distributing the superheated steam. These superheaters are still in successful operation and have cost nothing for repairs. About two years ago it was necessary to move one of the units containing one of the superheaters. The superheater had to be taken apart and was carefully examined. Absolutely no evidence existed of any deterioration in any way and the superheater was reërected in the boiler and went together as easily as when first installed. The superheater tubes are 7½ inches inside diameter, 12 feet 6 inches long, made of good gray iron, care being taken to secure sound castings. The people who built this superheater have changed the design of the superheater tube somewhat, although retaining cast iron as the best material to meet the hot gases and have installed upward of 1,000,000 horsepower of superheaters, and except in a very few isolated cases have used cast iron for all fittings connecting the superheater to the boiler and its various sections to a common outlet. Some of these fittings are in contact with hot gases, being inside the boiler settings, and have been in service since 1901. In not one single instance has trouble been reported in any of these fittings which could be traced in any way to the effect of superheated steam, and this company still continuous to use cast iron for all fittings and considers it to be the best material for the purpose.

The result of investigation at a plant where a large cast-iron fitting showed signs of weakness, and superheated steam was charged with being to blame, is interesting in this connection. The plant consists of 32 water-tube boilers arranged in two decks, 16 on the upper floor and 16 below. A steam header connects the boilers on each side of the upper boiler room and these headers come together in a tee at the end of the boiler room. This tee has an opening looking down which connects with a larger tee below, taking the steam from each side of the boiler room on the lower floor. The main steam line to the engines carrying all the steam generated starts from this tee. The large tee taking steam from the upper and lower boiler-room floors was the tee that failed. It showed surface cracks and was distorted. Investigation disclosed that only 14 of the boilers on the upper floor were equipped with superheaters, and that these superheaters were good for but 75 degrees of superheat. The superheated steam from these 14 boilers was mixed with the steam from 18 boilers furnishing saturated steam containing the usual percentage of moisture, so that the steam at the tee which failed could not have been superheated more than 30 degrees, and even the most ardent critics of superheat insist that more superheat than this is necessary to bear out their arguments. Further investigation disclosed other interesting facts. All of the fittings on the boiler and superheater outlets were of cast iron. The fittings on the boiler outlets downstairs (saturated steam) were all affected in the same manner as the large tee just described. The fittings on the superheater outlets upstairs (superheated steam) showed no such effect. The explanation is evident. The large tee most seriously damaged was subjected to varying temperatures, and consequently continually changing strains, due to the mixture therein of superheated steam with steam containing moisture. The fittings passing saturated steam only were probably attacked by some impurity in the feed water, while the fittings passing superheated steam escaped because all of the moisture was evaporated in the superheater and in this way were protected against the injurious action of the saturated steam. Here is a complete reversal of the situation, and yet this particular case has influenced many persons against superheat.

In addition to all this evidence exonerating superheated steam, and in order to be sure that at temperatures proper for use in engines and turbines it could have no possible effect on cast iron, a prominent foundryman, himself engaged in manufacturing steel fittings, and a well known metallurgist were consulted. Samples cut from cast-iron fittings on the inlet (saturated) and outlet (superheated) connections of a superheater in use for more than five years and superheating steam to 550 degrees Fahrenheit, were photographed under a microscope and carefully examined. The opinion of these experts is that there is no reason to expect any graphitic change in the iron at temperatures less than 700 degrees Fahrenheit. The only graphitic change which would seem possible in the metal would be the changing of graphitic to combined carbon, which would result in the hardening of the metal, slightly increasing its tensile strength. It is customary, in annealing furnaces to use a temperature in excess of 900 degrees Fahrenheit to produce any effect in gray iron. Micro-photographs taken of samples from the center of the cross-section of the inlet and outlet fittings showed no more difference in the amount of carbon present than would be expected at different points in the same cross-section, proving that there was no change in the carbon conditions by reason of superheated steam. Photographs of the edge of the polished cross-section were also examined, showing the close-grained iron which always occurs near the outlet surface, due to chilling contact with the sand in the mold. Here again the experts report no change in the condition of the carbon by reason of exposure to superheated steam. Photographs were also taken of the polished surfaces after being etched with acid of different samples from inlet and outlet fittings, but examination showed no effect of superheated steam.

The foregoing statements evidently prove that something more than superheat is necessary to destroy cast-iron fittings. Unusually high temperatures (it is possible to convey steam superheated as high as 1200 degrees Fahrenheit, and it is being done in this country) undoubtedly need special treatment, but for the ordinary steam-power plant the best results are obtained by superheating the steam to a final temperature not exceeding 500 degrees and in designing the superheater to maintain a closely constant temperature. At this temperature and under these conditions no ill effects need be feared from cast iron fittings, nor any other parts of the equipment. Sudden variation in temperature, or changes from superheated steam to steam containing large quantities of moisture are bound to result in troubles of all kinds, but the design of the superheat is to blame.

Efficiency

By F. L. Johnson

Someone had written an inquiry about the amount of water needed for the condensation of steam, and my thoughts turned toward general condenser problems. As I pictured in my mind one jet condenser after another, I dwelt longest on the one designed by Charles T. Porter. In his design there was a cone-pointed plunger running under water all the time, and attention has often been called to the point on the end, ascribing to it the cause of the quiet operation of the air pump.

As the plunger was submerged all the time I could not see that the shape of the end had anything to do with noise or lack of it. I could not understand that as long as the plunger was submerged it would matter whether the end was convex, flat or concave, and I was on the point of hunting up someone with fixed convictions as to the necessity of a pointed plunger in the Porter air pump when my friend Sawyer quietly entered. Handing me a cigar and a match, he said:

"I did not come in to stay long, for I shall be in the city a week or more and will see you often during that time. As I came down Broadway this morning I failed to see the wave-motor exhibit and that made me anxious to show you some sketches of wave motors that I attempted to elaborate during the first three or four years of my life in the East.

"The clotheslines, fence posts, sheave pulleys and cider barrels that traveled from our neighborhood to the beach at the end of the gas-house road to be used in the construction of wave motors would fill a junk shop. With my companions I built wave motors of all grades and types and every one of them would 'mote,' but they one and all lay right down as soon as any work was put on them; they took up a whole lot of room and worked to the 'queen's taste' until the load was put on. They seemed to lack in efficiency, and that reminds me that I recently attended a lecture on the subject of efficiency.

MAKING O'SULLIVAN HEELS FROM A NEW PUMP VALVE

"It was along slightly different lines from what I expected, as it related entirely to the efficiency of the human drudge, instead of the steam or gas engine, as I had hoped. But I do not think the time spent listening was entirely lost, for as the speaker described his particular plan for getting a big increase in the work done by a man for a small increase in the sum paid in wages, I could not help thinking of how he would tackle the modern power plant, how he would rate the different men employed and how he would decide which one of the many operatives was a man of one hundred per cent. efficiency.

"His talk was a description of one of the numerous different profit-sharing schemes which have been introduced in many manufacturing plants in the country, and if his program is applicable in one industry it should be in another. In the central station power is the product to which each worker contributes. Coal, water, oil and brains are among the articles of consumption and all are bought as cheaply as possible.

"Now, the question that bothered me all the evening was, how would the efficiency of the various brain purveyors in a steam plant be determined, for each worker is supposed to have enough intelligence to follow the lines of correct practice in small if not great emergencies. Of three or four subordinates in an engine room, each of whom attends to the same number of oil holes, wipes the same number of engines and polishes an equal area of bright work, can one show that he is more efficient than another?

"Then, at times a man is paid merely for being present in the plant, to be ready, like a cold chisel or a monkey wrench, for use if needed. How will such a man raise or lower his efficiency?

"In passing through the basement of a steam plant one day, all alone, I saw a man whose work at that particular hour I knew to be that of waiting for a signal to start the auxiliaries to a turbine. He was working at something. I looked over his shoulder to see what he was doing. He was making a pair of O'Sullivan heels for his shoes from a new pump valve. As the lecturer had said something about the question of efficiency being a moral one, I wondered how the moral attitude of the man who took supplies, which were bought for the purpose of keeping the plant in running order, for his private use affected his efficiency. And I would like to know, if I could, to what extent the economical practices of the amateur cobbler reacted on the efficiency of the man who lacked one valve the next day when he started to put a pump in order.

"In the discussion which followed the lecture, I put the question up to the speaker. He dodged it by saying that no man should be blamed for stealing if the opportunity occurred, provided he did not steal time that belonged to the employer, and that the management and not the men were responsible for petty thievery about a plant. These were not the exact words, but they convey the idea that he expressed. I did not ask any more questions, but I got a rather hazy idea of the lecturer's opinion of what constituted morality, when he stated that under his system wages could never be cut, but he admitted that they might under some circumstances be readjusted.

"Do you know that in all of the schemes that I have looked at (and they are not a few) for the betterment of conditions the viewpoint seems to be that of the owner and proprietor, and if anything comes to the men it is incidental and not a part of the original program? Unsightly but practically dustproof wood clothes closets are replaced by expanded metal lockers which allow more dust to settle on and into a man's street coat in a day than would be collected in a sea-of ordinary exposure on the primitive peg on the wall that satisfied my father. In these days of hustle and concentration my father's engine room, with its tallow-pot cylinder lubrication and red lead and hemp manhole gaskets, is pointed at as the horrible example of how things used to be before our day of the 'survival of the fittest.' I have noticed some differences that the molded gasket and the ready-to-wear packing salesmen overlooked.

"My father lived in his own house, were all-wool clothing and leather shoes, and ate good food, while his successor in the new engine room, with everything up-todate from the brass-bound, multiported valve engine to the expanded-metal locker through the meshes of which may be seen the premium lunch box, lives on a rented shelf in the side of a brick cliff, wears shoddy clothes and paper-soled shoes, and eats adulterated food.

"But I did not run in here to take up your time preaching discontent and I will cut it out right now, if you will tell me the difference between the rating of a boiler and its capacity."

THE MAN WHO LACKED A VALVE THE NEXT DAY

I said that I understood that the rating of a boiler was its capacity for doing work under prescribed or conventional conditions of grate area and draft, while its capacity may be made almost what is desired by varying the grate area and draft. Just here an inventor of a rotating-engine valve, which would never wear shoulders on itself or the seat because it traveled the same way all the time, was shown in and Sawyer, with just a hint of a wink, went out.

The California State association of the National Association of Stationary Engineers will hold its sixth annual convention during the week of June 14 to 19, inclusive, in the Auditorium, Page and Fillmore streets, San Francisco. In conjunction with the regular convention arrangements have been made to hold a mechanics' fair. The main floor of the Auditorium has been subdivided into booths which have been leased to all the great manufacturing firms doing business on the Pacific coast.

The Fuel Question in Texas

The question of fuel is a grave one in many parts of Texas. There is probably not a State in the Union where so many experiments are being carried on and where the methods of firing change so often as in Texas. Crude oil is preferred in the majority of places and seven out of twelve plants visited were equipped to burn oil—at the right price. But the price of oil in Texas is as changeable as the weather in Cleveland. In fact it is believed by many that a certain man in Cleveland has a great deal to do with the price of oil in Texas, but this was strenuously denied by an oil man with whom I talked the other day. Just at present the price of oil is soaring and this may or may not have some connection with the automobile full of Standard Oil money which was unloaded at the State capitol building at Austin a few days ago. Uncle Sam's big fine did not stick, but they do things differently in Texas. Perhaps Texas will pay it back in the long run. At any rate oil is up just now and several of the oil-burning traction plants are preparing to change back to coal.

Oil buying is a great gamble and the traction manager who can get in right at just the psychological moment can show beautiful decreases in his operating expenses as long as the contract holds good, but if his contract happens to expire at the wrong moment he is likely to find himself in a bad fix.

They say that the Chinese invented the idea of burning crude oil. At any rate the Chinese idea of selling goods has been adopted in selling oil. The Chinaman figures that if you buy a little, you don't need it very badly, but if you want a great deal of anything it shows you need it badly and the price increases correspondingly. It is so with oil in Texas. The oil man told me that the price on one car that day was 62 cents at the wells, but on a 100,000-barrel order the price was 88 cents. He explained that the price was regulated by the demand, and that usually the demand was greater than the supply. The benevolent oil company aims to let everyone have a bite; hence if you want a large supply you have to pay more for it. He also explained that some of the big steam roads were still buying under contracts made several years ago at around 27 cents, and the oil people shed tears every time they load a barrel of oil for this road. To make up for it, the people who want big supplies these days have to pay $1 and in some localities $1.25 for the same product. New fields are constantly being opened up and the price frequently fluctuates from 50 to 90 cents in a day or two. So the traction operator who burns oil usually sleeps with a ticker alongside of his bed. The oil man said that one barrel of oil was equal to one ton of coal, hence it was better to pay as high as $1.60 per barrel for oil than $5.50 per ton for coal, which is the price of good lump and slack in some portions of the State. A number of roads figure that $1 for oil is about the breaking point.

The best coal used in Texas comes from the McAlester district in Oklahoma. It is cheap at the mines, but the freight rates bring it up to from $4 to $5.50 in the southern part of the State. McAlester coal deteriorates rapidly when exposed to the air and is subject to spontaneous combustion if stored in large piles, so that it is difficult and undesirable to store it in large quantities.

The power stations at Temple and Austin are arranged to burn either oil or lignite. Lignite is a half-grown coal found in that immediate neighborhood. It shows fixed carbon 25.2 per cent., volatile matter 46.2 per cent., ash 9.5 per cent. and moisture 19.1 per cent., and it has a specific gravity of 1.32. It costs 75 cents at the mine, or $1.30 delivered at Temple, and in steam-producing properties it requires about 1.8 tons of lignite to equal 1 ton of McAlester coal. There is little ash and no clinkers, but the item of labor is largely increased on account of its free burning properties. The ash produced is high in acid and must be removed frequently.

At Abilene they burn lignite mixed with a high-grade oil, while the company at San Angelo uses lignite in a gas producer and uses the gas in a gas engine. The company at Texarkana has its plant arranged for either natural gas or crude oil and at present uses gas.—George S. Davis in *Electric Traction Weekly.*

Society for Promotion of Engineering Education

It has been decided to hold the seventeenth annual convention of the Society for the Promotion of Engineering Education at Columbia University and Pratt Institute, in New York and Brooklyn, on June 24, 25 and 26. These dates immediately precede those of the meetings of the American Institute of Electrical Engineers, the Society for Testing Materials and the American Society of Civil Engineers, and New York City is very near the geographical center of the meeting places of these three other societies.

An unusually attractive program has been arranged which will include the report of the joint committee of engineering societies on engineering education, by Dugald C. Jackson; a report of the committee on technical books for libraries, by Arthur H. Ford; a report of the committee on engineering degrees, by William F. M. Goss; a report of the committee on entrance requirements, by Robert Fletcher; besides contributed articles.

Real Relation of CO_2 to Chimney Losses

In Which Is Shown How Unreliable Is the Percentage of CO_2 in Determining Chimney Losses without Considering Hydrogen, CO and Moisture

BY JAMES E. STEELY

There has been considerable work done recently relating to the economic combustion of coal, and it is possible that the average engineer is led to believe that to secure a high economy it is necessary to get a high percentage of CO_2 in the flue gas. Under a very few conditions a high CO_2 and a low flue-gas temperature will indicate a high economy or at least a low chimney loss, but it is not to be supposed that these factors always indicate such a condition. It is an easy thing to get a continuous record of both the temperature and the percentage of CO_2 in the flue gas, as continuous recording machines are on the market, some of which will give as accurate an analysis as could be obtained with an Orsat apparatus. However, the fact seems to have been overlooked that while the percentage of CO_2 is a very desirable thing to know, it cannot be used with certainty in calculating chimney losses, and in most all cases it affords only a crude approximation, while in many it is 20 or 30 per cent. off the true loss.

Proximate and Ultimate Analyses

In spite of modern educational advantages the ordinary engineer has not the chemical foundation so helpful in the managing of a boiler house, and a little time devoted to the explanation of some boiler-house chemistry will no doubt be well spent. When a sample of coal is sent to a chemist for analysis, two reports usually come back with it as follows:

Proximate Analysis

Moisture	3.74
Volatile combustible	41.96
Fixed carbon	42.89
Ash	11.41

Ultimate Analysis

Hydrogen (H)	4.61
Carbon (C)	[illegible]
Oxygen (O)	[illegible]
Nitrogen (N)	0.87
Sulphur (S)	0.20
Ash	16.42

The proximate analysis is a sort of an arbitrary one. The moisture is the moisture or water in the coal. The volatile combustible is those gases which distil off when the coal is heated without access to air. This comprises all the hydrogen, some carbon and part of the sulphur.

When the coal is fired the volatile matter distils off first and burns with a long flame. If insufficient air is present or if the flame hits a cold surface such as a boiler tube, smoke is formed. Thus it will be seen that continuous firing, as with automatic stokers, would keep a little of these volatile gases coming off all the time, while hand firing would distil off a large quantity of combustible gases at once, which would only partly burn, thus causing loss and smoke. The remaining substance is nearly pure carbon mixed with the ash. The combustible in the ash and refuse from the boiler is also carbon. The hydrogen, nitrogen, part of the sulphur and oxygen have been burnt or distilled off.

Chemical Elements in Coal

In the ultimate analysis there are a series of chemical elements. Hydrogen is a combustible gas, but it exists in coal as a complex hydrocarbon. When the coal is heated it distils off as CH_4 or marsh gas. In burning, hydrogen combines with one-half of its volume or eight times its weight of oxygen, and as oxygen exists in the air to the extent of about 21 per cent. by volume or 23 per cent. by weight, the amount of air necessary for its combustion can be calculated.

Carbon is an amorphous solid which can burn to CO using 16 weights of oxygen to 12 of carbon, or it can burn to CO_2 using 32 weights of oxygen to 12 of carbon. The former is a combustible gas and is the principal constituent of producer gas, while CO_2 is the final product when CO burns as well as when the carbon burns completely.

A hydrocarbon is a compound consisting of hydrogen and carbon, which may be gas, a liquid or a solid. When a hydrocarbon burns with insufficient air, the hydrogen burns off and deposits the carbon as soot. This also happens if the flame is cooled.

Oxygen is a noncombustible gas, but it is the best known supporter of combustion. It exists in the coal in combination with the carbon and hydrogen, but exists in the air in a free state in the proportions previously given.

Nitrogen is noncombustible and does not support combustion. It is the most inert of the elements. It exists in the form of a gas and the air contains 79 per cent. of it by volume and 77 per cent. by weight. In the coal it is found in combination with the carbon and hydrogen.

Sulphur exists in coal as sulphide of iron or pyrites and also as sulphate of lime. The sulphur as sulphide will partly burn off. When sulphur burns it combines with an equal amount by weight of oxygen, forming SO_2. This is an acid when mixed with steam or water and will rapidly corrode iron and many metals. The ash in coal is the noncombustible mineral matter.

Mention might be made of chemical symbols and statement of chemical reactions. For abbreviation chemists use a kind of shorthand for representing elements. Thus the letter H represents the element hydrogen; C, carbon; S, sulphur; N, nitrogen; O, oxygen; CH_4, a hydrocarbon, etc. Now, when carbon burns as previously stated, it unites with oxygen to form CO and CO_2. This would be represented as follows:

	C + O = CO
Parts by weight	12 + 16 = 28
Parts by volume	– ½ 1

or

	$C + O_2 = CO_2$
Parts by weight	12 + 32 = 44
Parts by volume	. 1 1

The weights represent the combining weights of the elements and the volumes represent the volumes used or formed, as found by applying the well known law of Avogadro.

Theoretical Combustion

Combustion proper may now be treated from a theoretical standpoint, using the figures 21 per cent. by volume of oxygen and 79 per cent. of nitrogen as the composition of air.* If pure carbon was burned with the correct amount of air, a mixture of nitrogen and CO_2 would be obtained, which would analyze nitrogen 79 per cent. and CO_2 21 per cent. by volume, as oxygen in combining with carbon forms its own volume of CO_2. This is impossible under furnace conditions, but if there were nothing else in the coal and it were burnt, the percentage of CO_2 and O would always add up to 21 per cent. by volume, and the per cent. of CO_2 could be used accurately to determine chimney losses. However, there are a large number of reactions which take place, all of which remove the CO_2 farther and farther from the true indication.

Taking some of these reactions up separately, the effect of each can be seen. When hydrogen burns, it forms water, or steam if the temperature is above 212 degrees Fahrenheit. If pure hydrogen were to be burned with air in the exact amount, the resulting gas, when cooled, would be 100 per cent. nitrogen, as the hydrogen

*To be more exact it is 20.9 and 79.1.

would combine with all the oxygen and form water when the sample cooled. The same thing happens when the hydrogen in coal burns. When the flue-gas sample is taken, the steam condenses and the analyzed sample shows a slightly higher percentage of CO_2 than is really in the flue. Taking a coal with 75 per cent. carbon and 5 per cent. hydrogen, the flue gas, using theoretical amounts of air, would analyze as follows:

Steam by volume	0 69 per cent.
CO_2 by volume	20 59 per cent
Nitrogen by volume	78.72 per cent.

The sample which the chemist would get would analyze.

CO_2	20 73 per cent.
N	79.27 per cent.

on account of the condensation of the steam. This error, however slight, is actual, and the higher the percentage of hydrogen in the coal or fuel, the greater it is. Any steam moisture in coal or water put in the fire will also serve to dilute the chimney gas, but will not interfere with the calculation of the heat losses except insofar as it uses up heat in raising the moisture to the temperature of the flue gases. It will not cause error in the analysis of the gases actually caused by the burning of the coal. Even if it is decomposed by the fire, it will liberate the same heat as was used in decomposing it and also return to exactly the same amount of steam by weight.

The sulphur in the coal burns to SO_2, and this is easily absorbed by the potash solution which is used for absorbing the CO_2, thus tending to indicate a higher CO_2 than the true amount. CO also influences the result. Supposing that a flue gas containing 10 per cent. of CO_2, contains 0.2 per cent CO. The analysis of the CO_2 would indicate the following:

CO_2	10 per cent.
O	11 per cent.
N	79 per cent.

while the true analysis would be

CO_2	10.00 per cent.
O	10.88 per cent.
CO	0 2 per cent.
N	78.92 per cent.

These errors are ordinarily slight, but in extreme cases may be appreciable. They actually exist, no matter how carefully the CO_2 is determined.

Actual Analyses Show CO_2 Erratic

Taking some actual results and working out the losses, the percentage of CO_2 may be shown to be very erratic. The following two analyses were made by the U. S. Geological Survey at the fuel-testing plant in St. Louis. The coal used was New Mexico No. 1, and both samples were taken during the same test at different times:

Sample 1.		Sample 2.	
CO_2	8.7	CO_2	10.1
O	10.4	O	8 6
CO	0 0	CO	2.1
N	80.9	N	79.2

From the percentage of CO_2 it would be reasoned that Sample 2 was very much better, i.e., the chimney loss much less. The coal analyzed as follows:

	Combustible.	Coal.
Carbon	78.5	70.77
Hydrogen	5.51	4.97
Oxygen	14.01	12.63
Nitrogen	1.28	1.15
Sulphur	0.70	0.63
Ash	.....	9.85
	100.00	100.00

The ash and refuse analyzed: Carbon, 42.98, and earthy matter, 57.02, or 7.42 per cent. of the original combustible. Correcting the combustible in the coal for this, the theoretical analysis of the combustible as burnt is obtained as follows:

Carbon	76.96 per cent.
Hydrogen	6.04 per cent.
Oxygen	15.33 per cent.
Nitrogen	1.29 per cent.
Sulphur	0.38 per cent.

Supposing one-half the sulphur remains in the ash. Now, to burn one pound of this would require the following quantities of air:

0.7696 lb. carbon to CO_2	8.9196 lb. air
0.0604 lb. hydrogen to H_2O	2.1007 lb. air
0.0038 lb. sulphur to SO_2	0.0164 lb. air
Theoretical amount of air	11.0367
Correcting for oxygen in coal	0.6665
Theoretical amount of air	10.3702

This combustion would produce 11.3702 pounds of flue gas of the composition by volume as follows:

	By Volume.	By Weight
CO_2	16.88	24.80
CO	.....	.....
O	.....	.....
SO_2	0.13	0.28
Steam	7.96	4.78
Nitrogen	75.03	70.14
	100.00	100.00

On a dry-gas basis it would analyze:

CO_2	18.44
SO_2	0.14
N	81.42
	100.00

Since the SO_2 would be estimated as CO_2, add the SO_2 and CO_2, and call it CO_2. This would give,

CO_2	18.58
N	81.42
	100.00

It would be well to compare this with the original analysis and thereby note how the errors due to hydrogen and sulphur affect the CO_2 percentage. But in the analysis given the percentage of CO_2 was only 8.7. Calculating to this basis, the theoretical analysis of the gas is:

CO_2	8.7
O	11.0
CO	....
N	80.3
	100.0

This is almost identical with the analysis given.

Taking the other sample, or No. 2, 17.48 per cent. of the total carbon burns to CO. Thus we would have:

0.6371 lb. carbon to CO_2	7.3839 lb. air
0.1325 lb. carbon to CO	0.7685 lb. air
0.0604 lb. hydrogen to H_2O	2.1007 lb. air
0.0038 lb. sulphur to SO_2	0.0164 lb. air
	10.2695
Correcting for oxygen in coal	0.6665
Theoretical amount of air	9.6030

This would produce 10.603 pounds of flue gas of the composition:

	By Volume.	By Weight.
CO_2	14.22	21.23
CO	3.09	2.93
N	74.09	70.37
SO_2	0.15	0.31
H_2O	8.45	5.16
	100.00	100.00

On a dry basis this would be by volume:

CO_2	15.54
CO	3.37
SO_2	0.16
N	80.93
	100.00

On adding the CO_2 and SO_2 the percentages by volume would be:

CO_2	15.70
CO	3.37
N	80.93
	100.00

Figuring this down to the 10.1 per cent. CO_2 basis would give:

CO_2	10.1
CO	2.2
O	8.1
N	79.6

This also compares favorably with the original. In figuring the gas to a lower CO_2 percentage, the calculated amount of air is added, thus introducing some oxygen. The above will show how the errors compensate one another, so that the actual error might not be great in some cases. However, if the above gas still had its steam in it, the percentage of CO_2 would be 9.6 per cent. by volume instead of 10.1 per cent.

Heat Losses

The heat losses, which are more important, will now be given attention. Taking Sample 2, the analysis of the diluted gases by weight would be something like the following:

CO_2	13.71
CO	1.90
SO_2	0.19
H_2O	3.33
N	45.43
Air	35.44
	100.00

One pound of fuel would produce 16.31 pounds of flue gas. To make one pound of this mixture would require 0.938 pound of air. Supposing the air to be 72 degrees Fahrenheit and the flue gases to be 600 degrees Fahrenheit, the heat balance would be somewhat like the following:

	B.t.u.
Total heat in 0.1371 lb. CO_2 at 600° F.	16.89
Total heat in 0.0190 lb. CO at 600° F.	2.66
Total heat in 0.0019 lb. SO_2 at 600° F.	0.16
Total heat in 0.0333 lb. steam at 600° F.	44.60
Total heat in 0.4543 lb. N at 600° F.	62.73
Total heat in 0.3545 lb. air at 600° F.	47.80
Total heat above 32° F. in 1 lb. flue gas at 600° F.	174.84
Total heat above 32° F. in 0.938 lb. air at 72° F.	8.91
Loss due to hot flue gas	165.93
Loss due to unburnt CO	83.50
Total heat lost in 1 lb. flue gas	249.43

Calculating the heating value of the combustible from the theoretical analysis, gives 13,615.55 B.t.u. per pound, and as 1 pound makes 16.31 pounds of flue gas, the heating value of the amount necessary to make one pound of flue gas would be:

$$\frac{13,615.55}{16.31} = 834.8 \text{ B.t.u.}$$

As 249.43 B.t.u. are lost in the chimney, the loss in fuel would be 29.88 per cent.

Taking up Sample 1 and treating it in a similar manner, the diluted flue gas will analyze by weight,

CO_2	11.63
SO_2	0.13
H_2O	2.24
N	33.79
Air	52.21
	100.00

This mixture requires 0.959 pound air to make one pound. Taking the temperatures as in Sample 2, the following heat balance is obtained:

	B.t.u.
Total heat in 0.1163 lb. CO_2 at 600° F.	11.28
Total heat in 0.0013 lb. SO_2 at 600° F.	0.11
Total heat in 0.0224 lb. steam at 600° F.	33.01
Total heat in 0.3379 lb. N at 600° F.	45.38
Total heat in 0.5221 lb. air at 600° F.	71.78
Total heat above 32° F. in flue gas	161.56
Total heat above 32° F. in 0.959 lb. air	9.10
Total heat lost	152.46

One pound of fuel makes 24.26 pounds of this gas, therefore the heating value of the fuel required to make one pound of flue gas is 561.2 B.t.u., and the loss in fuel in this case would be 27 per cent.

The reader has no doubt noticed that in these two cases the highest economy was obtained with the lowest CO_2. If the sample with the highest CO_2 had been free from CO, the loss would have been but 18.06 per cent., or over 10 per cent. of the total fuel. This is an error of over 50 per cent. in what would be calculated from the CO_2 percentage alone. The fireman is urged to get a high CO_2. He gets it, but how much CO does he get along with it? His CO_2 determinations tell him he is saving 10 to 15 per cent. or more fuel, but possibly the complete analysis might show that he is merely adding to his losses.

Some types of boiler setting cause more loss and lower CO_2 than others. Thus, if the gases are cooled below the temperature at which combustion takes place before they are completely burned, there will be low CO_2 and some CO loss. At the St. Louis fuel-testing plant samples were taken of the gas over the fire and the gas at the rear of the combustion chamber. The analysis in test No. 360 are given as follows:

	Over Fire	Rear of Combustion Chamber
CO_2	6.1	11.4
O		7.1
CO	17.6	
H	1.3	
CH_4	2.8	
Other hydrocarbons	0.3	

Thus it will be seen that it is possible for a low CO_2 to be the cause of the boiler setting, and that it would be impossible for the fireman to raise it, and to see anything of the enormous loss of fuel attending.

Some may say that the examples given above are extremes. It may be true, but how is it known whether a certain case is an extreme or not? If the percentage of CO_2 is known and the percentage of CO is known, then the remainder of the analysis can be calculated from the analysis of the coal as above. If this article is followed carefully it will be seen how unreliable is the percentage of CO_2 when used alone, to calculate chimney losses. When a boiler test is made and the heat balance made up, the loss due to hydrogen in the coal and to the CO formed is always taken into consideration as well as moisture in the coal and the steam admitted into the fire. While these last two items add to the chimney losses, the only loss is the heat required to raise them up to the temperature of the flue gases.

Catechism of Electricity

1061. *Describe a modern direct-current generator of moderate or large output.*

Figs. 294 and 295 show two modern types of direct-connected generators, the former a 100-kilowatt machine with its field-magnet frame split vertically at a and c, while in the latter is a 250-kilowatt machine with the field-magnet frame split horizontally at v and x. In both cases the halves of the frame are provided with flanges at the joints to facilitate bolting them together. The magnet poles are built up of sheets of soft annealed steel and pressed together under pressure, after which they are bolted in place. The bolts as shown at d, Fig. 295, pass through the yoke and are fastened by lock washers on the outside; they are threaded and screwed well into the pole pieces, so as to give them a firm hold. The bolted-in pole construction allows the removal of any one of the field-magnet poles and its coil without disturbing any other part of the machine. The magnet pole-tips are spread to give a better commutating field under the pole tips and the extensions serve to support the field-magnet coils.

The shunt coils S, Fig. 295, and the series coils s are separately wound and insulated; an air space is provided between them for cooling purposes. The series coils are forged copper conductors of rectangular section carefully insulated. The shunt coils are machine wound and are taped and treated to make them moisture proof.

The brush-holder mechanism is carried by brackets mounted on a rocker ring l, Fig. 294, concentric with and carried on a machined seat on the front end of the field-magnet frame. As no part of the supporting ring projects over the commutator face, the brush holders and com-

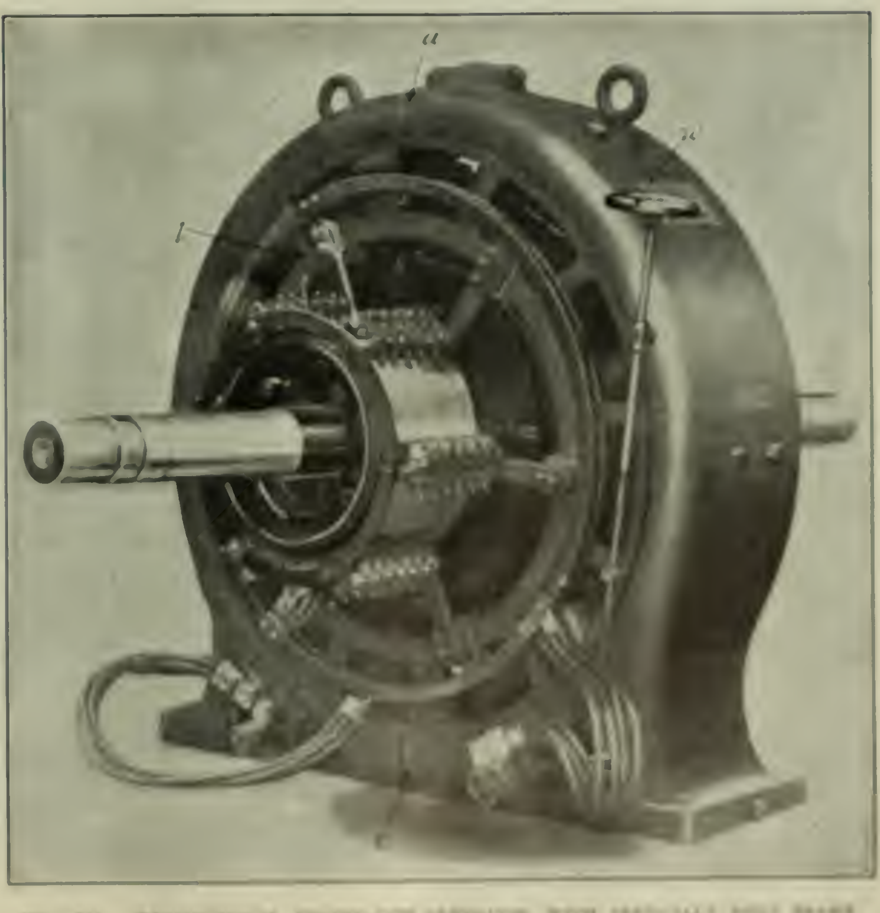

FIG. 294. WESTINGHOUSE ENGINE-TYPE GENERATOR, WITH VERTICALLY SPLIT FRAME

FIG. 295. FIELD FOR WESTINGHOUSE ENGINE-TYPE GENERATOR, WITH HORIZONTALLY SPLIT FRAME

mutator are readily accessible at any point. The rocker ring is operated by the hand wheel *w*. Copper-plated carbon brushes are used, and all brushes of the same polarity are maintained at the same potential by means of equalizing connections.

1062. *Why is it necessary to use equalizing connections in order that the brushes of the same polarity may be of the same potential?*

In the operation of large multipolar direct-current machines with parallel-wound armatures, such as the one being considered, it is difficult to secure exactly the same magnetic strength in all the field-magnet poles. Consequently, the potential generated in the conductors under one pole sometimes exceeds or is less than that generated in the conductors similarly situated under another pole of the same polarity, the result being a slight difference of potential between brushes of similar polarity which cause currents sometimes of considerable magnitude, to flow from one brush to another and from one section of the armature winding to another, attended by annoying and wasteful heating of the conductors and sparking at the brushes.

1063. *Explain the method used to correct this.*

A number of points in the armature winding which should be normally of equal potential are connected by leads outside the winding, through which currents may pass from one section to the others with which it is connected in parallel. These currents circulate through the armature conductors and are alternating in character; they lead or lag with reference to their respective electromotive forces, and thereby increase or decrease the strength of the field-magnet poles automatically so as to produce the necessary balance between them.

1064. *Do the equalizing connections serve any other purpose?*

Yes; they are advantageous in reducing any excess of magnetic pull on one side of the armature, should it get out of center by wear of the bearings, and also prevents the sparking which would be caused under such a condition, by the inequality of field-magnet strength due to the difference between the airgaps on opposite sides of the armature.

1065. *Are not the magnet poles of large direct-current generators sometimes cast into the yoke frames?*

Yes; some manufacturers employ this method of construction in all of their machines. Fig. 296 shows a six-pole belted direct-current generator of this construction. The base, field-magnet frame, magnet poles, all of one pedestal and part of the other pedestal are cast in one piece. The upper part *a* of the pedestal at the commutator side is a separate casting, but with this exception the entire frame is a single casting.

Inaccuracies of Indicator Diagrams

The article entitled "Inaccuracies of Indicator Diagrams," which appeared in the March 16 number, recalls some experiences not entirely satisfactory. I have used the spring calibration apparatus described in that article and have sometimes had trouble to hold the desired pressure steady owing to vibrations of line or exhaust pressure. To avoid this annoyance and enable attention to be concentrated on the work of calibration, I designed the combined weight table and regulating valve shown herewith.

Before steam is turned on, the plunger occupies its lowest position in the cylinder and its two ports register with the counterbore A, Fig. 1. When steam is admitted to this space, it surrounds the plunger, thus balancing the pressure on all sides. Passing through the ports, the steam flows down through the hollow plunger and into a reservoir on which the indicator is mounted.

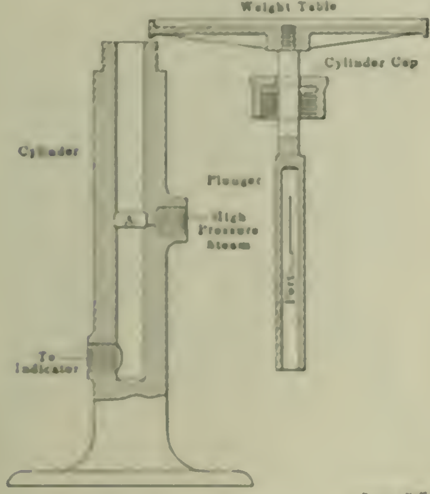

FIG. 1. REGULATING VALVE FOR INDICATOR-SPRING TESTER

The pressure rises until it is sufficient to push up the plunger, but as in doing the ports tend to pass beyond the counterbore and thus cut off the steam. Cutoff would actually occur were it not for the reduction of pressure due to condensation and leakage at the indicator. In its working position the valve remains open an appreciable amount in order to make up for these losses.

To prevent "hunting," it is desirable to make the cutoff as gradual as possible. This is accomplished by making the necessary port area of such shape that its dimension in the line of plunger travel is very large in comparison with the other dimension. Under these conditions, a given movement of the plunger will produce a minimum change of port area. The area required for initially raising the pressure is provided by the great length of port which is uncovered when the plunger occupies its lowest position.

To increase the pressure at the indicator, the proper weights are placed on the weight table, thus causing the plunger to descend. This produces a large port opening and consequently the desired pressure is promptly reached.

The lowering of pressure in the reservoir would be slow if dependent upon condensation and leakage; to obviate this, a pet cock on the reservoir is opened and the result is quickly obtained.

FIG. 2. COMBINED WEIGHT TABLE AND REGULATING VALVE

To secure records with rising pressure, it is necessary only to open the indicator cock *slowly*, thus preventing a "kick" of the indicator mechanism with probable overtravel of the pencil. To make a diagram with falling pressure, we proceed as follows: After placing the proper weights on the weight table, press it down with the hand for an instant, thus causing an excess of pressure. A gradual drop to normal will then follow as the result of leakage and may be hastened by use of the pet cock.

In the apparatus described, the plunger was finished [illegible] inch in diameter and the ports were cut with the thinnest available milling cutter 1/64 inch thick. The removal of condensation is conveniently provided for by a Durham trap.

On account of the smallness of the ports and the close fit of the plunger, I have found it desirable to protect the apparatus from damage due to scale and dirt by a strainer and settling chamber. Fig. 2 shows the apparatus connected up with an indicator.

J. B. Faulks, Jr.

Syracuse, N. Y.

Eccentric at Ninety Degrees

In regard to W. E. Crane's article in the March 30 number, I do not wish to discredit his statement, as he claims to have had experience, but when he says he can get a three-quarter cutoff with the eccentric set 90 degrees ahead of the crank, it needs some further explanation to show how he does it, as it looks to me like a physical impossibility.

Neglecting the angularity of the connecting rod, suppose we start with the engine on the center and the eccentric 90 degrees ahead of the crank. It is plain that the eccentric will reach its extreme travel at one-half stroke, after which it will be impossible to get a cutoff, as the trip lever will be moving away from the cam; consequently, the valve cannot be tripped off.

Hydraulic Information

Referring to the inquiry of William E. Piper, in the April 6 number, I presume Mr. Piper refers to miner's inches for the quantity of water mentioned, and without stating the miner's inch used the quantity is a little indefinite.

A number of western States in the last few years have passed laws legalizing a flow of $1\frac{1}{2}$ cubic feet per minute as a miner's inch, or 1 cubic foot per second to equal 40 miner's inches. In this section a miner's inch of 9 gallons per minute, 1 cubic foot per second, equalling 50 miner's inches, has been used by engineers for a good many years and is yet used more than the legalized miner's inch.

However, figuring on the legal miner's inch, 360 inches would be equal to 540 cubic feet per minute, and with a 150-foot fall would be equal to 153 theoretical horsepower. Allowing for loss in the pipe line and the efficiency of the wheel, it probably would not be practical to deliver more than 75 per cent. of this power to the generator, and if an automatic governor was applied to the wheel, it might be well to figure on not over 70 per cent., which would be equal to about 105 horsepower. For this head and quantity of water I should recommend an impulse wheel of the Pelton type, and about a 20- or 22-inch riveted steel pipe line. If the quantity of water is as stated in the foregoing, this would easily handle one thousand 16-candlepower incandescent lamps.

G. A. Reichard.

Los Angeles, Cal.

By reducing his available water supply to miner's inches, where 1 square inch of opening under a 6-inch head equals 11.655 United States gallons per minute, Mr. Piper has 180 inches, or 2097.9 gallons, or $279\frac{2}{3}$ cubic feet per minute. Now, as he has a fall of some 140 feet, 500 feet from proposed location of his plant he can figure the volume of water giving approximately 80 horsepower at the falls, using an 8 inch wheel at 1262 revolutions per minute.

As the velocity in feet per second for a distance of 500 feet should not exceed 2 to 2.2, it would be necessary to use a pipe of not less than 20 inches diameter for carrying the water from the falls to the plant. With this size pipe, the velocity and volume of water, he must allow 0.140 foot as a loss of head by friction in pipe for each 100 feet in length, or a total of 0.7.

As regards the grade of pipe to be used, I suggest that he use the best spiral riveted pipe, as being the most durable and economical for this class of work. As for the style of wheel best adapted for the conditions he enumerates the inward-flow turbine would be better than most any other form. This wheel has what is known as double-curve buckets, first inward then downward, thus retaining the water until it has received practically all of its initial power, and it will deliver at least 5 to 7 per cent. more efficiency than the outward-flow style of wheel, which receives its water near the axis, thence flowing outward through curved blades and delivering in an almost radial direction.

What is known as the impulse turbine is practically the best turbine yet devised, especially for great hights, say from 250 to 350 feet, or over, but for falls much lower than this they are not much more efficient than the inward-flow turbine. The impulse wheel depends for its energy solely upon the velocity of the water directed by means of a nozzle, or a set of nozzles, against a series of blades or vanes arranged on the periphery of the wheel, and the buckets or blades never stand full of water, as in the case of the first two wheels described.

Allowing about 20 per cent. of the estimated horsepower for friction of machinery, belts, pulleys, etc., and for loss of efficiency through his circuits of current distribution, Mr. Piper can figure safely on eight hundred and ninety 16-candlepower lamps.

J. L. Bradshaw.

Memphis, Tenn.

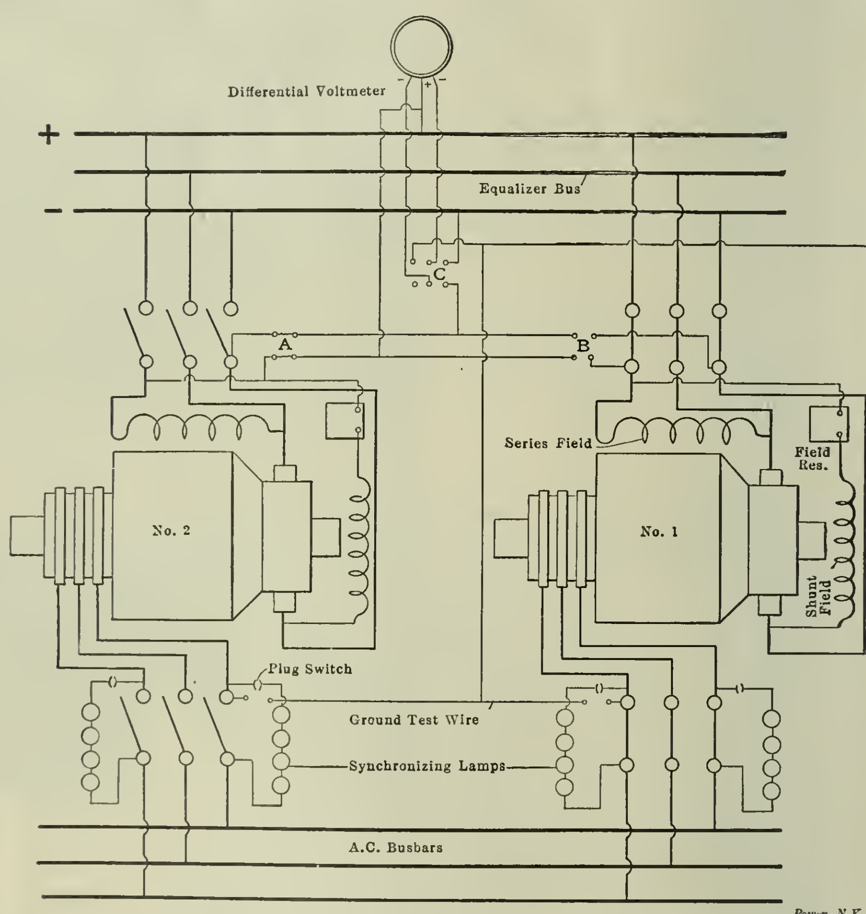
In the April 6 number, William E. Piper asks for hydraulic information. Assuming that he is speaking of miners' inches regarding the flow of water, the power which could be developed by a wheel should be in the neighborhood of 145 horsepower, which is capable of carrying approximately one thousand seven hundred 16-candlepower lamps, after making due allowance for generator and transmission losses. It would require a 20-inch wood-stave pipe and a wheel of either the modified Francis or impulse type.

Henry D. Jackson.

Boston, Mass.

A Peculiar Synchronizing Trouble

In the issue of April 20, there is an article entitled, "A Peculiar Synchronizing Trouble," by C. L. Greer. As I understand the conditions, he has, when plug *A* is in place, a circuit through the main line, through No. 1 rotary to the direct-current busbar, through switch *A* to No. 2 rotary, the plug switch and line, so that under these conditions he will get a blinking of the synchronizing lamps. The reason they probably burn at greater brilliancy than normal is because when the machines are not in synchronism, the voltage may be additive, making a considerably higher than normal voltage across the lamps. I should judge that at the time No. 2 rotary was thrown in, the machines were out of



CONNECTIONS OF ROTARY-CONVERTER INSTALLATION step, and probably directly out of step, that is, the voltage of No. 2 was added to the line, thereby putting far too great a voltage on the switch at *A* and temporarily unbalancing the entire system, putting too high a voltage on the direct-current side of the circuit, making No. 1 and No. 2 flash over.

Synchronizing by lamps is by no means as satisfactory as synchronizing by voltmeter. It takes a very short time to get used to the lag in the voltmeter, and after a little practice no difficulty will be found in bringing the machines up to synchronism and putting them on the circuit. The dark period with lamps is so long and the actual dark period of the lamps is so difficult to determine that it is frequently the case with synchronizing lamps that machines are thrown in when not in close synchronism, and with 60-cycle work this would be likely to make considerable trouble. The best method of synchronizing is unquestionably with the Lincoln or some similar type of synchronizer.

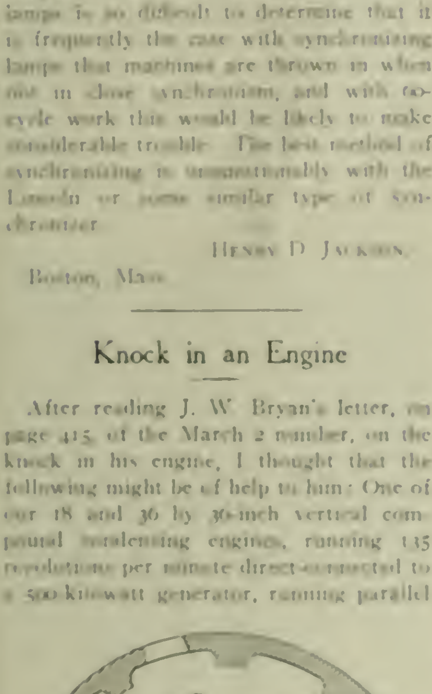
Boston, Mass.

Knock in an Engine

After reading J. W. Bryan's letter, on page 415 of the March 2 number, on the knock in his engine, I thought that the following might be of help to him: One of our 18 and 36 by 36-inch vertical compound condensing engines, running 135 revolutions per minute direct-connected to a 500-kilowatt generator, running parallel



WHAT CAUSED THE KNOCK IN THE ENGINE

with another engine, was shut down all right one night for the following morning, when started up, it had a knock or click something like Mr. Bryan speaks of, but at the head end only. As our load is varying, it would come and go at different loads, and would last for three or four revolutions, stop for awhile and then start again.

I came to the conclusion that the trouble was in the piston, and sure enough, after taking the cylinder head and follower plate off, I found the dowel or guide of the steam ring broken, as shown in the sketch; the ring was also badly worn. I put in a new ring and dowel. When everything was replaced and the engine started, the click was gone.

Thomas Sherman.

Pittsfield, Mass.

Safety of Pipe Fittings

In reply to the letter of I. A. Tenger, in the April 27 number, what I intended to say was that when the pressure on the under side of the valve bonnet equalled that due to the pressure caused by the screwing down of the cap screws, the pressure between the bonnet and the valve was balanced, or there was no pressure between them, unless it be such as is due to the weight of the valve bonnet and other parts supported by it.

Up to this point the steam pressure has been acting to relieve the pressure of the bonnet on the valve due to the tension of screwing down the cap screws, and until it equals this tension, or, more correctly speaking, exceeds it and tends to lift the bonnet from the valve body, there is no stress added to the initial stress on the screws, but when the steam pressure exceeds that due to the screws, by so much is the stress on the screws increased. Mr. Tenger, or anyone who doubts this, can very easily prove whether it be true or not, in the following manner: Secure two spring scales, of 25 pounds capacity, and suspend one of them from any convenient place overhead, attach a strong cord to the hook of the scale and tie a ring in the cord a few inches below the scale, put a screweye in the floor below the scale and pass the end of the cord through the eye and tighten until the scale shows 15 pounds, and make fast.

Now there is a stress or pull of 15 pounds on the cord between the scale and ring, which we will let represent the stress on the cap screws after tightening.

Take the second scale and hook it in the ring and pull down until it shows 10 pounds on the scale. If Mr. Tenger is correct in his statement that the two pressures should be added, the upper scale will now read 25 pounds, but if I am correct it will read 15 pounds, the same as before, and will continue to do so until a pull of more than 15 pounds is exerted on the lower scale, after which it will increase with the increased pull.

This is very plain if one stops to think how it acts. In the first place, the screweye and cord are sustaining a pull of 15 pounds and when a pull is exerted on the second scale hooked in the ring, it merely decreases the pull on the screweye and therefore adds nothing to the total pull, until it exceeds the pull which the eye sustained at first, 15 pounds.

Don't attach a 15-pound weight to the first scale, and then add a 10-pound weight and because the total then equals 25 pounds say I am wrong, for by doing so the conditions will be totally different from that of the valve bonnet and cap screws.

W. M. Perkins.

Bristol, Conn.

Dashpot Trouble

I have been greatly interested in the replies to Ellsworth Dale's appeal for assistance in connection with his dash-

SHOWING CAUSE OF DASHPOT TROUBLE

pot trouble. H. E. Scribner, in his letter on page 685, of the April 13 number, very frankly admits that he has failed to cure the dashpot at the head end of his engine of hanging up on a light load and causing consequent early cutoff with 125 pounds initial pressure.

On the high-pressure side of our cross-compound engine I had the same difficulty and did a number of things before I finally located the cause. In the meantime the working pressure was raised from 125 to 150 pounds, which, according to Mr. Scribner's theory, would make a bad matter worse. The dashpots of this engine are of the compressed type with the muffle case internally threaded and screwed down upon the externally threaded base, the threaded portion of the base has openings chipped with a "round-nose" chisel, across the threads from the vents in the lower cylinder of the pot. The threaded portion of the muffler case has similar openings, which, when the case is screwed home, are to coincide with those in the base, forming a passageway between the dashpot and the annular space inside the case. Investigation of the "bucking" dashpot revealed that the openings in the case were past those in the pot, enough to close the passages almost entirely, as shown in the illustration. New openings were made in the case and the dashpot works as well as the one at the crank end, although we are carrying 150 pounds pressure on an engine built for only 125 pounds.

M. E. Conway.

Alton, Ill.

What Would Happen If the Belt Came Off

In the issue of April 20, H. B. Adcock asks the consequence of an exciter belt breaking where two alternators are run in parallel, each having its own exciter, belt-driven from its shaft. The arrangement he describes would be a very bad one, as the alternator, deprived of its field charge due to the exciter belt breaking, or any other cause, would constitute a dead short-circuit on the other machine, and if not promptly disconnected by a fuse or automatic switch it would burn out one or both of the alternating-current armatures. A better arrangement would be to provide a direct-current busbar and connect both exciters to it, using a small breaker with a reverse-current release which would open in case one exciter failed to generate.

The alternator field coils should be connected to the busbar and a rheostat in its field to adjust its field charge, using the exciter rheostat to regulate the division of the load between the direct-current machine and to raise and lower the voltage of the alternating-current system as a whole.

Some years ago the writer operated a plant under conditions as stated by Mr. Adcock, except that the alternators were in stations a mile apart. The exciter of each machine was belted to its shaft and of course the distance prevented running the direct-current machines in multiple. After a burnout, due to a dog's tail being caught in the exciter belt and throwing it off, we installed automatic switches on the outgoing lines of each station, with reverse-current relays to open on heavy reverse current only. Fuses or overload breakers might have operated at both stations in case one machine lost its field charge, while the reverse-current relay would discriminate between heavy output or input.

Another experience of the writer was in a large two-phase light-tension station in New York City. The alternators were 750-kilowatt engine-driven units, operated in parallel and excited from a common busbar to which were connected four engine-driven 75-kilowatt exciters, without fuse or breaker. While in full operation and at the peak of the load the voltage of the system began dropping and the lights gradually went out, there being no flashing nor noise to indicate the cause. A hasty examination by lantern light showed that one of the exciters was not running but was acting as a short-circuit on the others, killing their fields. All the machinery was running at its normal speed, but all the voltmeters were down to zero and the system was "dead," the writer expected to synchronize and parallel all of these machines; but when the switch on the disabled exciter was opened, the lamp began to redden and the ammeter showed that the machines were pumping violently. After about a minute they steadied and the system became normal, the machines having forced themselves together with but four out of eleven becoming disconnected. The cause of the trouble was a valve disk which became loose from its stem and dropped onto its seat. The exciters were equipped with reverse-current breakers to guard against any further trouble.

LEWIS C. REYNOLDS.

Willard, N. Y.

Let us assume that the exciter of alternator *A*, Fig. 1, stops while both *A* and *B* are connected to the line. Then as the voltage of *A* decreases, current will flow from *B* through the busbars to *A*. The only impedance of this cross current is the synchronous reactance of the two armatures in series. Because of the high reactance, the current will lag strongly with respect to *B*, and have an equal lead with respect to *A*. This lagging current will react on the field of *B* and lower its voltage. At the same time the current

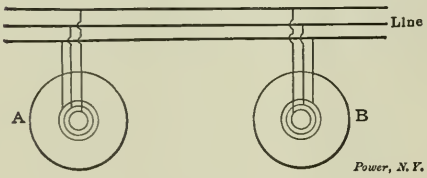


FIG. 1

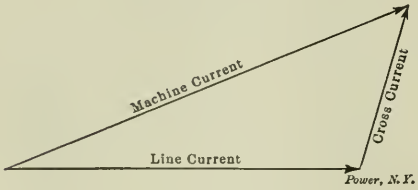

FIG. 2

through *A*, being leading, will induce a voltage in *A*. The result will be that both machines will divide and carry the load as before, but the line electromotive force will fall a few volts.

The current through the machines will be the sum of the line current and the cross current between the machine, Fig. 2. Since the cross current is nearly 90 degrees out of phase with the line, the total current through the machines will be increased only a few per cent. The cross current is so nearly wattless, that it means practically no loss of power.

The field of *A* may be even built up in an opposite direction to *B* and still carry load, but the cross current will be very heavy.

I have myself, tried this experiment and can vouch for its correctness.

EARL R. FILKINS.

Chicago, Ill.

I believe the plant would be thrown out of service, temporarily at least. The loss of the exciting current in one machine would prevent further generation of electromotive force by that machine. The two machines being connected to the same busbars would leave the armature windings of the disabled machine across the terminals of the live machine, therefore subjecting the latter machine to a short-circuit. Due to the resistance and self-induction of the winding of the disabled machine, I do not think the short-circuit would be of quite so severe a nature as though something of practically no impedance should fall directly across the terminals of an operating machine. The disabled machine would offer the impedance of its windings and with its field circuit being open would have, to a certain slight extent, an action quite similar to that of a transformer working with an open secondary. However, the self-induction of this winding would not be sufficient to prevent the flow of an abnormal current, quite comparable with that caused by a dead short-circuit. This rapid rush of current produces a condition in the live machine which would take it out of service.

As already stated, the current in the live machine rises to an abnormal value, and the first tendency of this suddenly rising current is to act on the voltage and flux of the machine. The induction of the winding is, however, greater than the resistance of the circuit; therefore, the resultant current caused by the short-circuit will be lagging and demagnetizing, and the effect will be immediately to pull down the flux and consequently the voltage of the machine to zero. The flux of the machine will be practically diminished although enough will be left to force full-load current or more through the impedance of the disabled machine.

After the switches controlling the disabled machine have been opened the remaining machine will immediately build up to full voltage and can be restored to the line. While all alternators should be able to stand such a performance it is undesirable, as short-circuits are racking on a machine and might result in displacement of coils or other disastrous effects.

J. A. LEES.

Quincy, Mass.

In the first place, unless the inductance of the machine is heavy, the machine which loses its field will take a very heavy current, and may cause trouble to it and to the other generator. The engine will probably tend to run away, but with a good governor this would not cause trouble. It might be that the poles of the generator without field might be sufficiently magnetized by the rotating field of the windings so as to operate as an induction generator. This, however, would be very unlikely. It would, therefore, appear that the principal trouble would be practically a short-circuit on the second machine.

HENRY D. JACKSON.

Boston, Mass.

Bracing Dome Heads

Referring to the article on bracing dome heads, on page 633 of the April 6 number, I should like to suggest another form of bracing for that part of the boiler shell to which the dome is attached.

As stated in the article, that part of the boiler shell surrounded by the dome shell is a neutral surface, that is, with equal pressure on both sides. The forces due to the internal pressure act radially, but the resultant forces will be on the projected area shown in Fig. 1. From this it will be seen that the tendency will be to distort the dome shell and cause a leaky joint.

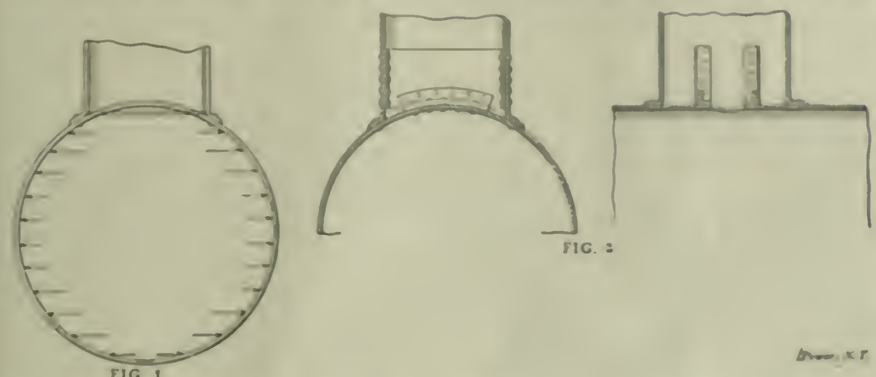

FIG. 1 FIG. 2

The most rational way to prevent such distortion and keep the original shape of the boiler would be to use a bracing such as shown in Fig. 2. It consists of a boiler plate riveted to the sides of the dome shell and an angle iron riveted to the lower edge, the angle iron to fit the outside of the boiler shell and bolted securely to it.

C. E. BOHMAN.

Auburn, N. Y.

Experience With Gas Power

On page 617 of the March 30 number, appeared an article by H. B. Messenger, giving an experience with gas power in displacing a steam plant driving a grist mill.

We have seen the statement in print that steam engineers are prejudiced against gas power, and that they are not fit for gas-engine operators. This may or may not be true, but it is certain that if engineers are opposed to gas engines it is up to them to run their plants so that there will be little gained in making the change. Gas-engine practice is not yet such an ideal proposition but what the average power-plant owner will require some very substantial reason for tearing out his steam plant and substituting gas power. Considering power alone, we know that even the best managed steam plant cannot compete with the gas engine in the way of economy, and in the case referred to it seems that the owner was well satisfied with the change.

The main reason for throwing out the 110-horsepower steam engine and substituting an 85-horsepower engine was lack of power.

In a mill like this the load would vary considerably, but to be on the safe side let us call it 85 horsepower continuously eleven hours per day. Half a ton of anthracite is used for the gas power, as against two tons of best Georges creek soft coal for steam, per day, at maximum load. A heat value of 13,000 B.t.u. would be a safe estimate for good soft coal. Now any engineer would undertake to put 65 per cent. of this heat into the boiler. As the feed water entered at "nearly the boiling point," let us say 210 degrees, it required about 1006 B.t.u. to every pound of steam and the evaporation would have been

$$\frac{13{,}000 \times 0.65}{1006} = 8.4.$$

pounds per pound of coal, or 33,600 pounds of steam in eleven hours, or about 36 pounds of steam per horsepower per hour. A "good automatic engine" would not fall down on this amount of steam if kept in good condition; besides, there was ample boiler capacity to care for occasional peak loads.

The saving in fuel is the difference in price between half a ton of anthracite and two tons of soft coal, but from this must be deducted the interest on the money paid out for the gas installation; still another deduction must be made for the coal burned during the cold season to heat the mill and office, evidently necessary judging from the fact that the gas-engine operator "comes into the office to get warm" at times. When everything is considered the saving may be so small that had the power not failed in the first place the steam plant may have held its own in this case, as it is likely to do in most places where the exhaust steam can be utilized at least six months of the year.

Gary, Ind.

Repairing a Center Crank

Reading Dennis Hanlon's letter, "Repairing a Center Crank," in the March 30 issue, page 600, brings to mind an old form of crank shaft that has been used in steam vessels in the merchant marine of Great Britain. While it is as "old as the hills," it may be new to many readers, and of value in such cases as Mr. Hanlon refers to. The accompanying sketch makes clear all that is requisite to an understanding of the idea.

Even under the most favorable conditions center-crank shafts have to endure severe stresses, and when the bearings wear out of line the stresses are intensified, so that it is only a question of time when something must yield. The crank in the sketch will yield and respond to ordinary inequalities met with in practice without breaking, as would happen eventually if the crank were solid throughout. The crank-pin connections are strong enough to transmit the power to the propeller on the end of the shaft. Why could not this form be applied to stationary work as well as to marine engines? It is all in the conical joint, which I think makes it a little better than the method adopted by Mr. Hanlon, although the surrounding conditions dictated his course of action to a great extent.

CHARLES J. MASON.

Scranton, Penn.

MARINE CENTER-CRANK SHAFT

Firing Boilers

The article which appeared in the April 6 number, by Victor White, is very interesting, viewed from more points than one. The working of boiler fires where there is any difficulty of getting steam is almost wholly a matter of practical experience. The rules are few and very elastic and it takes years of practice on different kinds of jobs with different kinds of coal to get them by heart. To learn firing by reading articles written thereon not only in periodicals, but in textbooks, is like learning to play the violin by carefully studying the make of the instrument and reading the tutor from cover to cover.

Taking a grate, say, 9 feet from the furnace door to the bridge and 3 feet 6 inches wide, Mr. White says eight or ten shovelfuls are sufficient. They are sufficient to stop the engine on the center on some jobs, but he does not mean it that way. Is this one of the rules of which he speaks?

A job where a man can fire heavily enough to get a quarter of an hour's spell and keep steam is not worth discussion. A man from the farm could do it with three days' apprenticeship. Any fireman worth his salt will tell you that he goes on duty to make steam, not fires. He resents any interference with the shape of his fires or whether they are light or heavy, and very properly, too, if the job is a stiff one, unless the engineer who interferes can show him that his way will also keep the steam.

The prime consideration in firing boilers is to raise steam, to prevent waste is a secondary one. Yet the whole trend of Mr. White's article seems to deal with the latter. Little information is proffered about the former, and that, in some instances, is very misleading.

A thin even fire is not essential in using small coal. He admits it, and treads very gingerly on his ground wherever he goes.

The lighter the load on the boiler the more can a man build up the fire until it is twice as heavy as it would be were the load at its heaviest. This would stop the draft struggling through so fast, and also keep the steam steadier, as the fire has more body. Frequent firing of slack coal on a thin fire acts like a flash in the pan, one moment a fierce heat, another moment all gone, with perhaps cold air struggling through a particularly thin place over the bars.

A very thin fire of 3½ or 4 inches, while necessary at times when the load is heavy, must be very carefully handled with the slice bar so as not to get the black coal upon the bars; if this occurs, goodby to the steam.

If a fire is dirty with clean hard clinker on the bars it is not necessary to slice this up every time the fire is sliced, only occasionally. When in the judgment of the fireman the draft is falling off, slice over the clinker and under the fire usually. If the slack coal cakes, don't break the slice right through to the boiler surface, but withdraw it when almost through the crust. This avoids mixing the fire up, getting black coal in between live char.

An easy job can be fired by anything in trousers, and it matters little what the shape of the fire is, level, piled up on the bridge, or like the waves of the sea, provided it is a fire and the load on the boiler is light enough.

To fire a grate, first one side and then the other might be an ideal way of causing smokeless combustion, but would it get the steam? According to Mr. White's statement the draft is the strongest through the least resisting places, therefore, the half of the grate not fired would get most of the draft. How much draft would the half get where he had just put the coal? Yet this is the side where it is most wanted. I assume he wants coal to burn or he would not have put it there.

Let us see if my way is the better one: Rake your fire on the slant, say, 3 or 4 inches at the bridge, slope up to 7 or 8 inches at the deadplate or even more if the heaviness of the fire warrants it; serve them all the same and then fire No. 1 boiler and don't throw any of the coal farther back than half way in the furnace, or say past the first set of bars. When all are fired, slice No. 1 boiler and then all the others in the same order, if the slice is necessary. Then glance at the steam gage and use your judgment as to the exact moment when the best results have been received from the sliced fires. Then rake again. When raking, however, notice which fire is lightest and always fire this one first, but try and get all of the same bulk.

If on a stiff job, never throw any of the coal into the back of the furnace, unless the coal is lumpy and a good wind is blowing and the draft is extra good; then a couple of shovelfuls extra may be thrown back. On no account throw dusty slack into the back of the fire if you would keep the steam up.

Don't fire too soon after raking, as this smothers a fire which is perhaps at its best, and take notice when raking if the fire feels hard and solid; if so, give it an extra slice up the middle and up each wing.

Mr. White takes a whole lot on his shoulders when he suggests that one man with a machine can do the work of four men firing by hand. I question very much the "entire satisfaction" and would like to know something more definite about the matter. Also, where is his authority for stating that when a boiler is taken out of action and not required again the proper course is to draw ash and clinker and quench them? Does he not know that this is a most prolific cause of tubes leaking? Would it not be better to leave the boiler shut up until the next day?

Let Mr. White give us the types of boiler which burn best with the different kinds of coal. I have fired with many kinds of anthracite from the big lumps on the west coast at Vancouver to all kinds of Welsh on different kinds of boiler, and have yet to find the long flaming coal.

W. Bowden.

West Toronto, Ont.

I have read the article entitled "Some Notes on Firing Boilers," by Victor White, which appeared in the April 6 number, wherein he conveys the idea that firing boilers is more a matter of practical experience than of theory. I should say that practice is applied theory, and when practice and theory do not agree it is because of the improper application of the theory. It follows from the universal law of nature that under the same circumstances cause and effect have the same relation, irrespective of time or place.

Regarding the subject of water in the ashpit, I believe that a certain amount of moisture in the coal is necessary for perfect combustion. Unquestionably there is a point beyond which the advantage ceases and, as stated, the loss would be that of superheating the steam at atmospheric pressure or thereabout.

I believe that the water is decomposed and the oxygen in the nascent state combines with the carbon with a considerably greater affinity than the free oxygen, whereas the hydrogen can combine with the oxygen in the free state with ease, the benefit being the combination of the precipitated carbon from the hydrocarbon gas distilled from the coal.

In general, smokeless combustion of coal is a problem that must be settled by applying the proper remedies for the particular characteristics of the firing. To my mind it is a function of three conditions: temperature, percentage of volatile matter and rate of combustion.

Raising the temperature means a shorter flame, large volatile percentage means a longer flame. The rate of combustion may mean a longer flame if the resultant temperature is not raised, or it may mean a shorter flame if the amount and distribution of the air are such as to satisfy the first requisite of high temperature.

The problem of designing a smokeless furnace is not so much a problem of furnace volume as it is of furnace length. Some fires give off a flame 20 feet long and should be reduced, and the baffles so arranged that the heating surface does not come in contact with the yellow flame, as this causes the precipitation of carbon, due to the cooling effect of the boiler tubes. This can be arranged for by using horizontal baffles on, say, a Babcock and Wilcox boiler, or by constructing a dutch oven of sufficient length to produce the same result. The air supply must be adjusted for every change in rate of combustion. The disadvantage of horizontal baffling, as is generally known, is due to the deposit of ashes on the heating surface.

An experiment with a bunsen burner will illustrate this. Suppose we allow the flame to burn yellow. The hydrocarbon gas loses its hydrogen first, in the process of combustion, and precipitates the carbon that at the resultant temperature renders it incandescent and hence luminous. Intercept this yellow flame with a cold piece of porcelain, for instance, and soot will immediately be deposited. The boiler presents a similar condition, and the soot will go up chimney, and we call it smoke.

Change the flame, by opening the holes at the bottom of the burner, and the flame burns blue. The cold porcelain will have no soot deposited on it, if placed in the flame. Were this to occur in the boiler, no smoke could possibly be formed. If it were possible to imitate the bunsen burner in boiler furnaces, we would have perfect combustion and a flame of no luminosity and absolutely smokeless.

In conclusion, one must not lose sight of the fact that heavy smoking is not a serious waste of coal, possibly not more than 1 per cent. The evil lies in its uncleanliness and the fact that its existence is so prominent.

ALPHONSE A. ADLER.

Brooklyn, N. Y.

In the April 6 number, Victor Wilson gives some good points on firing boilers. I do not agree, however, that a thin fire should be carried when burning small coal. It has been my experience to carry between 8 and 12 inches of fire to obtain the best results.

I had charge of a plant containing five boilers, each having 80 square feet of grate surface. When using bituminous screenings, we always carried 10 or 12 inches of fire, with good results. I do not believe that two men could have cleaned one of these furnaces in 10 minutes; in fact, it took just three hours to clean the five furnaces, and two men had to go some to do that and attend to the regular firing, as the boilers were generating about all the steam that could be got out of them with hand firing.

LOUIS B. CARL.

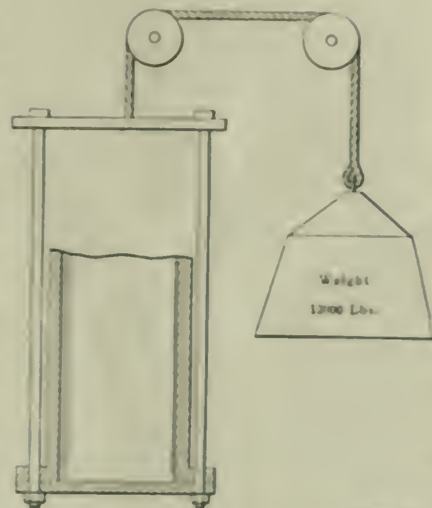
Marshfield, Wis.

Will the Load on the Bolts Change?

I once tried to follow the elaborate calculations of a very able writer who undertook to show in a similar case that part of the load, due to the pressure in the cylinder, is taken up by the bolts, causing additional stress in them, but I cannot say I was convinced of the truth of his figures. The way I look at the question is this:

Placing the cylinder in a vertical position and running the bolts on the outside of the cylinder, as shown in the accompanying sketch, will not affect the problem any. The weight will hold the head against the end of the cylinder, and at the same time produce the required stress of 1000 pounds in each of the twelve studs, as given in the problem.

The inside area of the head is given as 120 square inches and a pressure of 100 pounds per square inch, as set forth, will give a total weight or pressure of 12,000 pounds on the head.



Power, N.Y.

MR. CORRSBOOM'S SUGGESTION

Suppose we pile 12,000 pounds of scrap inside the cylinder instead of putting pressure on it, this weight of scrap resting on the head would represent the given condition, and being just sufficient to counterbalance the weight of 12,000 pounds, there is of course no additional stress on the bolts, only the original 1000 pounds apiece. If we have a ground joint or elastic packing between the flanges will not change conditions as far as I can see. When the pressure of 100 pounds per square inch is applied on the tank, the head will no longer be set up tight against the end flange, just merely touching the gasket and, as arranged in the sketch, a fraction of a pound added to the 12,000 pounds of scrap will cause the head to drop away from the cylinder entirely. If pressure was applied the gasket would blow out, as there is no compression to hold it in place. The studs themselves are elastic and of course will stretch a little under a load of 1000 pounds, and it may have been better to assume each one of the bolts to be a spring-balance scales registering 1000 pounds, but even then it is evident that the springs (studs) will not stretch any more, and consequently will not register any more until the load on the head exceeds 12,000 pounds. If the load should exceed 12,000 pounds the head will have a tendency to move away from the cylinder, the studs will stretch a little more and the additional load will show on the scales, but not till then.

B. CORRSBOOM.

Gary, Ind.

I should say that in the case of the ground joint the stress in the studs after the pressure has been turned on will be equal to the initial pressure, i.e., 1000 pounds, provided the bending of the flange of the cylinder head is neglected, as may be done in all practical cases, the design of the ground joint being assumed to be that shown in the illustration.

In the case of a joint with a gasket the stress on the studs will be the sum of the pressure of the steam plus the initial pressure on the gasket, i.e., 2000 pounds.

Although the problem is an impractical one, because the initial stress on a gasket joint should never be as high as the one on a ground joint, it leads to a very practical reflection on the screwing up of cylinder heads.

The most elastic medium holding cylinder and head tightly together with a ground joint is the body of the stud. The compression of the flange and joint of the cover may be neglected, as compared to the elongation of the stud, on account of their far greater sectional area.

Any pressure in the cylinder will decrease the pressure of the ground joint on its seat. In the case mentioned by Mr. Glick the pressure has been decreased to zero, and the least addition to the cylinder pressure would show a leak. It is, therefore, not practical to have the initial stress in the studs equal to the working pressure on the cylinder head, but about one-quarter more, and this addition should be taken into consideration when these details are designed. This initial stress once put on will remain unchanged, whether the cylinder is working or not.

The most elastic part in a gasket joint

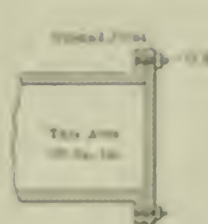


FIG. 1

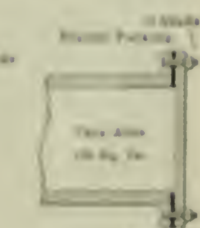

Power, N.Y.

FIG. 2

(Exaggerated)

is the gasket, and the elongation of the studs and the compression of the flange may be neglected. Any pressure in the cylinder lengthens the studs, so little, however, that the expansion of the gasket on account of this elongation does not appreciably decrease the initial pressure on the surfaces of the cylinder and flange and, through the latter, on the nuts of the studs. Therefore, the cylinder pressure added to the gasket pressure is transmitted to the nuts through the flange of the cylinder head.

The pressure on the gasket remains constant and, therefore, does not need to be as high as the working pressure in the cylinder, as was the case with the ground joint, but about one-half of it. During operation of the cylinder the stress on the studs will vary from ½ to 1½ times the total cylinder pressure, a condition which should be admitted only when absolutely necessary.

If the cylinder heads in each of Mr. Glick's cases had been screwed on as herewith described the studs of the ground joint would have been submitted to a constant stress of 1250 pounds; the stress on the studs of the gasket joint would have been between 500 and 1500 pounds.

RULOF KLEIN.

New York City.

Interesting Indicator Diagrams

Under the above caption, Mr. Berry in the April 6 issue, stated in his opening paragraph that the diagrams "were taken from the same engine under the same conditions of working, but with different valve setting." If the engine is carrying the same load in each instance, then Mr. Berry must have made a mistake somewhere.

If one takes the trouble to estimate the mean effective pressure of the different cards, it will be found that there is actually negative work done in Fig. 2, representing the low-pressure cylinder before changing the valve setting; so that this would leave the total work, or useful power, to be developed in the high-pressure cylinder. The constant for this cylinder is about 3.04 which, with a mean effective power of 24 pounds (in illustration) gives 72.96, say, 73 horsepower.

Computing the power of this side of the engine again after changing the valve setting, we get a mean effective pressure of 19.6 pounds, which would give 59.5 horsepower. In addition to this there is the power from the low-pressure cylinder to be added. The constant of this cylinder is about 8.7, which with the mean effective pressure of Fig. 4, gives

$$6.4 \times 8.7 = 55.7$$

horsepower, or a total of

$$59.5 + 55.7 = 115$$

horsepower. Hence, there is a difference of

$$115 - 73 = 42$$

horsepower to be accounted for between the two different valve settings. Of course there can be no question but that Mr. Berry's final cards are an immense improvement over the first ones, but there are some of us in this neck of the woods who would like an explanation of the running conditions.

J. A. CARRUTHERS.

Bankhead, Alberta

An Engine Accident

As to the defects in the diagrams of Mr. Sheehan, page 562, March 23 number, I consider them fairly good. The cutoff could be made a little earlier in the head-end diagram of the low-pressure cylinder. This diagram has the largest area and the greatest horsepower, showing that the greatest amount of work is on the low-pressure engine, head end. The total horsepower developed is 299.45. The receiver pressure will be governed by the load on the engine and the terminal pressure in the high-pressure cylinder. I cannot see what effect the receiver pressure would have in relation to the breaking of the high-pressure piston rod at the root of the threads.

I believe this break was due to a defective spot in the piston rod. A Whitworth thread on a piston rod is preferable to the sharp V-thread.

The diameter of the piston rod of the low-pressure engine seems a little small. Surely 3½ inches or 3¾ inches would be considered better practice. According to the *Engineering Bulletin* issued by the University of Wisconsin the average diameter of a piston rod for a 30-inch cylinder of a slow-speed Corliss engine should be about 3⅞ inches.

Occasionally it becomes necessary to put all the load on the low-pressure side of an engine, possibly just for a day or two, until the broken parts of the high-pressure side are repaired, and it is at such times that a good-sized piston rod on the low-pressure side would not do any harm.

JOHN I. BAKER.

Allentown, Penn.

Leaky Discharge Valves in Air Compressors

W. E. Turner, on page 726, says that he "can hardly agree" with me that leaky discharge valves in air compressors are not a cause of abnormal heating of the air and consequently of explosions which occur in compressed-air pipes.

Mr. Turner says: "If on account of leaky discharge valves the intake, or suction valve on that end does not lift, is it not an evident fact that as the piston moves back and forth there is a continual displacement, or churning, of air going on?"

In that case the compressor ceases to be a compressor. If it heats the air it does not deliver it, or send it along into the discharge pipe. In an indicator card from an air compressor in normal condition, when the return stroke begins, the reëxpansion line drops to atmospheric pressure very quickly and for the intake stroke the line is slightly below the atmosphere, showing that the cylinder fills with free air to be compressed and delivered upon the next stroke, and yet we know that explosions occur with compressors which thus indisputably take in and deliver merely a cylinderful of air for each stroke.

Mr. Turner should submit some indicator cards from the alleged compressors in which the intake valves cannot and do not open, as he assumes, an account of the freaks of the discharge valves. I am not clear as to how the same air can remain and play back and forth in the cylinder and become intensively overheated and at the same time be flowing along the discharge pipe.

FRANK RICHARDS.

New York City.

Compound Engines

G. W. Harding has a letter on compound engines in the April 20 number. It seems that he has the wrong idea of compounding. He states: "If we have two cylinders with a high-pressure cylinder giving 100 horsepower and the low-pressure 100, we have a 200-horsepower engine." Then he asks: "If we remove the low-pressure cylinder, do we still have a 200-horsepower engine?" We certainly do not, but if we remove the high-pressure cylinder and apply the same pressure of steam to the low- that we did to the high-, and carry the expansions of the steam in this low-pressure cylinder through the same extent that we carried it in the compound engine, we would have a 200-horsepower engine.

It certainly is cheaper to build a 200-horsepower simple engine than a 150-horsepower compound; but there are other points to consider than first cost. The principal advantage of a compound engine lies in the reduction of loss due to the difference in temperature in the cylinder between admission and exhaust, doing away with cylinder condensation. There are other advantages and very large reduction in the size of the castings, etc., as the low-pressure cylinder has so much lower steam pressures to carry.

A compound engine cannot be made to do twice the work of a simple engine, if the simple engine has the same diameter cylinder as that of the low-pressure cylinder in the compound; but it will be more economical, whether running condensing or noncondensing. The addition of a low-pressure cylinder to a simple engine gives more power because it adds to the range of pressures through which the engine works economically, and also adds a larger surface on which the steam pressure may act.

HENRY D. JACKSON.

Boston, Mass.

Official Report of Coal Consumption Tests of the New Scout Cruisers

The Navy Department has issued the memoranda shown in the accompanying table of the recent coal-consumption tests of the scout cruisers "Birmingham," "Chester" and "Salem." The "Birmingham" is equipped with reciprocating engines, the "Chester" with Parsons turbines and the "Salem" with Curtis turbines.

The first test, at 10 knots speed, began at 9:30 a.m., March 21, and ended at 9:30 a.m., March 25.

The second test, at 15 knots speed, began at 9:45 a.m., March 29, and ended at 11:45 a.m., March 31.

The third test, at 20 knots speed, began at 1 p.m., April 3, and ended at 3 p.m., April 7.

The fourth test, at maximum speed, began at 10:45 a.m., April 12, and ended at 10:45 a.m., April 13.

As stated in the May 11 number, the "Salem's" turbines were examined at the Fore River Shipbuilding Company's works, subsequently to the tests, and the Navy Department states that the examination showed that the buckets of the fifth stage of one of the turbines were very badly damaged (as shown in the May 18 number), apparently by a bolt which came in contact with them and injured them so seriously as materially to affect the performance of that turbine. Other damage, more or less serious, was found in this turbine, and also in the other, apparently caused by lack of rigidity between the turbine casings and the thrust bearings. Some of the nozzles were also found in a condition which indicated that they had been injured by small pieces of the buckets or by material of some kind which had been left in the turbine in process of manufacture.

The Navy Department further states that these defects are all being made good by the Fore River Shipbuilding Company and upon their completion it is the intention to repeat the water-consumption tests of the "Salem," and these may be followed by coal-consumption tests on the "Birmingham," "Chester" and "Salem," but final decision on this point has not been reached. It is probable that the "Salem's" tests will not be made until after she makes a trip to the coast of Africa, to join the other scout cruisers and return with them.

A press despatch stated on May 22 that "the 'Salem' will probably stay at the yard of the Fore River Shipbuilding Company three weeks longer. The original repairs contemplated to the turbine have been practically completed. The Government has, however, ordered the nozzles on the turbines changed to the new improved pattern, such as are being used on the 'North Dakota.' Under the old style, when a nozzle were out or needed repairing, it was necessary to send the vessel to the navy yard and knock her engines down. By the improved pattern the old nozzle can be taken off and a new one put on inside of 10 minutes."

Good Record by a Suction Producer and Hit-and-Miss Engine

By Wesley E. McAmbel

Having seen in a recent number of Power a description of a producer plant, and observing that others are having experience along the same line as myself, I have jotted down a brief recital of some of the queer situations and conditions that I have encountered in a brief twelve months' experience with a producer outfit.

There is located in Brooklyn, a gas producer power plant which supplies light and power to a machine shop and a handkerchief factory, the latter requiring a very steady power; variations in speed are not allowable because every fluctuation shows up on the finished product. The machine-shop people don't care how fast it goes as long as it keeps going, as it is a comparatively easy matter to speed up or down a lathe or other tool.

The engine is of the four-stroke-cycle horizontal type, with a 24-inch stroke and a bore of 6 inches; it is rated at 60 horsepower. Hit-and-miss governing is employed with a semi-automatic intake valve. It drives a 45-kilowatt bipolar compound-wound generator, by a belt. The current, at a voltage of 118 to 120, is distributed all over the building, there being about 150 amperes devoted to the lighting circuits and about 200 amperes taken by the various motors.

The engine, before the advent of the producer, ran on city gas at an average cost of $225 per month for gas and half of the wages of an attendant (who put in a large part of the day on other duties), which was $60 per month, the other half of which was borne by the machine shop in return for various services rendered by him.

With the producer, we use 10 tons of pea coal per month, costing $41. The man in charge of the plant receives $84 a month and devotes half of his time to other duties ranging from putting a lock on a door to repairing an automobile. The saving is the difference between $225 plus $30 and $41 plus $42. This saving effected by the producer amounts to about $2000 a year.

One minor defect which we remedied was a tendency the vaporizer had to run dry; this resulted in gas deficient in hydrogen. A common tank with a ball float in it corrected this difficulty and we have forgot that the plant contains such a thing as a vaporizer.

When the charge was made to producer gas, the compression of the engine was increased from 90 to 145 pounds, and an air compressor was installed in conjunction with a moderate-sized tank to replace the old hand pump used to force a mixture of air and gas into the cylinder to start up. An interesting fact is that the engine can be started up at present on 130 pounds of air pressure in spite of the fact that the engine has a compression of 145 pounds. This is possible because the air is delivered to the piston throughout the full length of the stroke, while the maximum pressure of 145 pounds is obtained only at the end of the compression stroke.

It was also found expedient to dig a well and use a larger quantity of water in the scrubber, for the reason that with a one-inch stream running through the engine jacket, another just like it doing business at the scrubber, and the vaporizer getting its quota, the water bill was almost as great as the coal bill.

We altered the ignition system because fine particles of ash would be carried along with the gas and deposited on the steel contacts of the make-and-break igniter. We have no difficulty with the present spark plugs; the jump-spark coils are operated by storage cells charged from the house current and every time the timer wipes by its contact, we know we are getting a spark in the cylinder.

The plant is operated by one man with ease, his duties being light. He gets to work three-quarters of an hour before the factory has to be running. He rakes out the fire in the producer until he has a bed of about six inches of good hot fire on the grates. He puts on the blower (formerly a hand blower, but now operated by a ¼-horsepower electric motor), dumps in a charge of 50 pounds of coal and proceeds to get the engine ready, filling up oil cups, testing the batteries, and so forth. Some ten minutes later he dumps two more charges (100 pounds) of coal on the fire. Soon the gas makes its appearance at one of the test cocks. A valve is then thrown over and the gas, urged along by the blower, drives out the air in the scrubber and in a minute or two the engine is ready to start. Starting the engine consists of getting it on what would be, if running, the power stroke, with the crank just enough above center to insure the engine turning over in the right direction; shutting off the blower at the producer; retarding the spark, and admitting air to the cylinder by means of a manually operated valve located in the exhaust passage between the exhaust valve and the cylinder proper. The piston moves forward, the exhaust valve opens and at the end of the exhaust stroke the gas is sucked in, compressed, exploded, and usually the engine runs right along without any trouble; if, however, it stops, it is due to insufficient blowing of the fire or too thick a bed of coal to suck the air steam through. The remedies are quite obvious.

During the day coal is charged as required. The usual method of handling the producer is as follows: After the engine has been running for a few moments, 100 pounds of coal is charged and half an hour later, 150 pounds more, this making in all about 300 pounds of coal, which is enough until 11:30, when another charge of 50 pounds is dropped. At noon, as soon as the load is off, the man gets to work at the producer with a poker and rakes out what is left of the fire carried over from the previous day. The fuel bed is then poked down through one of the poke holes in the top, and another charge of coal dumped in. Sometimes the engine slows down, but picks up again at once and is ready for the load at 12:30. At 1 o'clock, 150 pounds of coal is charged and this is usually enough for the afternoon; however, on dark days or in the winter, we usually give another charge at 4:30 and this carries the plant through the day.

Running on a load of 250 amperes, the producer consumes about 550 pounds per day. On dark days and during the winter the consumption is correspondingly greater. The coal consumption of the plant is approximately two pounds of coal per brake horsepower-hour.

In conclusion I would say that we have had some trouble, but it was due to lack of knowledge, the apparatus not being at fault. There have been discouraging times, it is true, when various troubles have arisen, such as a cracked vaporizer, unsuitable coal, leaky producer lining, and a thousand little things, but it has been well worth while to change from city gas to producer gas when one considers that the producer, which cost $1600, more than paid for itself the first year.

Lest the reference to the Foster fan-regulating valve in connection with the accident at the Concord (Mass.) Reformatory, on page 886, of our issue of May 18, be misunderstood as implicating the Foster valve in the responsibility for the accident, it is desired to state that the writer had been misinformed and that there was no Foster valve in use in the plant, and had there been and had it operated as was stated, it could not have been claimed that it contributed to the accident. By those connected with the plant, it was thought the accident was caused by the water carried over by the priming of the horizontal boiler, which was being crowded to the utmost at the time of the accident.

Recently contracts were let by the Government for what is expected to be the most powerful wireless station in the world. It will be erected in Washington, and when in working order it will be able to communicate with naval vessels 3000 miles away.

Depreciation of Power Plant Equipment

By F. H. Neely

This subject is one upon which few set ideas prevail. Practice appears to be as varied as power plants themselves. Directors, owners and operators are loath to regard this important item except in an abstract and unintelligible way, realizing it exists, but neglecting to analyze their own particular cases and making provision accordingly. It must be recognized that depreciation should enter into the cost of developing power just as surely and consistently as the monthly labor, coal, water and maintenance bills. No net profits can legitimately be declared earned, until the proper depreciation is deducted from the gross earnings. It will be argued that when by constant repair a plant is kept in first-class condition, no depreciation is necessary. This, of course, is a false theory, for the plant would then have an indefinite economic life. An occasional appraisal by a disinterested party will bring the owner to the realization that some consideration must be taken of this matter and that it must not be disregarded in the yearly financial adjustment of a severe burden is to be avoided in the end.

Some private and, unfortunately, a great many municipal plants make no depreciation provision whatsoever from their earnings. The ultimate result is to call on the stockholders for additional capital where replacement is necessary; in municipal plants, as a rule, bonds are issued for building and replacement. How often are 30- and 50-year electric-light and waterworks bonds issued, when it is known that the economic life of the plant built with this money cannot be over 25 years?

In order to arrive at the annual figure by which the gross earnings must be debited to care for depreciation, it is necessary to settle the number of years which will pass before the apparatus in a plant will arrive at a scrapping state and require renewal. In determining the efficient economic life, the engineer in charge of the plant should be looked to for the best judgment and advice. Segregation and grouping are necessary, for everyone realizes the inaccuracy that would come from considering all apparatus to have the same life. The engineer is in a position to know the relative life of a slow-speed, well-built Corliss engine as compared to a large, intricate gas engine having a multitude of moving parts. With a knowledge of the kind of boilers and the water and service, he can most intelligently determine the life of the boilers. Similarly, with due consideration of service, usage, mechanical makeup and obsolescence, the engineer should be able to assign a very close economic life to all of the machines and auxiliary equipment.

Fractional Method

Depreciation is commonly disposed of by charging, i.e., reducing the asset account an equal fraction yearly of the original cost of the productive plant based upon its estimated economic life. It is often that companies without any estimate as to the true life of machines or equipment will write off yearly 10 per cent. of the original cost, thus disposing of the total value in 10 years. It is argued that the machines are obsolete after 10 years' service owing to improvements in design, whereas some equipment is good for from 20 to 25 years.

Reducing-balance Method

This method of charging off for depreciation is at first sight rather deceiving, the charge falls toward the end of the period. The following example will show its action for a $1000 investment.

Years	Expense Outlay Charged Off	Interest Credited	Burden
1	$121.6	$ 40	$ 81.6
2	"	36	85.6
3	"	32	89.6
4	"	28	93.6
5	"	24	97.6
6	"	20	101.6
7	"	16	105.6
8	"	12	109.6
9	"	8	113.6
10	"	4	117.6
	$121.6	$220	$ 996.0

Here, of course, the interest, 4 per cent., is paper work, no real value developing as in the sinking-fund method following.

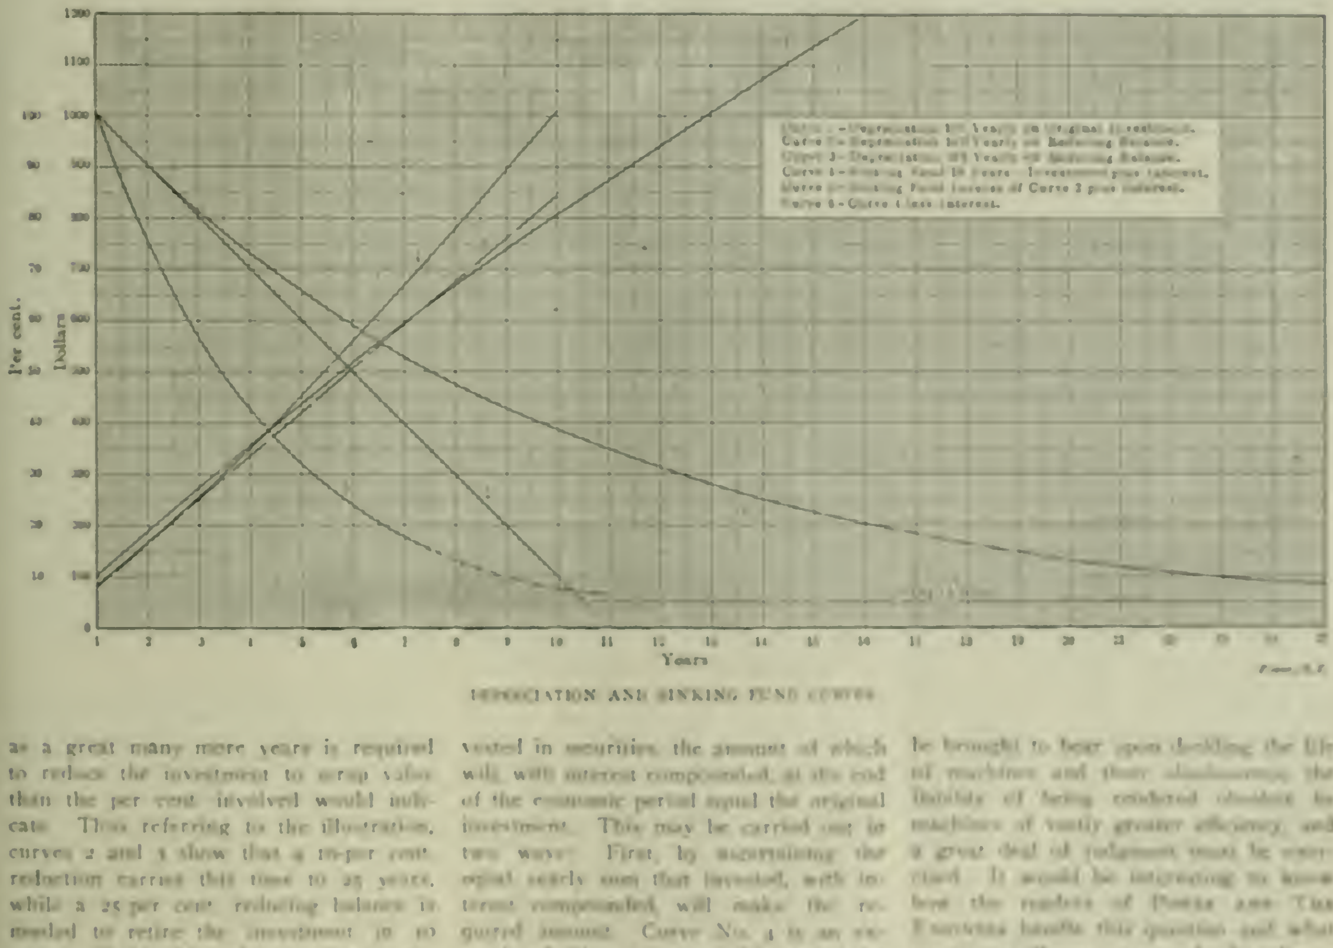
Sinking Fund

Here an annual sum is laid aside or invested in securities, the amount of which will, with interest compounded, at the end of the economic period equal the original investment. This may be carried out in two ways: First, by ascertaining the equal yearly sum that invested, with interest compounded, will make the required amount. Curve No. 4 is an example of this. A 10-year life period for $1000, interest 4 per cent., requires a yearly investment of $84.75, or 8.475 per cent. The second means of handling these payments is by having a yearly reducing investment, curve 5, where the investment corresponds to the yearly depreciation of the 10-per cent. reducing-balance method. The total original investment, $1000, is reached in less than 13 years, interest 4 per cent., which shows that the reducing-balance method used for determining the annual payment to the sinking fund is not of such long duration. This would appear to be the most just method of determining annual payments to the fund, as it must be realized that the upkeep, or maintenance cost rises as the apparatus gets older, so that it would seem only fair to gradually reduce the depreciation burden.

Replacement and Extension

In many instances it is difficult to distinguish between a replacement and extension. Very often new machinery is bought of a larger capacity and more improved design. The Massachusetts Railway Commission allows the value of the new apparatus less the estimated cost of exact replacement of the old machinery to be credited as increased assets, while the estimated cost of replacement is charged to renewals.

There are a great many points that may be brought to bear upon deciding the life of machines and their obsolescence, the liability of being rendered obsolete by machines of vastly greater efficiency, and a great deal of judgment must be exercised. It would be interesting to know how the readers of Power and The Engineer handle this question and what provisions, if any, are made for depreciation.



DEPRECIATION AND SINKING FUND CURVES

as a great many more years is required to reduce the investment to scrap value than the per cent. involved would indicate. Thus referring to the illustration, curves 2 and 3 show that a 10-per cent. reduction carries this time to 25 years, while a 25 per cent. reducing balance is needed to retire the investment in 10 years. Under this scheme a large proportion of the depreciation comes when the machine is new.

Annuity Method

In this method equal yearly sums are charged off sufficient to provide at the expiration of a stipulated life an amount equal to the original investment plus the interest on the capital remaining invested therein. The amounts which annually represent the interest are credited in yearly diminishing sums, so that the burden of

The announcement has just been made that Adolphus Busch has purchased, for cash, the patents, patent rights, good will and all unencumbered physical assets of the American Diesel Engine Company, and has established general offices in the South Side Bank building, St. Louis, Mo. It is Mr. Busch's intention to organize and finance a company in St. Louis in the near future.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for May, 1909, was (weekly and monthly) 152,000.

June 1 42,000
June 8 36,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

A Change of Heart

It is gratifying to notice that one of the principal American railroads has announced its intention to give the public through the newspapers prompt and accurate information regarding any accident which may occur on its lines.

There is a disposition upon the part of industrial concerns, as well as of railroads, to attempt to cover up any mishap which occurs in their plants and to refuse particulars even when forced to admit that there has been trouble. POWER has frequently sent a man across several States to investigate a report of a flywheel accident or a boiler explosion, only to be informed that the accident was a trifling affair, much exaggerated in the newspaper account, and that there was absolutely nothing to give out concerning it. If investigation is allowed and substantiates this view of the matter we are always glad to say so. If not, we publish what we can find out and emphasize the fact that information was refused.

The natural inference is that the facts if published would not look good for the management, or for the apparatus which failed. We are not responsible for the inference, if they wish to adopt that attitude. The usual excuse, when any excuse is given, is that every accident brings around such a flock of vultures in the shape of shyster lawyers and others seeking to profit from the misfortunes of the victims that absolute secrecy is the only safe policy. There is also a kindly disposition to shield the makers of the wrecked apparatus in view of negotiations for its replacement. Neither excuse is valid. If there has been such negligence as to entitle victims to damages, nobody can have any sympathy with the policy which locks the gate until such evidence can be destroyed. If the facts are such as to relieve the management of responsibility, an investigation of the accident by a trained observer will help to bring them out. If the boiler or engine is faulty in design or construction, or if it has been operated in such a way as to lead to destruction, the public is entitled to know it. If the fault is inherent in the type it should be exposed and corrected, if it is incidental to the individual machine or apparatus and could not have been avoided by ordinary care and inspection there can be no harm in making it known. If it was the result of faulty operation or use, an exposé of the condition might warn others against the same malpractice. If it was the result of poor design, cheap construction and wilfully hidden defects, it ought to be advertised.

No manufacturer likes to have his errors or misfortunes held up for analysis, but a reputation based upon a lot of concealed faults and blanketed failures is of no permanent worth, and the manufacturer who has faith in his apparatus and knows that it has failed only because of some exceptional reason, who faces the case like a man and satisfies himself and the public that he has found the cause and eradicated it, is the one who will win confidence and ultimate success.

Coke from Illinois Coal

To coke Western coals and obtain a product suitable for metallurgical use has for a long time been considered an impossible proposition, due to the fact that these coals contain only the lighter volatiles, and after driving off these constituents it was believed the result would be nothing more than coke breeze. The experiments made by the technological branch of the United States Geological Survey at the St. Louis exposition apparently verified this conclusion, for their tests did not result in any degree of success. It remained for Dr. R. S. Moss, an English expert on the subject, to prove that any Illinois coal would make a satisfactory coke.

From a study of Eastern coals, Dr. Moss discovered that their readiness to coke was due to the heavy hydrocarbons contained in them. To break up the lighter volatiles and produce these heavy hydrocarbons in Illinois coal was the problem, and the solution rested in quickly getting a high temperature and continuing the coking process for a period of much shorter duration than given to Eastern coals. Where forty-eight hours was formerly required to produce furnace coke and foundry coke was given seventy-two hours, a period of twenty-four to thirty hours sufficed for Illinois coal. When the coal last mentioned was coked according to the usual schedule, the result was invariably coke breeze, and it was found that the quicker the process, the better the quality and the more satisfactory the coke.

Aside from the advantages accruing to the furnace and foundry interests from such reduction in the time element, the discovery may have some bearing on the fuel question in Western cities, where the production of smoke from the use of bituminous coal has long been a matter of serious contention. No figures are available on the cost of production, but with a cheap fuel to begin with and the time of manufacture reduced by half, the price of the coke per ton should not be exorbitant. It might also be possible to follow the precedent of the New England Gas and Coke Company, of Everett, Mass., in selling the gas as a byproduct, and in this way materially reducing the cost. The coke produced by the new process might then be used to advantage under boilers for the purpose of eliminating the smoke nuisance, for heating and domestic purposes, and in suction gas producer plants instead of the anthracite now utilized. Such possibilities are worthy of investigation, which might well be undertaken by the Geological Survey in the interest of power users.

Futile Attempt to Secure New Boiler Inspection Bureau

For some time it has been the opinion of a number of engineers in Greater New York that the bureau for inspecting steam boilers and licensing steam engineers should not be under the control of the police department, and that a new bureau should be created which would be entirely independent of other departments of the city. While the New York charter commission was preparing its report and drafting the new charter, it was rumored that a change was contemplated in the sections pertaining to boiler inspection and engineers' licenses. To forestall any unfavorable legislation and to present their side of the question, the combined N. A. S. E. associations of Brooklyn drew up a bill, which in reality was a revised edition of the old La Fetra bill originally drawn up by the A. S. N. E., and invited the combined associations, ten in number, of Manhattan and the Bronx to coöperate with them. The various orders of the International Union of Steam Engineers in the city were also invited to coöperate, although they had not extended the same courtesy when preparing the Voss bill for presentation to the legislature. They, of course, could not agree with the proposed bill, and only two of the ten N. A. S. E. associations in Manhattan and the Bronx voted to support the Brooklyn movement. This was largely due to a feeling that with written examinations conducted on the civil-service plan instead of the oral examinations now given, the bureau might better be left under the control of the police department. The combined Brooklyn associations and the two of New York previously mentioned, however, presented the bill to the charter commission, offering it as a suggestion to amend the charter and for the creation of a new bureau to control the operation of steam boilers and the licensing of engineers and firemen.

According to the bill it would be the duty of the chamberlain to select a superintendent of boiler inspection who was a resident of the city and a citizen of the State of New York, and had been for ten years immediately preceding the date of his appointment an engineer engaged in the operation of steam engines and boilers under a license issued to him by the city of New York. All the powers and duties conferred upon the corporation of the city of New York or upon any board or any officer relating to the inspection or operation of steam boilers, or the examining and licensing of engineers and firemen were to devolve upon this superintendent, who was to appoint the examiners, boiler inspectors and other clerical and executive force necessary for carrying on the work of the bureau. Every subordinate engaged in carrying on this work was to be subject to the provisions of the civil service law of the State of New York and appointed from an eligible list prepared and certified by the municipal civil service commission of the city. An examiner must have had ten years' experience in the operation of steam engines and boilers under a license issued to him by the city of New York and the same length of service under the same conditions was imposed on the inspectors. The qualifications of applicants for examination and the general rules for inspection were much the same as the present law, and also the provisions for keeping records.

The suggestion was considered by the charter commission, but it was not incorporated in the report to the legislature. No amendment was made to this division of the old charter, and as the complete report of the charter commission was tabled, at least for the time being, by the legislature, the suggestion of the engineers, even if it had been incorporated in the new charter, would have received the same fate. Neither the Voss bill nor the recommendations of the combined N. A. S. E. receiving favorable attention, conditions are just the same as they were a year ago. The bureau of boiler inspection and licensing engineers is conducted by the police department as described in an article by A. C. Rowley in the April 20 number of POWER AND THE ENGINEER. A more recent article by the same author, which appears on page 1029 of this number will throw some light on the Voss bill and the recent attempt of the police department to secure an amendment giving them control over the low-pressure heating boilers of the city.

Switchboard Arrangement in Isolated Plants

In designing a switchboard layout for an isolated plant, almost the first point which has to be settled is the location of generating, measuring and distributing panels with respect to one another. Space conditions often limit the installation so much that the best results cannot be secured; but whether the amount of room at hand is small or large, a wise selection of panel locations will reduce the cost of installation and facilitate both the handling of the plant in service and its extension in the future when the load requirements call for the installation of additional machinery.

The majority of isolated plants supply electrical service for both lighting and power uses, the same generators being employed on the busbars and operated in multiple without regard to the actual distribution of the energy in the feeder system. The question of putting the generator panels in the middle or at the end of the board is important. If they are located at the end the plant may often be extended with more freedom, if the maximum installation is not determined at the time when the machinery is first put in. The entire current generated or the whole plant energy, if desired, can easily be measured on a bus panel in such a case. With a bracketed voltmeter or a synchroscope at the end of the board, the work of throwing generators into multiple operation is somewhat easier because greater accuracy can be obtained with the instruments near the generator panels than when a switchboard operator has to strain his eyes to see just where the voltage or phase pointer is located. In many cases where the board cannot be centrally located in the plant, it follows that the installation of the generator panels at one end makes the average cable run shorter between the dynamos and the board, although, in a symmetrical installation, the shortest cable run is obtained when these panels are in the middle.

Under favorable conditions, where a reasonable amount of room has been allowed for the generators and switchboard, and where the ultimate capacity of the plant can be known when the apparatus is first laid out, it is probable that the location of the generator panels in the center of the board results in maximum economy of cost and operation. With the lighting distribution panels on one side and the power panels on the other, the generators feed each way, and consequently the busbar sizes needed are reduced to the minimum consistent with the current passing across the board, and there will be required less copper for a given output in amperes than with a board where the generators are located at the end, since in the latter case an extra run of busbar will be required to feed the more distant sections of the board. If the lighting and power loads are of the same volume of current and operated at the same voltage, with half the board devoted to each service, fifty per cent. more bus copper will be needed for an installation of generator panels at the end, than when they are located centrally.

In the actual handling of the board in service a central location of generator panels facilitates operation, because the switchboard man has to travel only a minimum distance in making any changes in the connections. Where there are instruments located in the distribution circuits, a better watch can usually be maintained from a central point. Temporary connections and adjustments can be more quickly made, and the operations of throwing machines in multiple can be handled with reasonable ease if the normal voltage point is specially marked on the bracketed voltmeter scale.

Test of a Peerless "V" Belt Drive

Belt drives with short centers are always to be avoided if possible; yet there are cases where for lack of sufficient room, or for other good reasons, it becomes necessary to install a drive in the smallest possible space and overcome the attendant difficulties as well as may be under the circumstances. Such a condition ex-

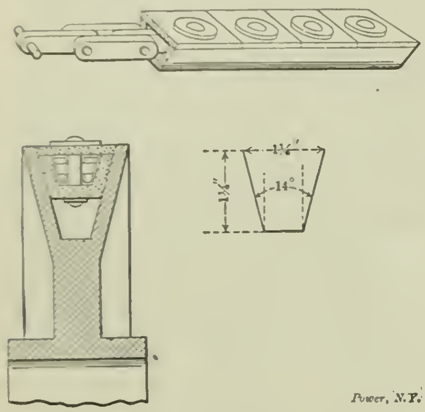

FIG. 1. DETAILS OF PEERLESS "V" BELT

isted in the engine room of the Chicago Savings Bank building, where some interesting data have been collected regarding belt drives on short centers. The equipment in question consists of three Laidlaw-Dunn-Gordon triplex hydraulic pumps, with 3½x12-inch single-acting water cylinders, furnishing a water pressure of 900 pounds per square inch for the operation of elevators. These pumps were all equipped with 50-horsepower motors having 11-inch pulleys at each end of the shaft and driving the pump by means of two 12-inch belts of double thickness, each belt having a 230-pound idler to increase the arc of contact on the driving pulley. As the diameter of the pump belt wheels was 9 feet, and the ratio of the driver to the driven pulley was approximately 1 to 10, with 11-foot centers as installed, the drives were far from being ideal.

Some time ago one of the drives was replaced by a new chain belt, made by the Peerless "V" Belt Company, 215 South Clinton street, Chicago, details of which are shown in Fig. 1. The core consists of a chain made of pack-hardened machine steel, V-shaped in section, incased in a continuous strip of specially prepared rawhide, which covers the bottom and two sides of the chain, giving a frictional surface to transmit the power. The upper part of the casing is a sectional strip of frictional material, one section to each link of the chain, and cut at an angle so as to continue the frictional surface of the sides. Each section is fastened to the link by a rivet passing through it, the head of the rivet also serving to bind the two side elements of the chain together. The belt is thus in effect a continuous wedge running on pulleys grooved at the same angle.

It will be noticed that the belt does not touch the bottom of the groove, as this would destroy the wedging effect, and as the rivets on top and bottom are not subjected to any wear, the belt is held together permanently. Besides affording a frictional surface for the belt, the rawhide casing protects the chain from dust and grit, and also effectually retains the chain lubricant.

Before changing the drives a test run of six days was made with the two 12-inch flat belts, weighed down with 230-pound idlers as previously described. It was found that one pump under these conditions could not do the work. When the accumulator descended to a certain point it was arranged to cut in another pump, and this intermittent starting materially increased the total current consumption. In the six days it was found that 3176 kilowatt-hours were consumed to run the elevator cars 401.5 miles, an expenditure of 7.91 kilowatt-hours per mile.

With the "V"-belt drive installed, Fig. 2, one pump carried the entire load and in a test run for six days, 2746 kilowatt-hours were consumed to run the cars 387 miles, giving an expenditure of 7.09 kilowatt-hours per mile; a saving of 0.82 kilowatt-hour per car mile, or 10.36 per cent. During the second run 14.5 miles less was made than in the first test. Adding the 102 kilowatt-hours necessary to make this mileage at the rate of 7.09 kilowatt-hours per car mile to the total of 2746, still leaves a net saving of 328 kilowatt-hours per week, or 17,056 kilowatt-hours per year, the cost of which would be more than sufficient to pay for the "V" belt.

Driven by flat belts, with the motor making 650 revolutions per minute, the speed of the driven pulleys should have been

$$\frac{650 \times 11}{108} = 66$$

revolutions per minute. In reality the revolutions were only 62, showing a loss of 6 per cent. of the total power through slippage. In changing drives the diameter of the driving pulleys were changed to 11.75 inches, and the driven pulleys to 109 inches. It was then found that the speed of the driven pulleys was raised to 70 revolutions per minute. Theoretically the number of revolutions per minute should be,

$$\frac{650 \times 11.75}{109} = 70.07,$$

which indicates that practically all slippage has been eliminated. As the drive may be run very slack, it follows that the journal friction is reduced to a mininum. Operation is entirely noiseless and considerable saving is found in brushes and controllers.

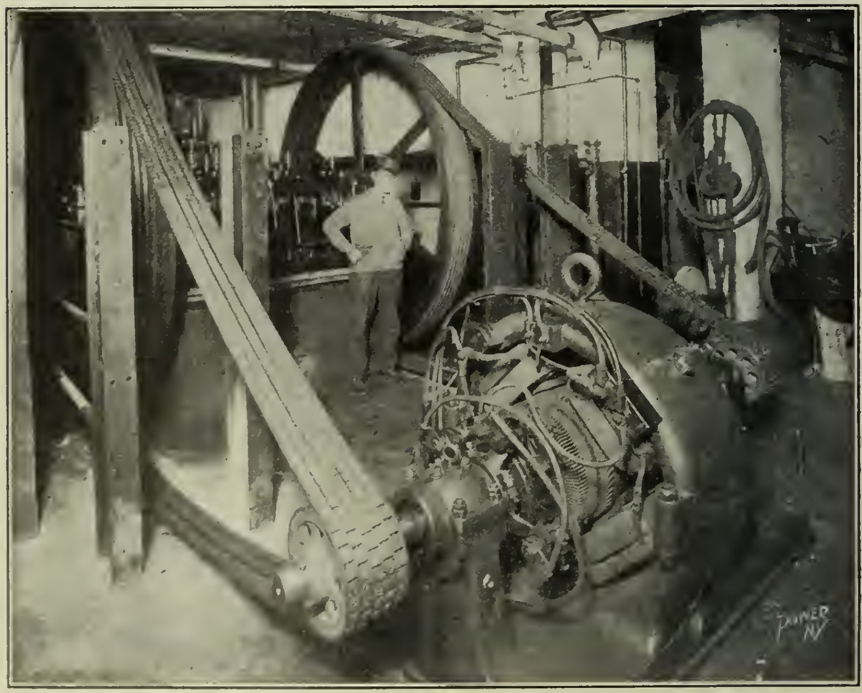

FIG. 2. PEERLESS "V" BELT DRIVE IN CHICAGO SAVINGS BANK BUILDING

Snoqualmie Falls provides the electric power for the Alaska-Yukon-Pacific exposition which opened June 1 at Seattle. Of the power brought down from the falls 10,000 kilowatts is delivered at the substation at the fair grounds. Of this the exposition takes 2500 kilowatths.

MUST BE NEW OR INTERESTING

A 42-inch Hydraulic Lift Gate Valve

This valve, two designs of which are [shown i]n Fig. 1, is of the Kennedy double-disk [p]arallel-seat gate type, operated by [h]ydraulic cylinders. When the valve on [th]e hydraulic piston is to be opened, the [fi]rst movement of the steam releases the [c]ams, Fig. 2, which have inclines in opposite directions on the faces coming into contact with similar inclines in opposite directions on the inside, or back of the disks, and owing to the abrupt pitch of these inclines, the disks at once fall away from any contact with their seats, thereby preventing any dragging against or grinding of the faces of the valve seats or disks in the opening of the valve.

In the closing of the valve these operations are reversed, the disks bearing the cams and cam rods there until opposite the ports, when the cam rod is brought to a stop by lugs cast on the inside of the body of the valve, bringing into operation the abrupt opposite inclined surfaces of the cams and disks, and at once closing the valve without injuring the faces.

This size of valve is made with bronze-mounted trimmings, the hydraulic cylinder being lined with bronze. The aggregate weight is 15 tons. It is manufactured by the Kennedy Valve Manufacturing Company, Elmira, N. Y.

Grease Lubrication for Cylinders

The Ohio Grease Lubricator Company, Loudonville, Ohio, manufactures a cylinder sight feed grease lubricator, which is illustrated herewith.

Its action is shown in Fig. 1. It keeps the grease in a melted state, feeding it by direct hydrostatic pressure, and forces it into the steam pipe and sprays or atomizes it, so that the steam can carry it to all parts of cylinder and valves.

The superheating is accomplished by a combining tube which, passing through the grease in the head portion, sets up a

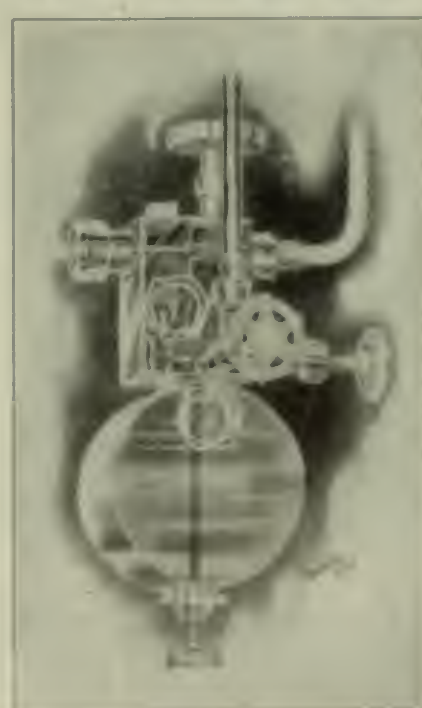

FIG. 1. [illegible]

circulation of the lubricant, and very quickly induces a uniform temperature of about 190 degrees, it is said.

The second function, developing pressure by condensation, is performed as usual by the condensing tube, and the

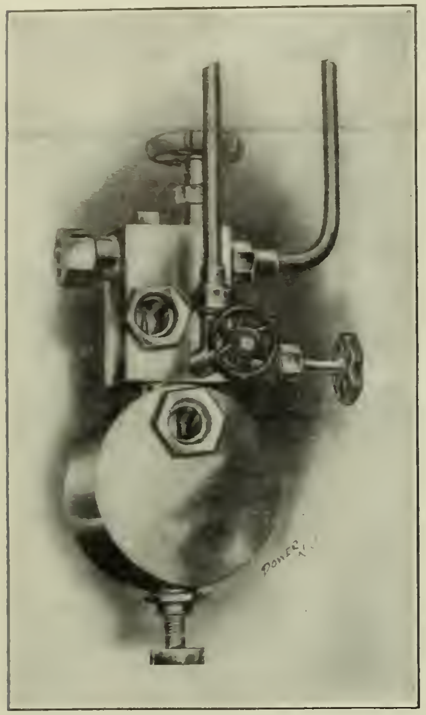

FIG. 2. EXTERIOR VIEW OF OHIO GREASE LUBRICATING COMPANY'S DEVICE

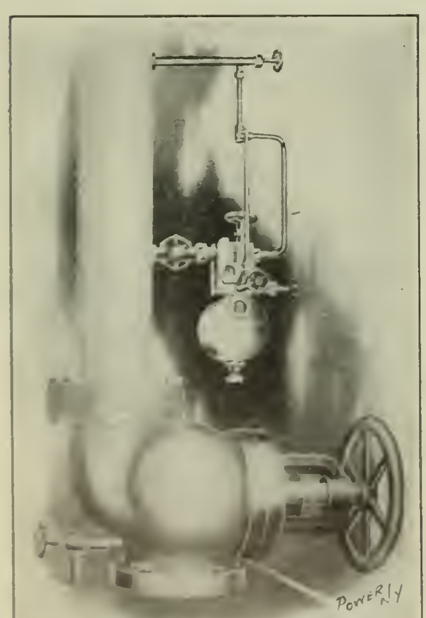

FIG. 3. METHOD OF ATTACHING LUBRICATOR TO STEAM PIPE

third function, forcing the grease into the steam line and atomizing it, is performed by the combining tube, which permits a stream of live steam to strike the heated and expanded drop of grease after it leaves the jet. Figs. 2 and 3 show respectively an exterior view and the method of attaching to the steam pipe. These lubricators are not sold, but are leased free of charge.

Welded Steel Headers

Robbins, Gamwell & Co., Pittsfield, Mass., manufacture welded steel headers on which the nozzles for outlets are

FIG. 1. NOZZLES WELDED TO STEEL HEADER

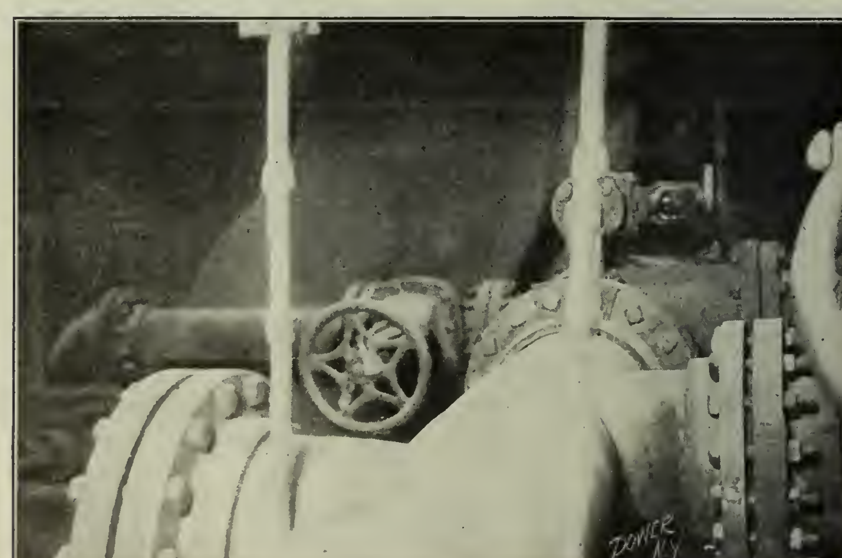

FIG. 2. ANOTHER SAMPLE OF NOZZLES WELDED TO HEADER

welded, by a special process of their own, directly to the pipe with which connection is desired, thus accomplishing the same results as obtained with fittings. A sample of such work is shown in Fig. 1, while Fig. 2 shows a welded steel header which is carrying 175 pounds steam pressure at 200 degrees superheat.

It will be recognized at once that this method has its advantages, as the number of joints and gaskets is considerably reduced and fittings are entirely eliminated, thus doing away with the possibility of faulty castings. In this work wrought steel, which is considered best adapted to withstand the high temperature of superheat, is used throughout. Pipe lines made up in this manner are, as a whole, lighter, owing to the omission of fittings, and the number of joints being reduced lessens the cost of installation. The only feature that prevents the length of run is the facility of shipping and convenience in erecting.

In welding flanges, the same method is employed as in welding the nozzles. The flange is made of the same material as the pipe itself, thereby producing a homogeneous metal of the pipe and flange. After a flange is welded to the pipe, it is faced and drilled and the faces back-machined.

The Lamson joint as made by this

company is made by lapping the pipe itself over on the face of the flange and the inside being faced there is no chance for leakage. The flanges swivel on the pipe, a point which is appreciated by the erecting men.

All the work sent out by this company is tested to 1000 pounds hydraulic pressure before shipment and is guaranteed for the conditions for which it is designed.

The Twiss Corliss Engine

In Fig. 1 is shown the general lines of the Twiss Corliss engine manufactured by Nelson W. Twiss, 28 Whitney avenue, New Haven, Conn. The frame is of the well-known Corliss girder type, the cylinder, frame and pillow block being cast separately and bolted together. The cylinder is provided with four double-ported Corliss valves, the exhaust valves being of the plug type with exhaust ports cored through them, thus securing a minimum amount of clearance. The steam valves are constructed to raise from their seats whenever the pressure in the cylinder exceeds the pressure in the steam chest. The valves are driven by means of suitable lugs or projections on the valves and corresponding recesses in the valve stems. The exhaust valves are operated by arms keyed to the outer ends of the valve stems, the arms being connected by an adjustable rod and operated through suitable connections, as is usually found in the Corliss type of engine.

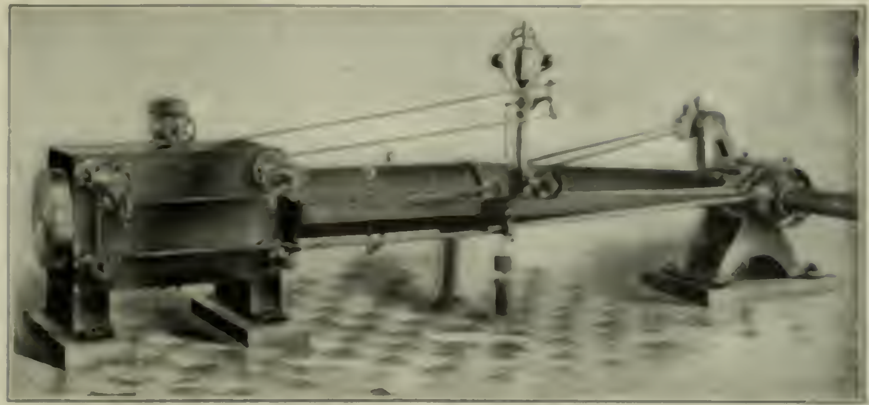

FIG. 1. VALVE-GEAR SIDE OF TWISS CORLISS ENGINE

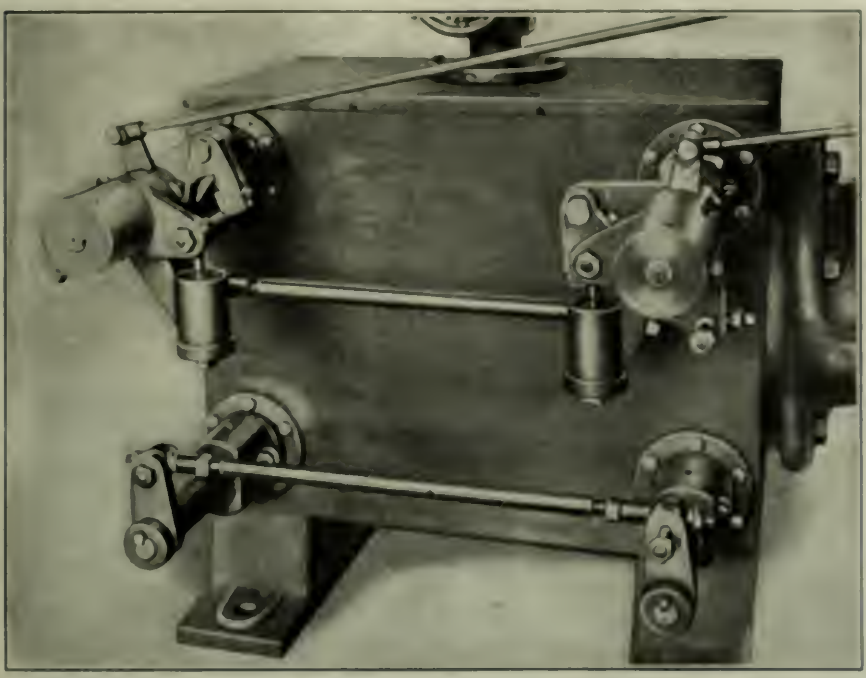

FIG. 2. NEAR VIEW OF VALVE GEAR

The main feature of this engine is the construction of the steam-valve gear, which is shown in Fig. 2. In Fig. 3 are shown all of the parts found in the valves and valve-gear construction. An explanation of the valve gear follows:

On a fixed extension of each steam bonnet, a bell-crank lever is journaled, the two being connected by an adjustable rod and operated by means of an eccentric rod; the eccentric rod not being shown in Fig. 2. On the arm of each bell crank is pivoted the steam hook which engages with the steam arm keyed to the valve stem. The bell-crank levers engage the steam-valve hook as is usual with Corliss engines; that is, when one of the steam hooks is engaged with the steam arm it opens the steam valve until the inner leg of the hook comes in contact with the trip toe on the knockoff lever, when it is disengaged and the valve immediately closed by a spiral spring on the extension of the valve stem. The inner end of each spring is connected with the outer end of each steam bonnet, the outer end being connected to the cap which covers the spring and is secured to the valve stem by set screws. This provides a convenient method of adjusting the tension

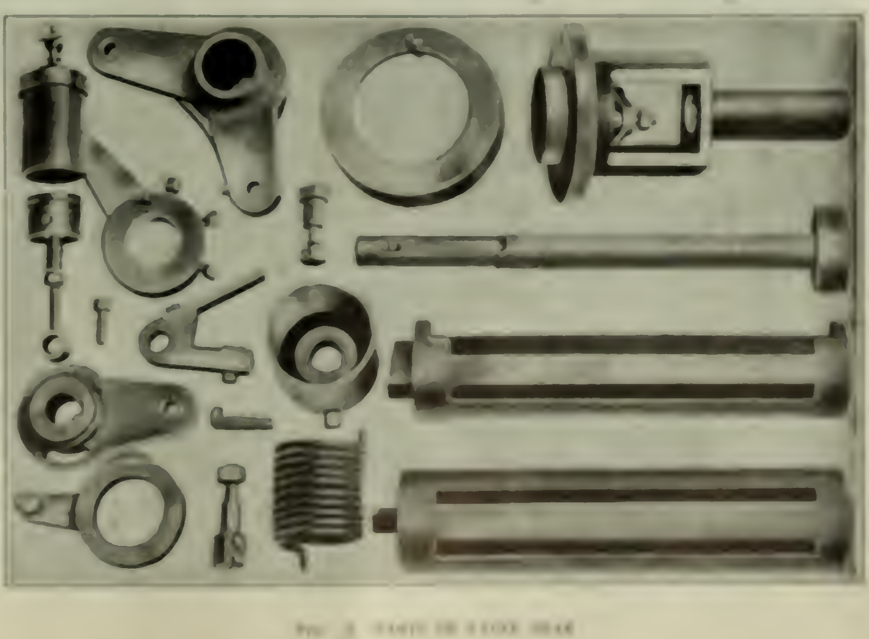

FIG. 3. PARTS OF VALVE GEAR

of the springs, and in order to do this it is only necessary to unscrew the set screws, shown in the cup, and with a small rod placed in the hole, shown on the right-hand valve, move the cup in the desired direction to adjust the spring with either more or less tension, as the case may demand.

On the Twiss engine no dashpots are employed, as the valves are closed by means of the wound spring, shown in Fig. 3, which is inclosed in the cup, shown at the end of the valve gear, Fig. 2. To insure noiseless closing of each steam valve, an air-tight piston is secured to the steam arm of each, as shown, fitted with a suitable adjusting snap ring and fitted in the cylinder which is supported by a bracket secured to the outer end of each steam bonnet. The bottom of each air pot is fitted with a leather washer, having a hole in it communicating to the pet cock screwed in the bottom. In the side of the air cylinder, not over ½ inch from the bottom, is drilled a ⅛-inch hole which is covered before the plunger reaches the bottom of the cylinder, but as the plunger is raised above the hole, air is admitted which permits the plunger to travel the rest of its movements without undue force being exerted upon it. As the spring closes the valve, the plunger is forced down into the cylinder with a free, easy movement until it passes the hole in the bottom of the cylinder, when air is entrapped and is then compressed, thus preventing any shock in the seating of the steam valve. The amount of air confined in the cylinder and compressed is regulated by a pet cock screwed in the bottom, but not shown in Fig. 2. By adjusting this pet cock the valve can be made to close practically noiselessly.

The knock-off levers are connected with the governor which regulates the point of cutoff as in all Corliss-engine construction. The exhaust valves are operated by a separate eccentric.

This valve gear can be placed upon any Corliss engine without making other changes. It is simple, does away with the cumbersome dashpot and admits of high speed for Corliss-engine operation.

Iowa State N. A. S. E. Convention

With more than one hundred delegates and visitors registered, the sixth annual convention of the Iowa State association of the N. A. S. E. was called to order May 21, 1909, at Cedar Rapids. President Abner Davis opened the proceedings by introducing Mayor J. T. Carmody, of Cedar Rapids, who is an active member of the association. In introducing His Honor, President Davis reviewed the history of the mayor, who worked himself up from machinist and fireman to the most prominent position in the city. At the close of President Davis' speech, Mayor Carmody welcomed the delegates and visitors to the city of Cedar Rapids and spoke of the untiring devotion to duty of the members of the local association in bringing No. 9 into sufficient prominence to entertain the State convention of Iowa. Mayor Carmody also had a good word for the commercial travelers and supplymen, whom he said had done more for the advancement of industrial progress than all the money and securities of the financiers. In closing, the mayor turned over the keys of the city to the visitors and said that everything possible would be done for their entertainment and comfort.

President Davis next introduced Fred. W. Raven, national secretary, of Chicago, who responded to the mayor with one of his characteristic speeches. Mr. Raven's talk was followed by a short address of welcome to the convention from its president, who then called the business session of the convention to order "for the purpose of the transaction of any business that may legally come before us, the work to be done in a fraternal spirit

DELEGATES AND VISITORS, IOWA STATE N. A. S. E. CONVENTION, CEDAR RAPIDS, MAY 20-22 and with a view to promoting the best interests of the order, treating each other as brothers and observing that strict consideration for the views and wishes of others to the end that harmony must prevail."

At the Saturday afternoon business session, after attending to many detail matters of importance in regard to facilitating the business of the order, Waterloo was chosen as the next place of meeting. Election of officers was then in order and resulted as follows: A. C. Wilford, of Waterloo, president; Ernst Bailey, Des Moines, vice-president; J. A. Coulson, Sioux city (reelected), secretary; G. H. Beebe, Marshalltown (reëlected), treasurer; H. Yust, Ottumwa, conductor; L. J. Shramek, Cedar Rapids, doorkeeper. The new officers were installed by National Secretary Raven.

Educational matters were not neglected. At the Friday afternoon session, F. W. Laas read a paper entitled, "Furnace Construction in Its Relation to Fuel Economy." This paper was illustrated with many sketches showing boiler settings and other details having to do with this question. During the discussion which followed, several engineers from the local association were called upon to give their experiences with various types of boiler setting installed in their plants. The discussion brought out many points in regard to economical boiler practice and was closely followed by all present.

Another interesting event on the program was a lecture on "Boiler Feed Waters, What They Contain, and Why They Cause Trouble," by W. A. Converse, of Chicago. During this lecture the process of feed-water analysis was followed out with apparatus in the same manner as when a sample is sent to the laboratory for test. The various constituents of the water were precipitated, and methods of determination were interestingly explained.

One of the features of the convention was the presence of many students from the neighboring universities and colleges. One party of [illegible] was present from Iowa City, and consisted of a number of instructors and students of the senior and junior classes of electrical, civil and mechanical engineering in this university. Other students were present from the Ames College of Applied Science and from Mt. Vernon. Much interest was shown by them in the display of mechanical goods in the lobby of the hotel.

A number of trips were taken to neighboring power houses and manufacturing establishments, one of the most interesting of which was that to the packing house of the T. M. Sinclair Company. The local entertainment committee had arranged for special cars to leave headquarters at the Montrose hotel for the excursion and officials at the packing house had kindly arranged for a killing in the afternoon so that the delegates had the opportunity of seeing in operation every branch of the establishment.

The social features wound up with a banquet given to the officers, delegates, members and supplymen in the dining room of the hotel. One hundred people were provided for and after being served with a tasty six-course dinner, E. A. Sherman, of Cedar Rapids, acting as toastmaster, introduced Fred W. Raven, who delivered a short address on the objects of the association and organization. A. C. Wilford, of Waterloo, then spoke on the benefits of a license law. Other speakers were: F. M. Williamson, J. T. Carmody, C. O. Bates, C. E. Tibbles and W. A. Converse. The success of the convention was such that upon leaving all visitors felt that they had added many names to their list of friends in Iowa.

It is with the deepest regret we have to record that early Monday morning, May 24, following the convention, Mayor Carmody, who so warmly welcomed the convention to Cedar Rapids, was shot in the abdomen in an encounter with a burglar at his residence, the bullet inflicting a serious flesh wound. Latest advices are to the effect that Mr. Carmody's condition is as satisfactory as can be expected under the circumstances, and although the bullet had not been found at this writing, he will recover.

Ohio Society of Mechanical, Electrical and Steam Engineers

The nineteenth meeting of the Ohio Society of Mechanical, Electrical and Steam Engineers was held at Canton, May 21 and 22, with headquarters at the Hotel Courtland.

The meeting was called to order by President F. W. Ballard, who introduced Charles A. Dougherty, president of the Canton Board of Trade, who welcomed the society to the city. Mr. Dougherty made it evident that Canton in his estimation at least, is the fairest city in the country, and from the applause he received, it would appear that others were of the same opinion. Among other things he said that more than 6000 special articles are manufactured in the city and county.

President Ballard brought out and dwelt upon the thought that the engineering profession is one of utmost importance, and that mankind owes more to it than to medicine, law, or other professions.

A departure was made in the manner of presenting the various papers to the society. Instead of the authors reading their papers, as printed in the journal, a condensed presentation of the salient points in each paper was given by the author. The members, who were supposed to have familiarized themselves with the text matter of each paper, were then given an opportunity to discuss the original paper. This plan gave very pleasing results, and with the exception of such as did not refer particularly to steam or electrical matters, the papers were fairly well discussed.

The first paper treated upon "Hot, Soft Water for Steam Boilers," by G. H. Gibson. He described the manner in which scale forming particles get into feed water in the first place, and gave the chemical action that occurs when various chemicals are introduced into the feed water. The point was made that some engineers are under the impression that some feed waters are chemically pure; pure water, however, can only be obtained by distillation.

The method of testing water for solids was discussed, also the effect of scale in a boiler, but the predominating thought in this connection was that, although scale undoubtedly makes an increase in coal consumption, and has a great bearing as to the matter of economy, these factors are of less importance than that of safety in operation, and the cost of repairs, due to a reduction of labor expenses. The matter of safety being the leading feature in boiler practice, scale should be eliminated for that reason if for no other.

In discussing the treatment of scale with soda ash, it was brought out that care should be exercised, as it tends to pass into the steam lines and dissolve the rubber gaskets in the flange joints, and that as a remedy a steam separator would in most instances eliminate this trouble. The separator, however, should be provided with a drip pipe of sufficient dimensions to take care of all water the separator would be apt to handle. Another factor in dealing with the use of soda ash was relative to the injurious effect it has on brass seats and disks of blowoff valves, and copper seats and disks were recommended.

The second paper read dealt with "The Interpole Motor," by Prof. H. B. Dates. He stated that it was not a new idea, probably about 25 years old, and undoubtedly originated abroad. The motor is found extremely useful in cases where the machine is to work with high-speed tools which require special speeds. A brief description of the motor was entered into in which was incorporated the statement that there are indications that the electrical companies are inclined to work the interpole idea overtime in order to be sure that trouble will not occur from sparking commutators. Another advantage of this type of motor is that it is available for [illegible] service, as it will produce the same power, although occupying less space than the ordinary type. Another thing, the idea is not limited to motors, but can be applied to generators where trouble has been encountered with sparking at the commutator.

A paper on "Heat Treatment" was well received. Mr. [illegible], the author, was not pres... and an abstract of the paper was given by W. L. Brown, who said, among other things, that the subject of thoroughly insulating steam pipes has become of great importance, especially since the introduction of superheated steam, and that the best results are now being obtained by 85 per cent. asbestos covering, the thickness and style of application being governed by the temperature of the steam. There are three kinds of covering; that suitable for low-pressure plants, that adaptable for a steam pressures up to 150 pounds per square inch, and superheated steam. No pipe covering is made that will withstand moisture to any great extent, was the statement made to inquiries relative to this point.

"On the Ethics of Society Membership," a paper presented by David Gaehr, contained much of benefit to the members of the society. It pointed out how each member could, and should promote the interest of the society by meeting every obligation as it came to him, by attending the meetings, by obtaining new members, by preparing a paper to be read at some meeting of the society on a subject thoroughly understood by the author, and to take an active part in the discussion of papers presented to the meeting.

"Lubrication of Steam Cylinders by Grease" was a paper prepared by B. F. Fisher. The matter of cylinder lubrication was taken up to some extent, as well as the composition of various oils used for that purpose, the main portion of the paper being devoted to the method of lubricating cylinders with grease of a special mixture and with a special feeding device. This paper aroused about as much interest as any that was presented. In the discussion that followed the reading of the paper it was brought out that one plant had operated for 72 hours on one pound of grease, costing 12½ cents, as compared with five gallons of cylinder oil, costing 58 cents a gallon. It was claimed that the grease softened up old packing and made it pliable, thus adding to its life.

At 2:30 p.m., the members of the society were taken on an inspection trip in a special car about the beautiful city of Canton, a visit being made to the works of the Canton Steam Pump Company and the Canton boiler works. On Saturday afternoon the members were taken by trolley to the power station of the Northern Ohio Traction Company, where the opportunity of viewing the dissected parts of a Curtis turbine was afforded. Next a visit was made to the city pumping station and from there to the McKinley Memorial.

The most important business transacted by the society was the nomination of the following committees: Research Committee, to carry on the work of getting together important data from any available source relating to the work of the society regarding steam, electrical and mechanical engineering; Membership Committee; Publicity Committee and Advertising Committee, the three latter to attend to such matters as their names signify.

Thirty-three active members and one associate member were received into the society. The next meeting will be held at Lima, O., Friday and Saturday, November 19 and 20, 1909.

Annual Convention of the A. I. E. E.

The next annual convention of the American Institute of Electrical Engineers will be held at Hotel Frontenac, Thousand Islands, Frontenac, N. Y., beginning Monday, June 28, 1909. A tentative list of the papers to be presented is as follows:

"Some Consideration in Designing Heavy Capacity Fuses," by L. W. Downes.

"A Sketch of the Theory of the Adjustable Speed Single-phase Shunt Induction Motor," by F. Creedy.

"Calculation of the High Tension," by Percy H. Thomas.

Transmission Paper, by W. S. Moody.

"Effect of Frequency upon the Cost of Alternators," by C. J. Fechheimer.

Two papers on high-tension transmission subjects, by R. D. Mershon.

"The Reduction in Capacity of Induction Motors due to Unbalancing in Voltage," by S. B. Charters and W. A. Hillebrand.

"The Heating of Induction Motors," by Alexander M. Gray.

Telephone paper, by J. J. Carty.

Three Industrial Power papers, by D. B. Rushmore.

"The Resistance and Reactance of Armored Cables," by J. B. Whitehead.

Two Educational papers, by A. S. Langsdorf and H. J. Ryan.

"Generation for 100,000 Cycles," by E. F. Alexanderson.

"Repulsion Motors with Variable-Speed Shunt Characteristics," by E. F. Alexanderson.

"Auxiliary Poles for Direct-current Machines," by John N. Dodd.

"The Thermal Convection from Thin Copper Wire Supported in Air," by A. E. Kennelly, C. A. Wright and J. S. Bylevelt.

Two papers, by Comfort A. Adams.

"Harmonics, Even and Odd," by J. B. Taylor.

"Electric Measuring Devices," by L. T. Robinson.

"The Purification of Boiler Feed Water" is the subject of two tables published by the Harrison Safety Boiler Works, of Philadelphia. The larger of these gives the characteristics and reactions accompanying purification of water according to Stingl, as given in "Analysis and Softening of Boiler Feed Water," by Wehrenfennig. The paper first enumerates seven classes of material occurring in water. Under each class is indicated the scale formation due to its presence. The third section gives the degree of solubility in natural water; the fourth, the means of causing precipitation and transposition; the fifth section indicates the procedure and the reactions occurring thereunder; the sixth and seventh sections give, respectively, the substances remaining in solution and in the precipitates after the precipitation or transposition occurs. The chart is 9x22 inches and contains in this condensed form a fund of information which will be valuable to the engineer. The smaller table is reprinted from a paper read by Messrs. Hunt and Clapp before the American Society of Mechanical Engineers, and accredited by them to Prof. S. M. Norton, giving the cures recommended for such troubles as incrustation, corrosion and priming. These charts, we understand, will be sent gratuitously to any applying for them, the interest of the Harrison Safety Boiler Works in the matter being due to the fact that the charts show that the purification of water for boiler-feeding purposes can be accomplished in a commercially successful manner by the proper application of heat and soda ash, as is done in their open heater system; that is, that these two remedies will protect the boilers from corrosion, since they completely neutralize any acid which may be in the water, and from the formation of hard scale, since heating water by spraying through the steam takes the place of the caustic lime or caustic soda used in other processes for taking up carbon dioxide.

Personal

Charles K. Thomas, formerly sales agent of the D. T. Williams Valve Company, of Cincinnati, has been elected vice-president of the company, to succeed the late Francis X. Pund.

Obituary

The late Francis X. Pund, whose death, on May 8, was announced in the June 1 number, was born in Cincinnati and at an early age secured a position with Post & Co., and after faithfully serving this firm for eight years, he and one of his fellow employees, George Puchta, bought out Post & Co., and continued business under the name of Puchta, Pund & Co., and later as the Queen City Supply Company, which became one of the best known mill and factory supply houses in the country. In 1904 he entered the manufacturing business and with David T. Williams, formerly general manager of the Lunkenheimer Company, founded the well-known D. T. Williams Valve Company.

Book Reviews

FREEHAND AND PERSPECTIVE DRAWING. By Herbert E. Everett and William H. Lawrence. Published by the American School of Correspondence, Chicago, 1909. Cloth; 126 pages, 6½x9½ inches; 83 illustrations. Price, $1.

This book, which is one of a series of handbooks on a great variety of subjects, published by the American School, is divided into two parts, the first containing 62 pages on freehand drawing and Part II 64 pages on perspective drawing, the author of each part being given in respective order. As usual with these volumes, the book has been prepared for home study in a style easily within range of common understanding. Part I contains the fundamental principles of freehand drawing, a number of elementary exercises and some plates of the common types of ornament of Egyptian, Assyrian, Greek and Italian design. Part II is devoted to definitions, the general theory of perspective drawing briefly treated, methods employed and a number of problems in perspective.

WATER POWER ENGINEERING. By Daniel W. Mead. Published by McGraw Publishing Company, New York, 1908. Cloth; 787 pages, 6x9 inches; 413 illustrations; 89 tables. Price, $6.

In the compilation of this book the author has recognized that a knowledge of design and construction is by no means all that is required in the development of a water-power project. Other factors, such as the adequacy of supply, the head and power available and the probable variations, the plan for development, cost of construction and operation, and the advisability of the investment are quite as important and each factor must be carefully considered to assure ultimate success. The author has drawn freely from his 25 years of professional practice and his lectures to the senior class of the University of Wisconsin, and an extended acquaintance with the literature on the subject is shown by the number of references given at the end of the various chapters. The book is specific and thorough in its treatment of the various phases of water-power engineering, and to the student or the hydraulic engineer should prove to be a valued edition.

Beginning with a short introduction on the history of water-power development, a second chapter on power and a third giving the basic principles of hydraulics, a series of five chapters is devoted to the method of studying stream flow by actual or comparative hydrographs. The determination of available head for all conditions of flow and all conditions of use is given considerable space and a method outlined for the consideration of possible variations in flow during periods for which no measurements are available based on the rainfall records, the effect of variations in head and that of pondage on the amount of power developed being duly noted. In this portion of the book rainfall and its disposal, run-off, stream flow and its measurement are given due attention. Following in natural sequence are chapters on the water wheel, turbine details, hydraulics of the turbine and a chapter of some length on turbine testing. A method of turbine analysis and selection based on actual tests is presented, and a careful study of these chapters should enable the engineer to intelligently select a turbine for any particular condition of service and closely approximate the results which would be obtained during all conditions of flow and variations in head.

Load factors, speed regulation and water-wheel governors, arrangement of the reaction wheel, selection of machinery and design of plant, examples of water-power plants, construction of dams, pondage and storage, cost and sale of power, and the investigation of water-power projects are all subjects treated in the concluding chapters of the book, and these are followed by appendices on water hammer, speed regulation, the standpipe, test data of turbine water wheels, effect of an umbrella upon formation of vortices, evaporation tables, two new water-wheel governors, and miscellaneous tables.

Supplemental to the text are charts of stream flow, rainfall, evaporation and run-off, horsepower curves, load curves and curves characteristic of various turbines, in addition to other information in chart and curve form. The illustrations are numerous and well chosen, and in all, the book is a highly commendable treatise on the subject.

HYDRO-ELECTRIC PRACTICE. By H. A. E. C. von Schon. Published by J. B. Lippincott Company, Philadelphia and London, 1908. Cloth; 382 pages, 7¼x9½ inches; 256 illustrations; 33 tables. Price, $6.

This book is a treatment of hydro-electric practice worthy of the highest comment. It is divided into two parts. The first division, containing 80 pages, presents the commercial side of the subject, and as it is devoid of technical treatment no special engineering training nor experience is required to clearly understand and appreciate the contents. Chapter I treats briefly of the market of electric current; Chapter II discusses the power opportunity, with articles on flow, drainage, precipitation, evaporation, available fall, power output, etc.; Chapter III relates to the practicability of the development; Chapter IV gives a synopsis of the cost of development, including cost of dam, diversion work, power house, reservoir embankments, power equipment and transmission lines. Chapter V concludes the first part with a review of the value of the project and suggests its proper presentation. Although the various subjects enumerated are presented briefly, enough is given to acquaint the reader with the requirements of the work, the probable cost and the feasibility of any particular installation.

Part II is devoted to the designing and equipping of the plant and was written for the student and engineer in practical work. To appreciate fully this section a knowledge of the principles of surveying and the rudiments of hydrology, hydrostatics and dynamics is required. The technic in this part is elementary and methods or deductions are presented for the most part without complexity. Useful constants are reduced to diagrammatic form and features of importance are illustrated by sketches or views from existing plants.

Beginning with the surveys, flow measurements by different methods, and development programs covering the many possibilities presented by various conditions, the second part continues with a chapter of 136 pages on structural types, including the theory and constants of concrete-steel construction, methods of cofferring preparatory to dam and power-house construction, with tables of quantities for dikes, sheet pile and wall curtains, and the various types of spill structures. The subject of dams and spillways is introduced by an extended consideration of the theories of pressure and resistance and the underlying principles, with determinations of practical constants for a variety of designs. The concrete-steel gravity dam is fully detailed and some space devoted to diversion works embracing open channels, flumes and pipe lines, with data on flow, slope and velocities. Power-station construction is treated in detail of foundation, pits, penstocks and the operating floor, and special attention is given to the submerged power station.

Following is a chapter on power equipment, including the various types of turbine, their designs and efficiencies, hydraulic governors, the electrical generator and minor apparatus, and the transmission line. Part of the space devoted to electrical equipment is taken by an elementary consideration of magneto-dynamic theories, alternating current, purpose and design of the various parts of a dynamo, etc., all of which would appear a little out of place in a book of this character. A brief generalization on constructing the plant, incorporating the preparation of plans, estimates and specifications, closes the book.

Part II is a little brief in places, touching features on the surface only, but in a book on such a diversity of subjects and using 12-point type, although a little wider than usual, this is to be expected. Points most pertinent to the subject in hand are given a reasonable amount of space, and the book in its entirety should be a most desirable and useful contribution.

Business Items

A very neat and handy telephone index is being sent out by R. F. Morse, 74 Weybosset street, Providence, R. I. Send and get one—it is free.

The American Steam Gauge and Valve Manufacturing Company made more than seventy thousand safety and relief valves during a single year.

The Builders' Iron Foundry, Providence, R. I., is the licensee and builder of the new transmission dynamometer described by William H. Kenerson in a paper read at the recent A.S.M.E. meeting at Washington, D. C.

The Gatesville Electric Light Company, Gatesville, Tex., has awarded a contract to the Minneapolis Steel and Machinery Company for a 75-horsepower Muenzel gas engine and lignite producer which is to be installed in a new plant now being built.

The Lincoln Motor Works Company, of Cleveland, has changed its corporate name to the Reliance Electric and Engineering Company. The management remains the same. They will continue to build the Lincoln variable-speed motor, and will also add a complete line of constant speed motors.

The Sight Feed Oil Company, of Milwaukee, Wis., is building a new plant for the manufacture of the Richardson oil pump, and it is expected to be ready for occupancy August 1. The business of this company has increased so during the past eight years that it has had to enlarge its works several times.

The Murphy Iron Works announces that its New York office has been removed to room 1671, Hudson Terminal building, 50 Church street. H. W. Cunning, formerly representing this company in Birmingham, will be in charge as district manager, and will be pleased to give prompt attention to any request for information with regard to Murphy automatic smokeless furnaces.

Adam Happel, 408 East Ninety-third street, New York, is having a 12x30 Corliss girder-frame engine built by the Hewes & Phillips Iron Works for operating one of his plahts. This is the second engine order Hewes & Phillips have from Mr. Happel. The Hewes & Phillips Iron Works also reports an increasing demand for its high-grade castings. All pig iron, coke and other materials entering into the work is first subjected to chemical analysis and the company can satisfy the most critical buyers.

The Museum of Safety and Sanitation announces the election of Arthur Williams to the board of trustees. Mr. Williams is the general inspector of the New York Edison Company and a member of the American Institute of Electrical Engineers. In 1907 he was decorated by the French government. He is a member of the American section of the Internationl Housing Congress and was a member of the Eighth International Congress of Social Insurance at Rome, 1908. Mr. Williams will serve on the lecture committee of the Museum of Safety and Sanitation.

Circular 1502 issued by the Westinghouse Electric and Manufacturing Company contains much valuable information on alternating-current distribution, covering transformers, lightning arresters, insulators, cross arms, etc. Considerable space is devoted to underground and overhead construction applicable to congested and scattered districts. There is also given information on potential regulating systems. The circular contains 52 pages of information of value to any central-station man or any other connected in any way with the distribution of power by alternating-current lines.

The purification of boiler feed water is the subject of two charts reprinted from well-known authorities upon this subject by the Harrison Safety Boiler Works, Seventeenth and Clearfield streets, Philadelphia. The charts show that the purification of water for boiler feeding purposes can be accomplished in a commercially successful manner by the proper application of heat and soda ash; that is, that these two remedies will entirely protect the boilers from corrosion and from the formation of hard scale, since boiler feed water should be heated in any case and since heating water by spraying through steam takes the place of the caustic lime or caustic soda used in other processes for taking up carbon dioxide.

The Wisconsin Engine Company, of Corliss, Wis., has just shipped to the Allegheny Valley Street Railway Company, of Pittsburg, two horizontal cross-compound heavy-duty Corliss engines of its "higher speed" type. Each engine will develop 750 horsepower and is direct-connected to a 500-kilowatt generator operating at 150 revolutions per minute, a speed usually thought to be beyond the limit of the Corliss engine. The Wisconsin Engine Company, however, has made a specialty of what it calls its "higher speed" Corliss engines and has built a large number of them, all of which are operating very successfully. One of the engines afore mentioned drives a direct-current generator the other an alternating-current generator.

Keystone grease, manufactured by the Keystone Lubricating Company, Philadelphia, is used as a lubricant for pumping-station machinery at a number of large private water companies in the vicinity of New York City. One of these is the Hackensack Water Company, operating two triple-expansion vertical Allis pumping engines at 170 pounds steam pressure, with a duty of 20,000,000 gallons per 24 hours against a head of 180 pounds. This plant supplies a large section from Spring Valley, N. Y., to Weehawken, N. J. The pressure on the engine journals is 290 pounds per square inch. No. 4 density Keystone grease is used on these engines, at a reported saving of 52.5 per cent. in cost of lubricant over the lubricating oil formerly used, and with no increase in the friction load. There is also a decided saving of labor, and of mess under the pumps. This water company is now putting in a new 12,000,000 gallon unit of the same type, which will also be lubricatd with Keystone grease.

"The Proper Care of Belts" is the title of a new booklet of 24 pages, recently prepared by the Joseph Dixon Crucible Company, Jersey City, N. J. It is divided into three sections, headed respectively: Belts; Belt Dressings; and Hints, Kinks, Tables. The first section deals with the running condition of belts; the second takes up treatment with various preparations; and the third, as the title indicates, has some general points upon belting and its use. This last section contains some interesting matter collected from several sources. It tells what results were secured in a plant where records were kept over a period of years; gives the economical speeds at which leather belts should be run; has some matter telling of the different styles of joints, illustrating three methods of leather lacing; contains rules for calculating speed of pulleys; gives horsepower transmitted by various sizes of single and double belts, etc. While it is got out in the interests of the traction and solid belt dressings that the Dixon company place on the market, it contains so much matter of general interest as to be valuable to the practical man.

New Equipment

The Newport (Tenn.) Bottling Works will install ice-making plant.

The I. T. Goodrich Company, Savannah, Ga., will install a 20-ton refrigerating machine.

The F. Mayer Boot and Shoe Company, Milwaukee, Wis., will erect a new power plant.

The Lytle Creek Power Company, San Bernardino, Cal., will increase output of plant.

The city of Crockett, Tex., has issued $25,000 bonds for the construction of new water works.

The Striffler Ice and Coal Company, Springfield, Ill., is erecting a new ice and cold-storage plant.

City of Canyon, Tex., will vote on issuance of $33,000 bonds for water works and sewer system.

The Westfield (Mass.) Power Company has awarded contract for the construction of a new building.

The Middletown (Ohio) Gas and Electric Light Company will erect a new electric light power house.

The city of Bessemer, Mich., is contemplating replacement of boilers, pumps, etc., for water-works system.

The Edison Company, New York, has filed plans for a new power-house on 26th street, near Sixth avenue.

The El Paso (Tex.) Electric Railway Company will erect an addition to power house to cost $14,000.

City of Appalachia, Va., will issue $50,000 bonds for construction of water works. Address the mayor.

City of Newberry, S. C., voted to issue $40,000 bonds ror extension of sewer and water systems. Address the mayor.

The Eastern Wisconsin Traction Company, Fond du Lac, Wis., is planning to abolish line shaft changing to direct-connected generators. Will change from 8000-volt series direct-current to 660 volts, 7 lights in series.

Help Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

WANTED—Steam specialty salesmen on commission. Reiter Boiler Cleaner Co., Elgin, Ill.

SELLING ENGINEER wanted for steam condensers. Schutte & Koerting Co., Philadelphia, Pa.

WANTED—Thoroughly competent steam specialty salesman; one that can sell high-grade goods. Address "M. M. Co.," POWER.

AN ENGINEER in each town to sell the best rocking grate for steam boilers. Write Martin Grate Co., 281 Dearborn St., Chicago.

WANTED—First-class foreman blacksmith, capable of handling shop doing both hand and machine work, and of developing new methods. Box 57, POWER.

DRAFTSMAN WANTED—Steam engine or turbine experience essential. Write, giving age, experience and salary required. The Terry Steam Turbine Company, Hartford, Conn.

Situations Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

SITUATION as Corliss engineer in some mill or plant. Box 58, POWER.

DRAFTSMAN—Three years' experience in engineering and steam turbine power station design, and three years in steel plant. Box 56, POWER.

CORNELL GRADUATE, age 32, desires position. Practical experience includes power plant and shop superintendence; electric and pneumatic power distribution; applications of electricity in manufacturing plants, particularly individual motor drive; specification work and correspondence. Broad knowledge of general machinery. Executive and business ability. Highest endorsements. Box 59, POWER.

Miscellaneous

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

WANTED—From 500 to 1500 horsepower of B. & W. water tube boilers in units of 250 horsepower each. Must be in A-1 condition. Inquire of J. F. Cargill, Room 1630, Frick Building, Pittsburg, Pa.

The New Keystone Watch Case Co. Plant

How an Old Plant Was Remodeled and Made Uptodate During a Busy Period, without Interrupting the Service; the Units Installed

BY F. L. JOHNSON

When an engineer sees a new uptodate power plant operating in an industry where he knows for a certainty that only a short time before the same ground was occupied by old boilers, old engines and apparatus generally, and when he learns that the change from return tubular boilers to water-tube boilers, from slow-speed belted engines to higher-speed engines with electric generators on the shafts, from wide and long main driving belts to small wires, carrying power to widely distributed motors, and, in fact, from everything that was old in the methods of power transmission to all that is new, without a moment's interruption in the service, the story of the manifold steps in the transformation excites as much interest as, if not more than, the perfect working of the plant.

Early in 1907, as a basis for other improvements, the management of the Keystone Watch Case Company decided to remodel the power plant of the factory, changing it from a belt- to a motor-driven system which would embody all of the later and better improvements in individual and group machine driving. Some idea of the problems to be solved in the change may be had when it is understood that from the engine, boiler and pump rooms there were taken four horizontal return-tubular boilers, two pumps, three engines, one feed-water heater, four electric generators and two motors, with all accompanying smoke flues, steam and exhaust piping, switchboard, etc., and there were installed in these same rooms three water-tube boilers, three engines with direct-connected generators, six pumps, two air compressors, one elevator, switchboards, gage boards, oil filters for machine and cylinder oils with the necessary storage tanks and everything that goes into the makeup of a modern manufacturing power plant.

After the change was decided upon but before any work was started the chief engineer under whose direct supervision the project was to be carried out prepared a schedule or a sort of scorecard on which all the steps of the proposed renovation were set down in the probable order in which they would take place, it being his intention to mark all completed steps by drawing a pencil mark through each paragraph as the work indicated in it was completed. One copy was furnished to Treasurer and Secretary Charles M. Fogg, by which he was enabled to see at a glance just how much progress was being made from day to day.

After several consultations between the manager and the chief engineer, it was decided to proceed with the work, even though the demands on the capacity of the factory had never been greater than at that time. Contracts for the new equipment were given out and operations following the lines of a well-digested plan were begun. It being summer, when little power was needed for lights, one of

FINISHED WALL OF ENGINE AND BOILER HOUSE

the four 72-inch by 18-foot boilers could be spared. It was disconnected from the system and taken out, and in its place was installed the first of the three Maxim water-tube boilers, of 300 horsepower each which were contracted for. This boiler was connected to a temporary stack and to the engines by a temporary steam main. By means of forced draft and increase in coal used it was made to develop more than 300 boiler horsepower. In a shed just outside the engine room there was an Erie City Iron Works 12x12 high-speed engine, with a 70-kilowatt Diehl generator on the shaft, and wired to motors which were installed in different parts of the factory to drive the shafting that had been belted to one of the engines. The belted engine was taken out and in its place on a new foundation one of the two new Murray Iron Works Corliss engines which had been purchased was installed. Each of the new engines was what is commonly called direct-connected to Diehl compound-wound electric generators.

During the time that the engines were furnished with steam from the single Maxim boiler connected to its temporary stack, the permanent stack, which had been in use for 20 years and was in need of repairs, was relined with brick.

When the first Murray-Corliss engine was erected it was connected, like the high-speed engine in the shed, to the boiler by a temporary steam pipe and put into service. This, in connection with the small engine in the yard, furnished the electric current which through motors drove the entire factory, and another engine was taken out and in its place the second Murray-Corliss was erected.

As the work in the engine room progressed the boiler room was not neglected. In the place formerly occupied by the three horizontal tubular boilers which had furnished steam for the engines and pumps while the first Maxim boiler was being installed, there were two more Maxim boilers erected and equipped with temporary stacks. While the engines were being erected the permanent steam main was constructed.

Crane "Ferrosteel" extra-heavy nonreturn stop valves for a working pressure of 250 pounds were provided for the boiler nozzles, and to these the 10-inch extra-heavy steam main, with Van Stone joints and Crane "Ferrosteel" valves, was finally connected. This main after leaving the boilers runs first backward and then down by long-turn bends and passes under the engine-room floor, branching on the way to several directions leading to other points where steam is needed, either for heat or motive power. Individual pipes to each engine leave the main by long bends upward, passing considerably above the cylinders, and by return bends of long radius turned downward to the throttle valves. Notwithstanding several is used throughout and in the engine room this is covered by a jacket of planished russia iron with half-oval bands of brass at the joints.

In the pump room, which is on the boiler-room floor level, are six steam

CHIEF ENGINEER'S OFFICE

pumps of various sizes, four of which are so connected by the water piping that they may be independently or collectively used for boiler feeding or for fire pumps in addition to the regular Underwriters' fire pump, which stands alone in the fire-pump room at the right-hand end of the boiler room. All drips from the engines and pumps are led to a large settling and separating tank set below the floor of the pump room which, while it allows the water to flow away to the sewer, collects and retains all of the oil, which is automatically returned to the lubricating-oil filter tank. Settling and separating tanks are quite an important feature in this establishment, as all the waste water from the laundry and wash sinks is carefully treated for the purpose of recovering the gold and silver that are washed from the hands, faces and clothing of the operatives, something like $18,000 worth of the precious metals being recovered by this process each year.

Large quantities of hot water are used in all parts of the factory and in the laundry, where all of the outer clothing of the operatives is washed. This water is supplied from the boiler feed-water pipe leading from a 1000-horsepower Ferguson feed-water heater conveniently located under the engine room, a pressure regulating valve maintaining a constant pressure of 40 pounds on the factory system. The exhaust-steam and water piping are so arranged that the heater can be bypassed any time it is necessary to examine or repair the heater.

Although a delivery and erection of all of the steam and electrical apparatus necessitated in the new installation was required within 60 days of the date of the

FRONT WALL OF ENGINE AND BOILER ROOMS WHILE WORK WAS GOING ON

signing of the contracts, nothing that was not of the highest grade in design, workmanship and efficiency was considered; guarantees for efficiency and satisfactory operation under normal and overload conditions were exacted and exhaustive tests were conducted, substantiating by their results all claims made. Not until the new plant had been in operation several months and everything was going on in the regular routine was any attempt made to conduct tests. The boilers, three in number, are Maxim water-tube boilers, with the lower drum separated from the combustion space by firebrick arches and connected to the upper drum by six rows of specially bent tubes, the grates extending the entire length of the boiler, as described and illustrated in POWER of August 11, 1908.

Tests for the purpose of determining the capacity and efficiency of the boiler were conducted on April 1 and May 12, 1908, the results of which appear in the tabulated report on the opposite page.

The electrical apparatus for the plant was furnished by the Diehl Manufacturing Company, of Elizabethport, N. J., and consists of one 200-kilowatt and one 170-kilowatt engine-type generators, running at 125 revolutions per minute, and one 75-kilowatt generator operated at 250 revolutions per minute, for night and holiday service. During the changes from belt drive to motor equipment, two engines and generators did severe service, running night and day, with, very frequently, long 50 per cent. overload periods.

The motor equipment consists of about 60 motors, ranging from 2 to 30 horsepower, all except five being of slow speed, ranging from 350 to 600 revolutions per minute, mostly of the ceiling suspension type, and in many of the rooms the motors have been so placed that they are scarcely

REPORT OF TESTS AT THE PLANT OF THE KEYSTONE WATCH CASE COMPANY ON MAXIM WATER-TUBE BOILERS.

Date of test	April 1, 1908	May 12, 1908.
Duration of test	10 hours	10 hours
Number of boilers	2	3
Heating surface of each boiler	2,500 sq.ft	2,500 sq.ft.
Area of grate of each boiler	70 sq.ft	70 sq.ft
Ratio of heating to grate surface	35.7	35.7
Kind of draft used	steam blower	natural draft 0.44"
Average temperature of feed water	62.5° F	67° F.
Average temperature of steam	387° F	3[illegible]° F
Highest temperature of escaping gases	370° F.	667° F
Lowest temperature of escaping gases	300° F	310° F
Average temperature of escaping gases	312° F	381° F
Kind of fuel used	Buckwheat No. 2 or rice	
Total fuel used	13,800 lb.	22,400 lb
Moisture in fuel	1,104 lb.	1,344 lb.
Percentage of moisture in fuel	8%	6%
Weight of refuse	3,725 lb	4,946 lb.
Percentage of refuse	26.9%	23.16%
Total combustible (dry weight of fuel less refuse)	8,973 lb.	16,110 lb.
Quality of steam	99.5	99.16
Percentage of moisture in steam	0.5%	0.84%
Total water fed to boiler, actual	91,367 lb	181,458 lb
Water actually evaporated corrected for moisture in steam	90,911 lb.	180,186 lb
Equivalent water actually evaporated from and at 212° per pound of combustible	12.177 lb	11.145 lb

noticeable. The motors driving the polishing lathes are of the floor type, 4 to 20 horsepower, direct-connected to the shaft and running at an average speed of 320 revolutions per minute. The electroplating department and engine-turning rooms are equipped with motor-generator sets. The blower and air-compressor motors are of the variable-speed type, with a 2 to 1 variation.

Practically everything around the factory is motor-equipped, fans, elevators, pumps, exhaust wheels, blowers, mills, etc., motors being selected of types and speeds to suit the various conditions to be met. All the starting and controlling apparatus are of the Cutler-Hammer type.

The new boilers, engines and generators are located in the rooms occupied by the old apparatus. Every detail of this plant was worked out with such precision that no changes or alterations have been made since starting, and on the whole the plant will compare favorably with any in the country.

16X30 MURRAY-CORLISS ENGINE WITH 170-KILOWATT SOFT GENERATOR

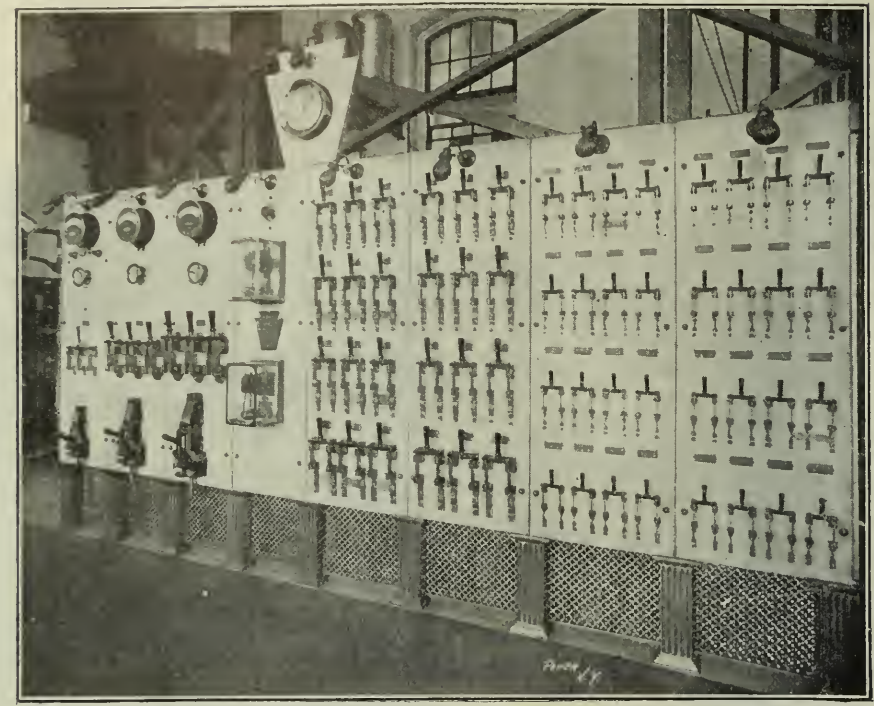
16X30 MURRAY-CORLISS AND 12X15 ERIE CITY IRON WORKS ENGINES, WITH 2[illegible]0 AND 70-KILOWATT SOFT GENERATORS

It was demonstrated by the acceptance tests of the installment that the guaranteed efficiency was far higher for all machinery than was provided for in the specifications. All the generators and motors have been run many times longer than three hours with an overload of more than 50 per cent., without sparking or heating above the limit specified.

The contract for the Murray Iron Works Corliss engines allowed an extremely short time, about 60 days, for delivery and installation, but each engine was delivered considerably ahead of time. The contract provided that the engines should operate noncondensing under a steam pressure of 150 pounds at 125 revolutions per minute, with a water consumption not exceeding 24½ pounds per indicated horsepower per hour. After the installation of the engines a 10-hour test, at which both parties to the contract were duly represented, was run on March 31, 1908, the water consumed by the engines being weighed to the boilers, and all the precautions taken to insure exact results. During this test, indicator diagrams were taken every 10 minutes, a nearly constant load being maintained, the results showing a water consumption of 22.36 pounds per indicated horsepower-hour. Succeeding this, a test was run for overloads, and upon the engine rated at 254 indicated horsepower a load of 400 indicated horsepower was maintained for several hours, an equivalent to 57 per cent. overload. The cutoff of the engine at this load shown by the diagrams, was 43 per cent. of the stroke and as the engine is of the long-range cutoff type, guaranteed to maintain control from lead to 5/8 of the stroke, it is evident that a considerably heavier overload could have been carried. The speed of the engine on the rated load tests was 127 revolutions per minute, steam pressure 140 pounds. On the overloads, the steam pressure was the same, and the speed fell to 126 revolutions per minute, showing a change in regulation maintained with an overload of 83 per cent. of less than 3/4 of 1 per cent. variation.

Both Corliss engines are equipped with Murray high-speed governor which operate at about twice the speed of the engine, while the economical features were the result of extremely close cylinder clearances, adjustable bearings and the special double-ported Murray steam and exhaust valves, with the valve gearing operated by double eccentrics and dashpots, so perfected as to produce instantaneous release at the desired moment.

The frames are of one-piece castings, designed by Frederick W. Salmon. An interesting feature is the introduction of a large wedge, controlled by a screw, placed immediately under the bottom bearing box, on each bearing, whereby the engine shaft can be kept in constant alinement, by the simple use of a wrench, as the babbitt wears.



SWITCHBOARD CONTROLLING ALL MOTORS AND LAMPS IN THE FACTORY

The engines have been in operation for about a year and a half and, notwithstanding the high speed under which they have been operated, show no signs of wear on any of the parts and have given no trouble, but have operated smoothly and easily during this time, although frequent overloads of 50 per cent. have been carried at various times. Fifty-six single-throw switches on the marble switchboard in front of the engines, with ample floor space both front and rear, give the engineer control of each group of motors and the lights in every department of the entire factory. This board was designed by the chief engineer and built to the specifications furnished by him, and, with its circuit-breakers, ammeters, voltmeters and automatic controlling instruments, provides for any demand or emergency

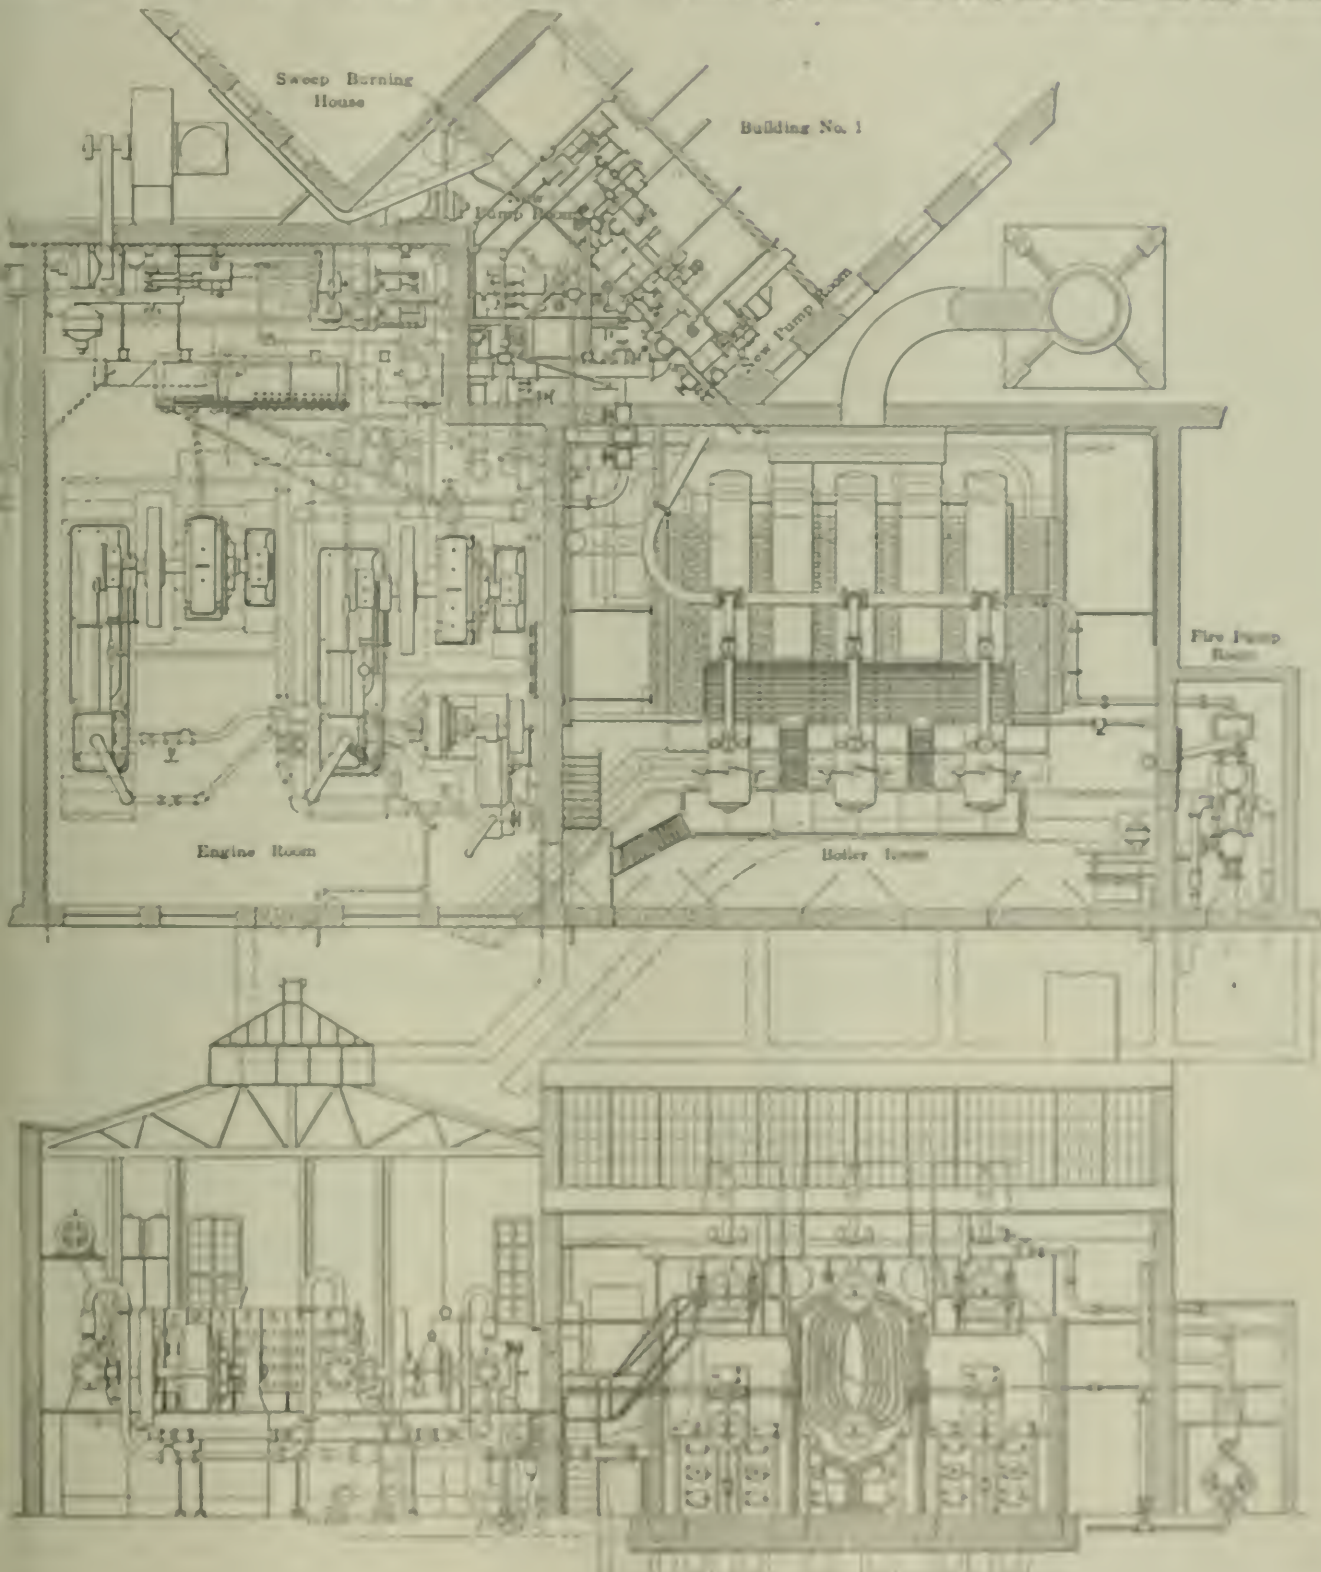
BOILER FRONTS DURING CHANGE

BOILER FRONTS AFTER CHANGE

that could possibly arise in the distribution of power.

From the extreme end of the boiler room where the 1000-gallon Wheeler Underwriters' fire pump stands ready for instant service, through the boiler, pump and engine rooms, through the machine, blacksmith and carpenter shops, to the chief engineer's office on the third floor, everything is at all times in first-class working order. Every detail gives evidence of thought given by a master mind. Chief Engineer F. Mink is a thorough organizer and from the daily reports in each department he makes up the complete report for the motive power department.

He can tell to the fraction of a cent the cost of power for each day of the year and his monthly statements show every item of expense. If it should appear that the motive power for December of one year cost more than for December of any other year, the statement shows whether this extra cost was due to labor, inferior or higher-priced coal, a few extra jobs for repairs, a new boiler tube, or what not. For more than 20 years these records have been kept and at a glance the cost of motive power for any month of that time and every item of that cost may be seen.



ELEVATION AND PLAN OF BOILER AND ENGINE ROOMS

Care and Management of the Horizontal Tubular Boiler

By William Kavanagh

The horizontal tubular boiler is very reliable and economical when properly handled and cared for. It is capable of storing large quantities of heat; its longevity is equal if not superior to any other type of boiler; it is cheap to install and repair; simple to handle and not at all difficult to clean, although one of the stock arguments against this type of boiler is that it is difficult to clean; when, however, the correct method of cleaning this boiler is properly understood there will be no difficulty found in keeping it clean and free from scale, making it one of the most economical boilers to operate.

Assuming that the boiler is under steam pressure and it has been decided to shut it down for cleaning, the correct way to clean it is as follows: Having shut the main stop valve, clean the furnace of ashes and whatever fire remains after the run, and close every door and damper on the boiler. Let the water remain in the boiler and allow the brickwork, boiler and water to cool together. When the process of cooling is over, open the safety valve and blow-down cock and let the water run off. After the water is out of the boiler, take off the manhole and handhole plates and put a wooden or other plug in the blow-down connection. Take a hose and enter the boiler on top, and having secured a light in a convenient position, play a strong stream of water between the tubes and around the shell, especially near the head flanges. It will be found that the most scale and mud will accumulate around the head

FIG. 3

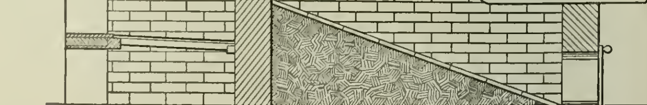


FIG. 4.

flanges and particular attention must be given to these parts.

Having given the boiler a thorough washing down, come out and, after playing a strong stream of water between the tubes either through the handhole or lower manhole, take a long-handled light hoe and collect all of the scale and mud at the nearest and most convenient opening. With a short, light hoe haul out all sediment and dirt. This part of the cleaning process being over, once more enter the boiler through the upper manhole and, having secured a light in a handy place, take a flat bar of sufficient length to reach from the top row of tubes down to and below the lowest row of tubes, as shown in Fig. 1, and swing this bar lengthwise of the boiler and between each row of tubes, being sure not to miss any of the rows, which will effectively clean out all scale.

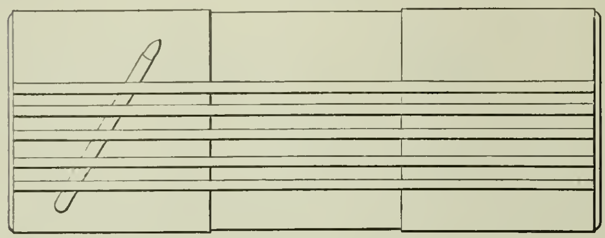

FIG. 1

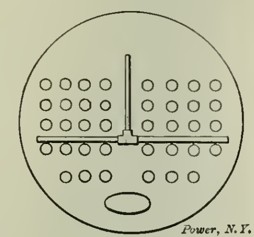

FIG. 2

When the use of the flat bar is finished, take a tee-bar, as shown in Fig. 2, and by placing it across and between each row of tubes and drawing the bar from head to head, all or nearly all of the scale lying between the tubes in the crosswise direction will be knocked down on the crown sheet. The scraping of the tubes being over, now inspect them to see how well it has been done.

While in the boiler have a boiler-room employee fix an incandescent lamp on a long, light, wooden or iron rod or pipe, and then by having the light placed beneath the tubes and shifted from row to row, and along the rows, you can look downward between the tubes and see how clean they are.

After this mode of cleaning the tubes is finished, play a fresh stream of water once more around the tubes and shell and then have all of the scale removed. Before leaving the inside of the boiler, inspect it for loose braces. By striking the braces with a light hammer you can easily discover if any is loose, and all braces found loose must be tightened.

When a loose brace is struck with a hammer the vibrations set up in the brace are long and slow, and the tone or "ring" is low. If the brace is taut, the "ring" or tone will be sharp and the vibrations short and rapid. A loose brace can also be detected by placing the thumb and forefinger on the rivet, when the looseness can be felt as the brace is struck. Again, a loose brace can be detected by comparing the ring of two or more braces having the same length and diameter. The ear can detect the difference in sound, the brace under the least tension having the lowest tone. Usually long braces are fitted with turnbuckles for the purpose of keeping them taut, while the short flat braces are riveted to the head and shell and are not provided with means for keeping them taut. The short braces seldom get loose.

Being satisfied that the braces are in good order, inspect the shell along the water line for corrosion, sometimes called "pitting" and "grooving." Pitting can be detected by dull, red spots, and grooving by seams, small channels or grooves. The corrosion runs along the line coincident with the hight the water is carried and will be heaviest where the hight of the water varies most.

When pitting and grooving occur sufficiently to cause a suspicion of the weakening of the shell or tubes, it will be necessary to follow up these signs and learn how deep the corrosive action has eaten into the metal. If of a depth to weaken the plate seriously, a hole should be drilled at each end of the groove or weakened spot and a patch riveted on. Corrosion attacks the tubes mostly near a point where they enter the boiler heads. By striking the tubes with a small peen hammer, the weakened tubes will become dented or bent inward. Good strong tubes are not easily bent or dented with a blow of a light peen hammer. All weakened tubes should be taken out and replaced with good ones.

After inspecting the tubes for flat spots, weakened or corrosive parts, inspect for leaky riveted seams. If a seam leaks, take a calking tool and close up the leak, and if a loose rivet is found it may be made steam-tight with the calking tool; if not, the rivet should be cut out and a fuller rivet inserted. The inside of the boiler having been properly inspected, pass out all tools, lights, etc., and enter the furnace and inspect the crown sheet for blisters, etc. That part of the crown sheet directly over the bridgewall should receive particular attention. By using a light ball peen hammer and tapping the sheet carefully one is apt to locate any weak spots or injured parts. If a blister is found the skin of the blister should be cut off and trimmed all round, as by doing this you will be enabled to tell the depth or thickness of the metal cut away and the thickness of the remaining sheet. If the sheet has been weakened too much a patch must be riveted over the weakened spot.

The back-connection sheet should receive a similar test to the fire sheet. The tubes in the back head must be inspected, as the portion of the tube extending beyond the head becomes eaten away by the action of the heat. If the handhole has been leaking for some time the head sheet will become corroded and weakened around the handhole. This is often a source of great danger, because when the boiler is under steam it is difficult to see if the handhole plate is tight or leaking. A good plan is to take an incandescent lamp and run its wires through a piece of pipe. Then by cutting a hole in the wall opposite the handhole the lamp can be pushed in near the boiler head, thus affording an excellent opportunity for inspection of the rear tube sheet.

Having thoroughly inspected the outside of the boiler, take out the plug in the blow-down connection, put on the handhole and manhole plates and make them tight. Take a stiff broom and attach it to a handle and rub off the dust from the fire sheet and tube sheets. Mix some fireclay to the consistency of stiff putty and plaster it around the rear handhole nut and stem. This will protect the nut and stem from the heat action. There are asbestos guards made for this purpose and their use will be found superior to fireclay.

In Fig. 3 is shown how the lamp is inserted through the hole at *A*. After using the lamp, the hole can be closed by dropping the door *B* over it. In this way cold air is excluded and the draft is unimpaired.

Fig. 4 shows an improved method of feeding a horizontal tubular boiler, and it will be noticed the feed water can be discharged either into the front or rear water arches, as indicated by the arrows. This method of boiler feeding does away with repairs to or falling rear arches, besides adding considerable heat to the feed water.

It is almost needless to add that in raising steam it should be done as slowly as possible, the slower the better; the steam gage and safety valve should be reliable and in good working condition; the gage cocks and water column connections should be clean and all passages free from scale.

Close Regulation of Ridgway Engines

The accompanying diagrams were taken from Ridgway engines and generators being installed in the Edgmere clubhouse, Edgmere, L. I., by C. F. Piehl, chief engineer, during two days' tests.

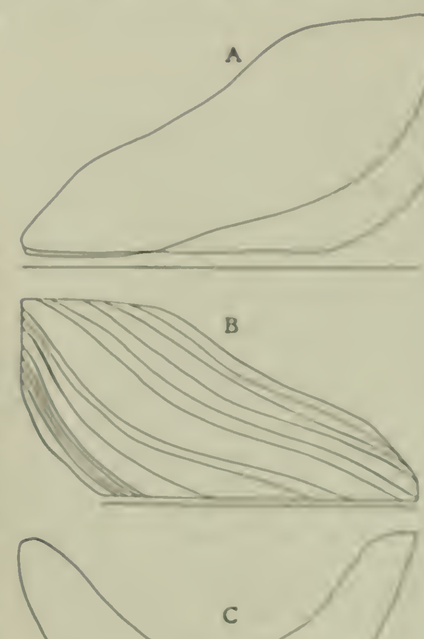
There are two units, one of 30 kilowatts, 125 volts and 325 revolutions per minute, and one of 50 kilowatts, 125 volts, 300 revolutions per minute. The 30-kilowatt set is for carrying the day load from 1 a.m. to 4 p.m., during which time the lighting load is from 80 to 100 amperes, and an additional elevator load, which consists of one Sprague 4000-pound-capacity passenger elevator.

The 50-kilowatt set is for the night service, from 4 p.m. to 1 a.m., when the lighting load is about 300 to 350 amperes, in addition to the elevator service. These conditions require very close regulation of engines and generators.

The governors are of the Ridgway type, applied to side-crank construction, and operate without dashpots. The very quick action of this governor is evidenced by card *A*, which shows that the governor made the complete change from full to no load in less than two revolutions, when the circuit-breaker was thrown out. The card *B* shows the change with a load quickly applied, which illustrates changes in the form of the card for different loads. Representative indicator cards are shown by *C*, *D* and *E*.

The full elevator load of about 140 amperes thrown on or off either of these units instantaneously produces a change of less than one volt in the circuit. With this amount of load thrown on or off instantaneously, and the two units in parallel, the instantaneous change of voltage is less than one-half a volt. These governors were tested with adjustment for a rise of speed of 5 revolutions when the load was applied and operated entirely satisfactorily. This was done to test their stability without dashpots. They were also adjusted to run at exactly the same speed, when fully loaded as when light, under which condition they operated without fluctuation, apparently as satisfactorily as when set for a falling off in speed of 1 or 2 revolutions.

The generators are of the Ridgway type, with compensating winding. With full load on the 50-kilowatt generator for 5 hours, the compensating winding rise was only 56 degrees Fahrenheit above the atmosphere, and on the 30-kilowatt machine, for the same length of time, 65 degrees Fahrenheit. The field-coil rise for the 30-kilowatt generator was 56 de-



INDICATOR DIAGRAMS FROM RIDGWAY ENGINES

grees Fahrenheit, and for the 50-kilowatt, 60 degrees Fahrenheit. The armature rise was 60 degrees Fahrenheit for the 30-kilowatt and 58 degrees Fahrenheit for the 50-kilowatt machine. The commutator rise was 65 degrees for the 30-kilowatt machine and [illegible] degrees for the 50-kilowatt generator.

According to a consular report, 1230 foreign students are enrolled at the nine leading German engineering schools.

"Phasing" Alternating Current Generators

Curves Explaining Principles Involved in Phasing Out, and the Result of Throwing in Parallel Machines Not Properly Phased Out

BY F. J. FOOTE

Phasing is not the same as synchronizing, although the two operations are very closely related. Briefly stated, phasing consists in determining whether the phases of alternating-current generators are connected in the proper relation to the switchboard or other apparatus.

The principles involved in phasing out and the consequences of throwing the machines together in parallel that are not properly phased out are best illustrated and explained by means of curves representing the names of electromotive forces generated by the machines.

In Fig. 1 is shown the armature connections for two machines connected through switches to busbars. These machines may be generators, synchronous motors, rotary converters, or a combination of any of these, as the problem is the same in any case. I have chosen two-phase machines for the explanation because two-phase curves are simpler than three-phase curves, and practically the same measuring applies to both two-phase and three-phase machines.

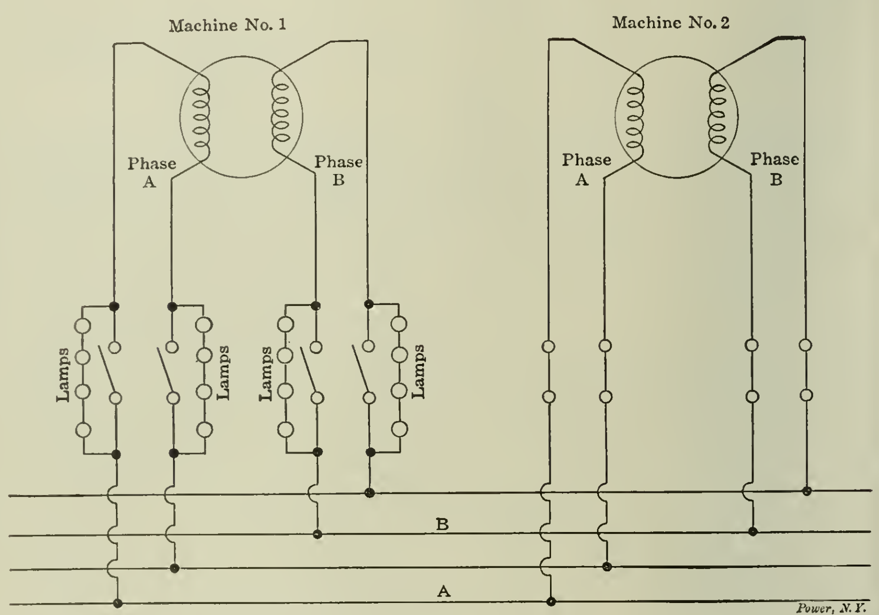


FIG. 1

In practice the machine to be put in service is phased simply with the busbars of the switchboard on the lines running to the machine, without considering the other machines that are already in operation. In the diagrams, however, I have shown the second machine in the hope of making the explanation clearer.

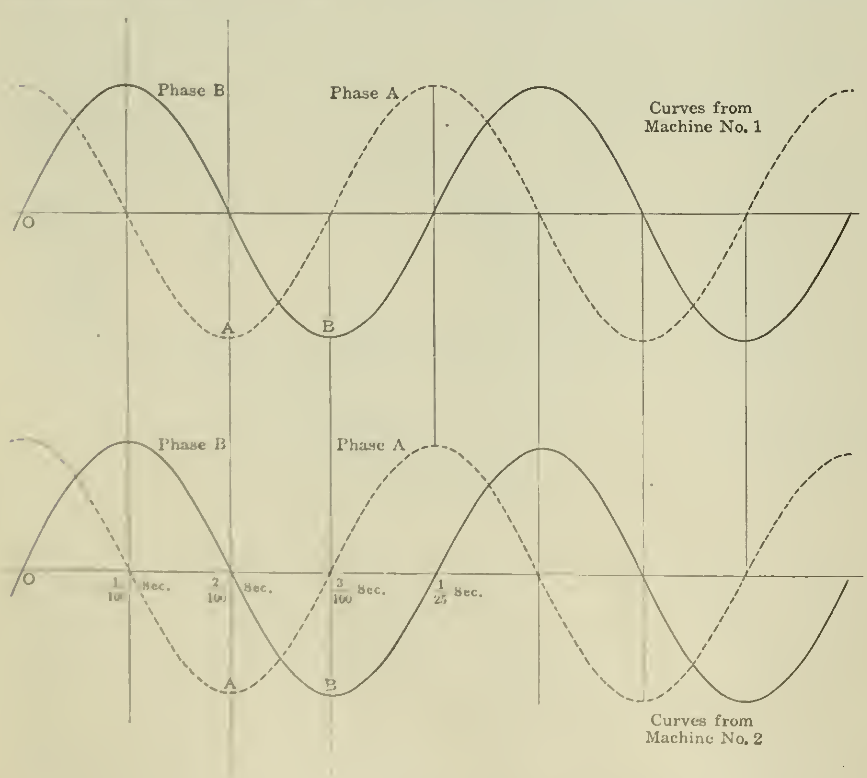

FIG. 2

How to Use the Curves

In Fig. 1 the switches of machine No. 2 are shown closed, while those of machine No. 1 are open. In this case machine No. 1 is to be put into commission. In Fig. 2 are shown the voltage curves for machines No. 1 and No. 2 of Fig. 1. The frequency chosen is 25 cycles per second, so that a complete cycle will occur in 1/25 second, as shown. In all these curves the distance horizontally is a measure of time in fractions of a second, and the distance vertically is a measure of the voltage at any instant of time. In all cases the curve generated by phase *A* is shown by dotted lines, and the curve generated by phase *B* is shown by solid lines.

Considering Fig. 2, the dotted curve *A* represents the instantaneous voltage generated in the armature coils of phase *A*. The straight horizontal line through the center of these curves is called the axis of the curves and at the instant a curve crosses this line it indicates that the voltage in the corresponding phase is zero. It is evident that phases *A* in both machine No. 1 and machine No. 2 reach their maximum at the same instant, so that if the *A* phases of the machines were connected together while they are running in this way there would be no tendency for current to flow from one machine to the other. The *B* phases of both machines also reach their positive and negative maximum values at the same

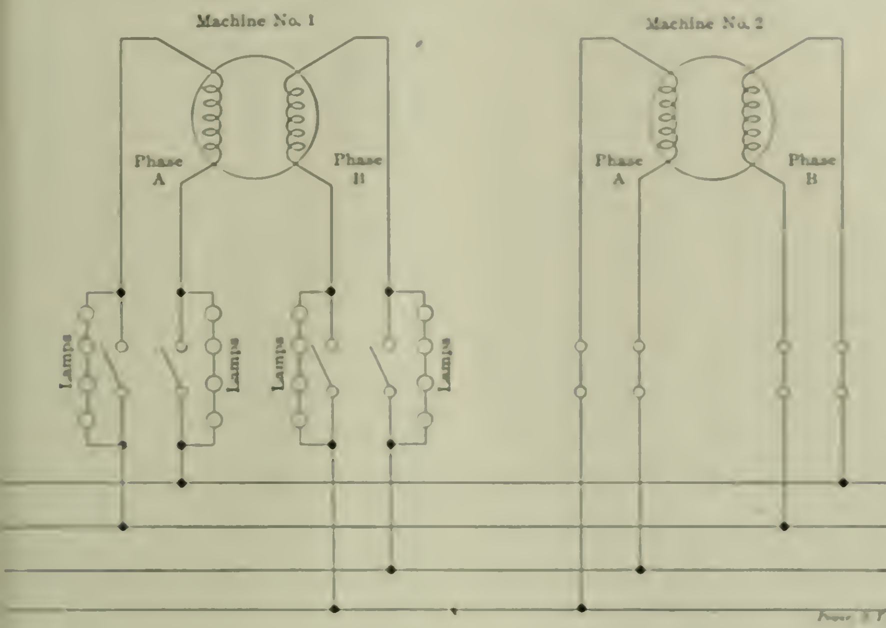

FIG. 3

instant, so that the *B* phases could also be connected together without tendency for current to flow between them. In other words Fig. 2 shows the correct conditions for throwing the machines in parallel, that is, they "phase out" correctly.

Suppose for simplicity that the machines represented diagrammatically in Fig. 1 have a normal voltage of about 400 volts, so that a bank of four 100-volt lamps in series would come up to full brightness if connected across one phase. If two such sets of series lamps are connected around the two open switches of phase *A* of machine No. 1, with both machines running at normal voltage, the lamps will alternately come up to full brightness, then become entirely dark, the rapidity of this action depending on the *difference* in speed of the two machines (assuming the machines to have same number of poles).

We can explain this action by means of the curves in Fig. 2, in this way: As long as the machines run at exactly the same speed, and the curves of the two machines have the relation they have in Fig. 2, the lamps will remain dark. As soon, however, as one of the machines, say No. 2, begins to lag behind the other, its voltage will reach the maximum at a later instant than that of machine No. 1, and there will be a tendency for current to flow from one machine to the other through the lamps. The more machine No. 2 lags behind No. 1, the greater will be this tendency, so that when machine No. 2 has lagged one-half cycle behind No. 1, phase *A* of machine No. 2 will be a maximum negative voltage, while phase *A* of machine No. 1 is at maximum positive voltage; consequently, the lamps on phase *A* will burn at full brightness.

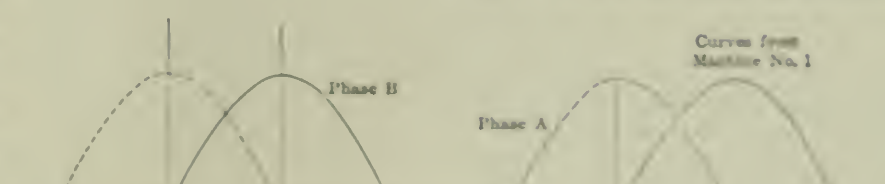

FIG. 4

How to Get a Clear Idea of the Action

A clearer idea of the exact action taking place may be obtained by placing a strip of transparent celluloid or very thin tracing cloth over the curves, say of machine No. 1, making a tracing of them, and then moving this tracing along, keeping the axis of the curves on the tracing cloth directly over the axis beneath. The vertical distances between the *A* curve of the original and that of the tracing at any point will be a measure of the voltage tending to cause current to flow through the lamps. Move the tracing along one-half a cycle, or a distance equal to that between 0 and 180. The maximum distance between the curves will then be twice the maximum hight of one curve, and since one machine gives 400 volts, the two machines connected as per Fig. 1 will give 800 volts, which will bring the eight 100-volt lamps to full brightness.

With the connections of Fig. 1, what was said about phase *A* will also apply to phase *B* in each case. Consequently, the lamps on both phases will glow and grow dark together. This is the test that shows that the machines are properly phased out.

Suppose that we have a case like that shown in Fig. 3, where by accident the phases are "crossed," that is, phase *B* of machine No. 1 is connected to phase *A* of machine No. 2, and phase *A* of machine No. 1 is connected to phase *B* of machine No. 2. In this case when the machines are running at normal voltage, the sets of lamps on the two phases will alternate in lighting up, the lamps on phase *A* being bright while those on phase *B* are dark, and vice versa.

By examining Fig. 4, the reader can

see just why this is. Fig. 4 represents the curves generated by the machines when the lamps on phase *B* of machine No. 1 (see Fig. 3) are dark. This is seen to be true since phase *B* of machine No. 1 is connected to phase *A* of machine No. 2, and curve *B* of machine No. 1 and curve *A* of machine No. 2 both reach their positive maximum values at the same instant, so that there will be no tendency for the current to flow through the lamps.

The switches on phase *B* of machine No. 1 could be closed under these conditions without injury to the apparatus, but this is not true of the switches on phase *A* of this machine. Again referring to Fig. 4 and remembering that the phases of each machine are one-quarter of a cycle apart, it is evident that phase *A* of machine No. 1 will reach its maximum one quarter of a cycle *ahead* of phase *B* of machine No. 1, and that phase *B* of machine No. 2 will reach its maximum one quarter cycle *behind* phase *A* of machine No. 2. In other words, phase *A* of machine No. 1 is one-half cycle ahead of phase *B* of machine No. 2. These phases being connected by means of the lamps, these lamps will be bright while the other lamps are dark, and the result of throwing the machines together at this time and with this connection would be to cause a heavy current to pass between these last named phases and might cause great damage.

How to Correct a Wrong Connection

Having discovered by means of the lamps that there is a wrong connection, the next thing is to decide how to correct it.

If it is desired simply to put the machines into operating condition without regard to the appearance of the connections, all that is required is to reverse the leads on either phase of one of the machines. It will then be found that the lamps will light up together, and the switches on both phases can be closed with safety.

A third case may occur from crossing the leads of one phase, as represented in Fig. 5, where the *B* phases are correctly connected, but the leads of phase *A*, machine No. 1, are "crossed" or reversed. In this case, just as in the previous case, the lamps will alternate in brightness.

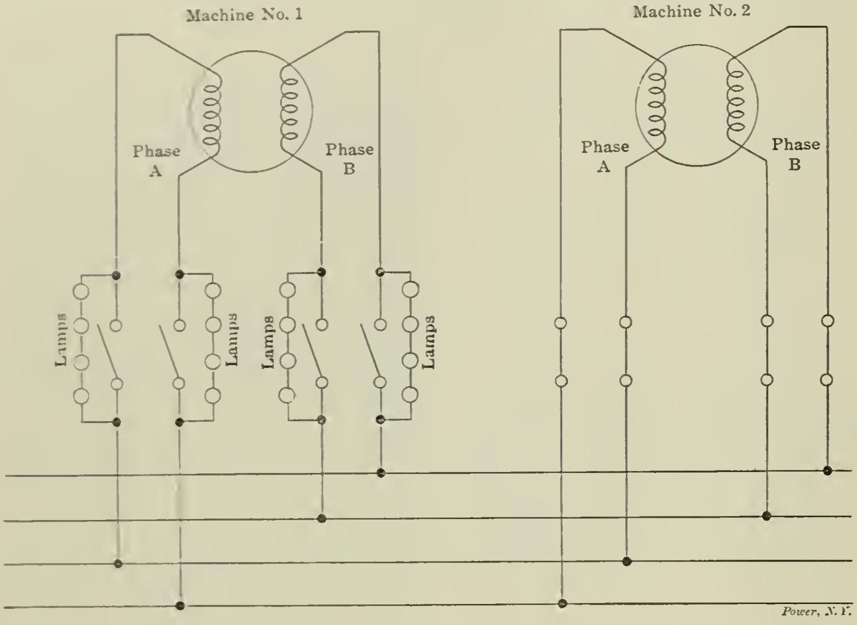

FIG. 5

The corresponding generator curves are drawn in Fig. 6. These curves show that when the *B* phases are in step, that is, they come to a positive maximum at the same instant, the *A* phases are in direct opposition, the *A* phase in machine No. 1 being at positive maximum and the *A* phase of machine No. 2 being at negative maximum simultaneously. The results of throwing the machines together with this connection will be just as disastrous as in the previous case. The correct thing to do, of course, is to reverse the leads of phase *A*, machine No. 1, although as far as operation is concerned the leads of phase *B*, machine No. 1, could be reversed instead, as may be proved from the curves in Fig. 6.

Where the operating voltage is below 400 or 500 volts, the method described of putting sets of lamps around the open switches will be found the simplest and most satisfactory.

Where the operating voltage is above 500 volts the direct method requires so many lamps that it becomes inconvenient and in such cases small transformers are used to "step down" the generator voltage to suit the lamps. The results with transformers are the same as with the direct method, but especial care must be exercised to make sure the connections are correct, because there are errors possible in using transformers that are impossible with the direct method.

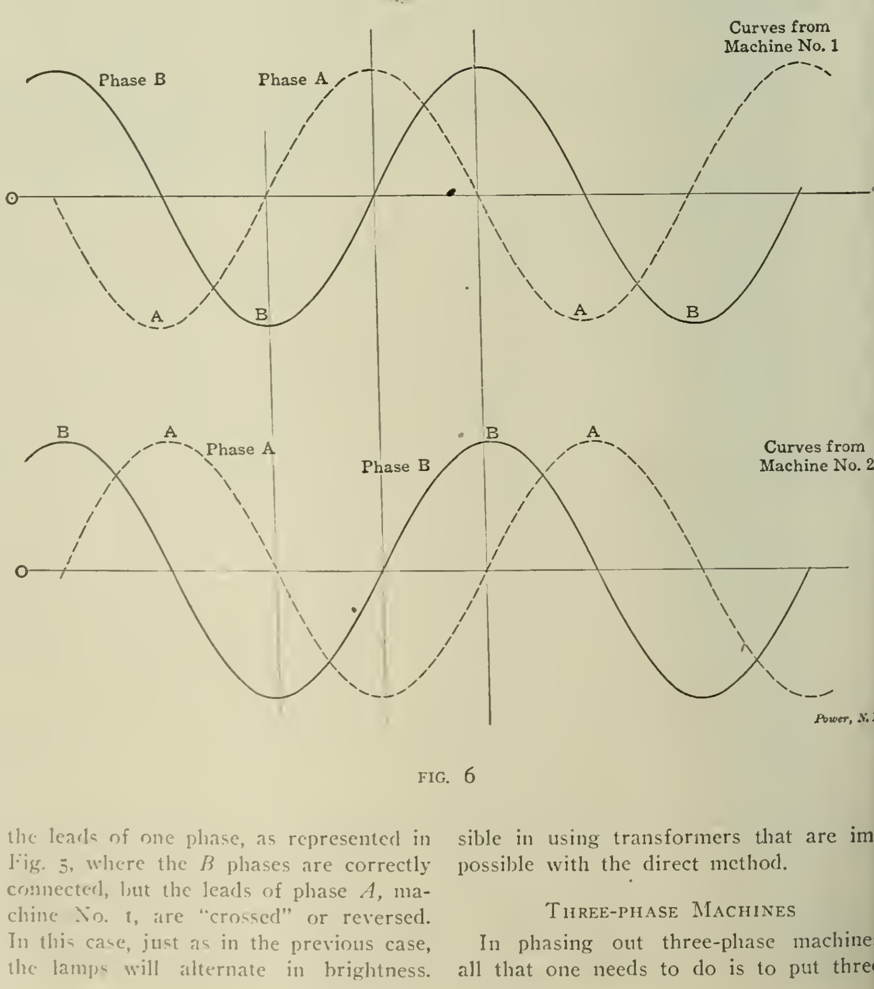

FIG. 6

Three-phase Machines

In phasing out three-phase machines all that one needs to do is to put three sets of lamps around the three open switches, or poles, of a three-pole switch, assuming, of course, that the direct method can be used. If the machine is properly phased out, all three sets of lamps will become bright at the same time. If not properly phased, the lamps will become bright at different moments, one set following another at regular intervals; in this case, if any two leads are reversed the machine will be properly phased.

Leather Belts for the Transmission of Power *

By Harrington Emerson

Leather is tough, elastic, strong, flexible and durable. Nothing has superseded it for the soles of shoes, nothing has superseded it for the uppers where real, not fancy, service is wanted. Rubber, although soft and tough, cannot compete. A good leather sole will outlast two sets of the best rubber heels, a good leather sole will outlast the hob nails with which it is studded. Canvas is not even thought of for soles. For durability in the rough service of a man's shoe, subjected to sopping wetness, to burning dryness, to cutting sharpness and to abrading grit, leather has held undisputed superiority over any other substance.

It is because of these inherent qualities that leather belting has been used for the transmission of power, and just as leather soles are more lasting than soles of either canvas or rubber or rawhide, so good leather belts are better than transmission belts of canvas or rubber or of rawhide.

Belts often have to run in damp or wet places. Before waterproofed leather belting was developed, leather belts deteriorated very rapidly under these conditions. Rubber belts by their very name gave promise of lasting longer, and they did last longer, but not as long as waterproofed leather belts last today.

The chief excuse for other substitutes for leather is that they are cheaper. If a leather belt which ought to last for twenty years is subjected to such wear and tear as to give out in a few weeks, it would be better to use a cheaper substitute, but in such a case it is preferable to improve conditions so that leather again becomes the cheaper. Hide from which leather is made even before tanning is one of the toughest substances in nature. The object of tanning is not to change the originally good qualities but to make them better. Both rubber and cotton are treated to give them qualities which they do not possess in their natural states. It is easy to test leather belting, for stretch and permanent set under load, for breaking strain, and ability to stand sharp bending. A knowledge of these will enable a belt repairer soon to become fairly expert as to quality. Similar tests cannot be applied to either cotton or rubber.

Leather belting is made from steer hides. Rubber comes from wholly different sources and its quality varies greatly; some contains as little as 1 per cent., other samples as much as 20 per cent. resin. The best grades of rubber come from Para, but there is no practical way of telling whether a sample of rubber is Para or not. Rubber is useless in its native state as it absorbs water and oxidizes. When mixed with sulphur at a temperature above 250 degrees Fahrenheit and below 300 degrees Fahrenheit a combination takes place which preserves the rubber and also increases its strength. After it has been vulcanized, as this process is called, 60 per cent. to 70 per cent. adulterant can be added. If natural rubber is overworked, if it is not properly vulcanized (each kind of rubber requiring different treatment), if it is adulterated with mineral oils, or if it is exposed to light, it deteriorates rapidly. Everyone knows that even the best Para rubber bands rot in a few years.

Recently, conveyer belting made of different materials was submitted to a sandblast test for 45 minutes and the loss of weight compared.

Considering best rubber belting as the unit:

Rubber	1
Balata	5
Woven cotton, 1st quality	5
Stitched cotton	8
Woven cotton, ordinary quality	12

The cotton belting wore out 5 to 12 times as rapidly as rubber belting, which in turn deteriorates much faster than leather belting.

Grease or oil will soon ruin any rubber belt, but a good oil enlivens a leather belt. Cotton belts are usually filled with oil, paraffin or other substances, the outside being coated with a waterproof pigment. When new they are fairly flexible but soon become as stiff as not to run true or straight. They are sensitive to atmospheric changes and require constant adjustment of the takeup to keep them at proper driving tension. The main claim for cotton belts is low first cost, but they should not be used for permanent installation.

Rubber belts are waterproof only when the cover is intact. If water reaches the duck through cuts or punctures in the cover, the duck absorbs water, causing the rubber to lose its hold, forming a blister which grows every time it passes over the pulley. The splicing of either rubber or cotton belts is always difficult.

Canvas is not as durable, is much less elastic, much harder to splice than leather belting. It is cheaper per foot, and if belting is to be neglected so that it is to be ruined in a few weeks or months, canvas belting would not cost as much, but if leather belting is properly cared for and maintained it will cost in the long run far less than canvas belting, which is peculiarly hard on shafting and bearings, owing to the variations of tension due to change of weather.

Rubber, if good, is much more expensive and deteriorates rapidly even if not used. There are modern waterproofing treatments which render leather belts capable of running continuously under water, so that even for installations of this kind leather belting can now be used.

The most highly efficient, reliable and cheapest power installations and transmissions with which the writer is acquainted are natural-gas engines with a leather-belt drive to main shafts, to countershafts and to machines. If in special cases there are serious practical operating objections to leather belting, other forms of transmission will have to be considered.

Because it did not require any high-class skill to install belting so that it would work somehow, most belting installations have been badly planned and badly installed. The makers of the earliest types of machine tools were also partly responsible for this. Not only was it cheaper to build a machine tool with light and narrow pulleys, but this feature was also a good talking point, as the very lightness of the pulleys and cones seemed to indicate that the machine tool would require very little power. If wide pulleys were made part of the machine, competitors at once claimed that this was because the machine was a power eater, and the argument had its effect. The consequence was that the pulleys were undersized and the belts were overloaded.

The sellers of highly accurate, carefully designed and carefully installed chain, rope and individual motor drives have not allowed the opportunity to escape to compare these modern transmissions with very inferior and out-of-date belting equipment. Because electric trolleys have replaced horse traction, because elevators moved by wire ropes have taken the place of stairs, because the modern automobile uses a chain drive, because high-speed steel has replaced carbon steel, conclusions have been fostered that all modern installations must be superior in the same degree to older methods. It is, however, not to be overlooked that recent years have brought about very great improvements in matters that were very old. Wheeled vehicles are very, very old, but both the bicycle and the automobile are wheeled vehicles. It is overlooked that the great efficiency engineer, F. W. Taylor, who discovered high-speed steels, then revolutionizing all modern shop methods and

---

*Abstract of paper presented to the Leather Belting Manufacturers' Association, February 1, 1909.

practices, also, after nine years of observation and study, laid down rules for proper installation, operation and maintenance of belting. ("Notes on Belting." F. W. Taylor, part of Vol. 15 of the *Transactions* of the A. S. M. E.

If any industrial plant does not recognize the importance of high-grade installations of all kinds, a constant care over them and best maintenance, if it is to be a slipshod, happy-go-lucky plant (many plants are of this character), then it is better to install belting and stick to it, as it will stand more ignorance, abuse and neglect than any other installation.

One of the fundamental peculiarities of leather belting is elasticity. If belting were not elastic, could not stretch, it would lose most of its value as a transmitter of power. It fills the same purpose between shaft and tool that a pneumatic tire does between road and automobile or bicycle. It absorbs shock that otherwise would cause smashing and breaking, but it does more than this. If the strain becomes too great, the belt either slips or in the worst case breaks. In either case repairs are promptly made with minimum expense.

The inclination to change length under load or when the weather changes is the cause of all the legitimate wear on belts; it is the main difficulty in the way of correct operation and maintenance. A great majority of belt installations do not admit of adjustable pulleys, adjustable shafts, nor tightener pulleys by which the belt tension can be regulated. In the shops of the Santa Fe Railroad a method has been evolved which permits tightening belts, which could not be made endless, with very little trouble and delay. When first put on the belt was cut 6 inches short, and a 6-inch piece was used to fill the gap. This insert was connected at both ends to the belt by rawhide lacing or spiral wire hinge. At the end of a few hours the 6-inch piece was taken out, returned to the belt room and a 5-inch piece inserted. This change required a very short time. At the end of a day a 4-inch piece replaced the 5 inch piece, and as the belt gradually lengthened, shorter and shorter insert pieces were put in, thus at all times adjusting the tension to climatic and service conditions.

The whole of correct belting operation can be summed up in a very few principles. There should be allowed 1080 feet per minute of double belt, 1 inch wide, per horsepower. The lowest initial tension should be used under which the belt will pull without slip.*

A tension of 35 pounds per inch of double belt exclusive of load is sufficient. The result will be that the creep of the belt should be a minimum and extend through a very small angle on the face of the pulley.

A belt runs to the driving pulley under tension and it runs off the driving pulley slack or under less tension. When under tension the belt stretches. When the tension is lessened it shortens. This shortening must take place on the face of the driving pulley. The stretch must take place on the face of the driven pulley. As a consequence the belt creeps against the direction of its running on the driving pulley and creeps in the direction of the running on the driven pulley.

If the load is heavy, the stretch is great and the creep is great. If the load is light the creep is small. If the hug of the belt to the pulley is close, the creep, whether great or little, is through a small angle. If the hug of belt to pulley is poor, the creep whether great or little is through a large angle.

To insure, therefore, a minimum creep through a small angle the load should be light and the hug close.

Oak-tanned and fulled belts last longer, cause fewer interruptions to manufacture, stretch more evenly, cost less per year of service, require tightening less often and give less trouble when first started than others.

The belt itself must unroll straight, and be of even quality and thickness throughout.

The less the normal load the more elastic the belt can be.

The number of lineal feet of double belt, 1 inch wide, passing around a pulley per minute, to transmit 1 horsepower is about 450 feet.

The belt speed for maximum economy is between 4000 to 4500 feet per minute, but for main-drive belts it can be considerably higher.

Leather belts are more durable and work more satisfactorily when made narrow and thick rather than wide and thin. The best plan is to use single leather belts on pulleys less than 12 inches in diameter, double belts on pulleys less than 20 inches in diameter and triple belts on pulleys less than 30 inches in diameter.

The ends of belts should be either spliced or cemented or be joined by removable insert pieces, which may be either laced with rawhide or united by spiral wire hinge with removable rawhide pin.

Belts which will not run by the hug of their own sag, as long driving belts, should be put on or retightened under a stretch of ½ to 1 inch per 10 feet of belt.

Belts should be kept clean, soft and pliable.

Belts should be continually inspected so as to repair weaknesses and prevent breakdowns.

Pulleys should be 25 per cent. wider than the belts running on them.

They should be very smooth, very slightly crowned, if at all, it being essential that the crowning be absolutely central; the pulleys must be perfectly round, run true and be in perfect alinement.

Belts of any width can be successfully shifted backward and forward on tight and loose pulleys. Belts running 6000 feet a minute and driving 300 horsepower, are daily shifted on tight and loose pulleys to throw lines of shafting in and out of use.

Shifting pulleys are preferable to cut-off couplings or friction clutch pulleys for throwing heavy lines of shafting in and out of use.

Old-time belt installations and many present ones suffer from two main faults —lack of convenient means of shortening or lengthening the belt, and too high a working load. As a consequence belts stretched rapidly were subjected to excessive creep, wore out rapidly and broke often.

To provide some means of taking up the recurring slack, all the poor methods of belt fastening came into use, the English overlap, brass studs, riveted hinges, claws, unnecessarily large holes for rawhide lacing. To prevent the excessive creep and slip, all sorts of belt dopes came into use, from powdered resin up, and the maintenance and care of the belts were generally intrusted to the mechanic in charge of the machine.

A perfectly clean, soft hand will not slip easily even on smooth glass or polished wood. Leather was once skin, and soft clean leather will not slip easily on a smooth, bright pulley surface.

A belt ought to slip if the strain is too great. Keep the load down by making the belt large enough, let the hug be close, and there will be very little creep, or slip or wear.

In most mill and machine-shop installations, leather belting will prove least expensive to install, least expensive to operate and least expensive to maintain.

For distant transmissions, half a mile and upward, where it is impossible to subdivide the prime mover, as from a waterfall, electric transmission is the cheapest, although, per horsepower to be transmitted, first cost is very high.

For medium distance, where the power can be subdivided or closely located as from one mill to another, or from a water power several hundred feet away to a mill, the choice will lie between rope, either wire or fiber and shaft drive.

For immediate transmission, whether from steam engines, gas or oil engine, or electric motor to mill and shop machinery, the combination of shafting and leather belts is the best.

*This rule is not applicable to heavy main-drive belts. "Kent's Pocket Book," page 882 gives the reason for this rule. The question is not how narrow a belt can be to transmit a given horsepower but how wide it must be to transmit the given horsepower with the minimum cost in time and worry and power for reliable operation. A single belt 1 inch wide running 550 feet per minute may transmit a horsepower without immediately breaking, but it will not do it as reliably nor economically as a double belt running 1000 feet per minute.

Reclaiming Coal from the Culm Pile

Description of the Operation of Washeries in the Anthracite Region, by Means of Which Immense Quantities of Fuel Are Recovered

BY WARREN O. ROGERS

FIG. 1. A ONE-HUNDRED-MILLION-TON CULM BANK

As early as ten years ago the question was asked: "Cannot some use be made of the large banks of culm and waste found at all the collieries through the anthracite regions of Pennsylvania?" Up to this time the question had been actively discussed by anthracite men and something had been done toward reclaiming the smaller sizes of coal that had been thrown away years before. At several places coal-washing and screening plants had been established to wash out the small coal, consisting largely of chestnut, pea, buckwheat and rice, to be used for steam purposes. This industry has grown until the original huge culm banks are fast disappearing and in a few years will be worked out.

Culm Piles and Washeries

There are two different types of culm pile. The original culm pile consists of slate, bone and waste coal which was thrown away during the period when there was no demand for the smaller sizes of coal for steam purposes. As the accumulation had been going on for about twenty years, it is not surprising that the culm piles reached enormous proportions and that thousands and thousands of tons of good, marketable coal was mixed in with the refuse and only awaited the ingenuity of man to place it in a marketable condition. The first separator or washery for this purpose was erected about 1890, and the work has so progressed that at present practically every anthracite mine is reclaiming its culm piles at a cost which nets a very good return for the time and money invested.

The second type of culm pile which is being made today consists of very fine particles of dust and dirt suitable only for the manufacture of briquets or for pulverizing, to be burnt in suitable furnaces for this kind of fuel.

It is claimed by those who know that during the early operation of coal mining less than 50 per cent. of the coal mined was marketed, this inefficiency being largely due to the crude methods used in mining and preparing the coal for shipment. In those days a different idea was held as to the coal areas than is held

FIG. 3. CONVEYERS AT THE TOP OF THE WASHERY

FIG. 2. CULM ELEVATOR TO WASHERY

today, some thinking that the mountains in the coal-bearing district were one huge mass of coal. With a supposedly unlimited amount of coal in sight, it is not strange that considerable careless waste took place, and those who have traveled through the anthracite region have had their attention attracted to huge culm piles, in the vicinity of the mine shafts, which are directly traceable to the early wasteful methods of mining.

The smallest coal marketable prior to 1866 was the nut size which would pass through a $1\frac{3}{8}$-inch mesh and over a screen with meshes 1 inch square. A year later pea coal was first prepared for the market and, it is said, was a means of saving 15 per cent. of the total amount of coal mined. Buckwheat coal was introduced in 1877 for steaming purposes, and rice, barley and culm were first shipped to market during that year.

One reason why the character of the culm pile is different today than formerly is because the small sizes of coal, which then went to the culm bank, are now sent to market; the percentages running about 10 per cent. for chestnut, 20 per cent. for pea, 30 per cent. for buckwheat, 25 per cent. for rice and 15 per cent. for barley. It is estimated that during the past eighteen or twenty years more than 4,000,000 tons of coal for use under boilers has been saved from culm piles, and it is estimated that there still remains in the culm piles 286,000,000 tons of small-sized coal.

A washery capable of treating 500 tons of coal per day will cost about $30,000, depending largely, of course, upon the kind of machinery installed. In many instances old collieries have used old breakers by transforming them into washeries, in which case the cost of remodeling them amounted to an insignificant sum.

FIG. 4. THE TWO-DECK SHAKING SCREEN

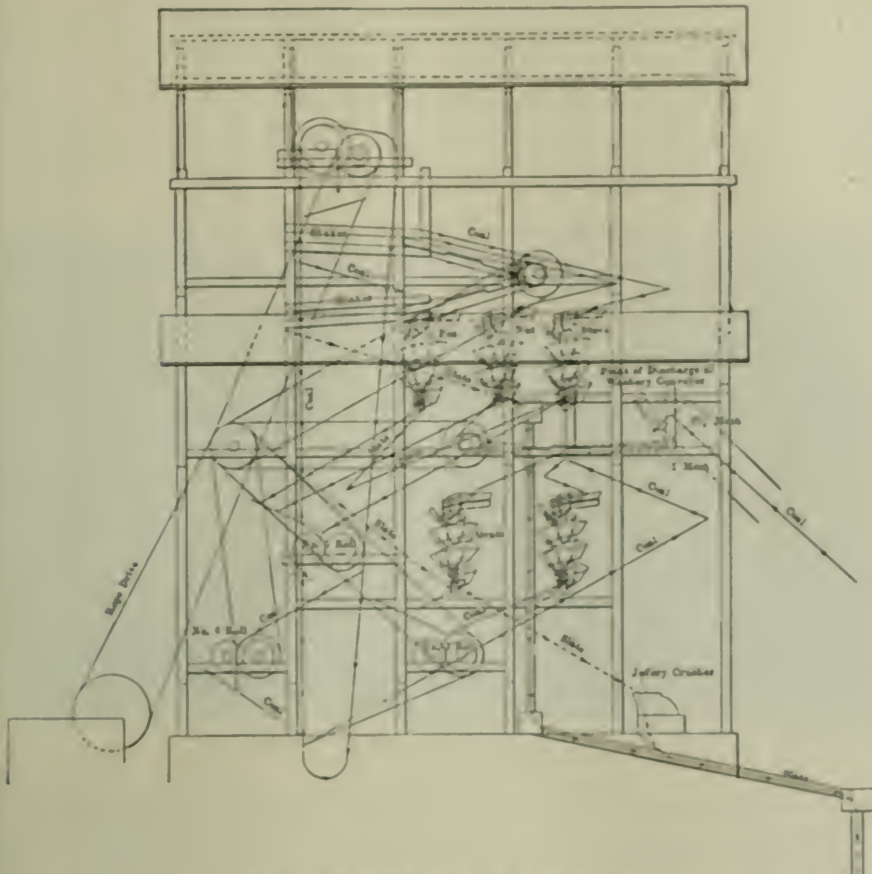

FIG. 5. ELEVATION OF NO. 2 WASHERY

Power, N.Y.

In washing the coal from the dirt, slate and bone of the culm pile the whole is usually elevated to the highest part of the building by a bucket elevator and discharged into a hopper placed over two screens, through which the material is separated into various sizes. The upper screen usually has 1½ inch openings for a part of its length and then the spaces become larger, while the lower screen contains ⅜-inch holes. In some of the older and larger washeries the material in passing over the first screen is dropped into a chute, where the usual method of hand picking of slate, by boys, is still observed. The largest sizes of coal, such as egg, stove and nut, are separated by means of screens. The chief machinery found in such a structure consists of screens, a picker roll, a crusher and the separators. In separating the culm from the coal, water is used in large quantities, it being estimated that approximately 500 gallons of water is required per ton of washed coal. After washing the silt from the coal, the water is usually conveyed through an iron pipe into abandoned mine workings, where it fills up the worked-out chambers.

Several methods are used in conveying culm to the washeries. In most instances the culm is flushed into a series of conveyers by water, the conveyers being from 100 to 300 feet long and placed in series, where more than two are used, one forming a permanent line to the washer and the other designed to allow for swinging or extending as the supply of culm in the pile recedes. A set of conveyers is usually operated by a separate engine. The general arrangement of a conveyer includes a wooden framework on which the conveyer runs, the conveyer consisting of an endless chain on which are suspended travelers which convey the culm from one end of the trough to the other, where it is delivered to the next conveyer, and so on, until it reaches the washery. The conveyers are fed with culm by means of water which flushes the material from the pile into the temporary trough. The water is supplied through a hose and nozzle and two men are sufficient to keep in continuous operation one of the conveyer systems, it being estimated that about 175 gallons of water per ton is necessary to do this work.

The Kingston Washery

It was the writer's privilege recently to visit the No. 2 washery of the Kingston Coal Company's mine, at Kingston, Penn., and following is a description of the method employed in washing the coal from the culm bank at this washery.

Fig. 1 is a sectional view of a tremendous culm pile in which it is estimated there are about one hundred million tons of material. It will be seen that there are two men engaged in washing the culm

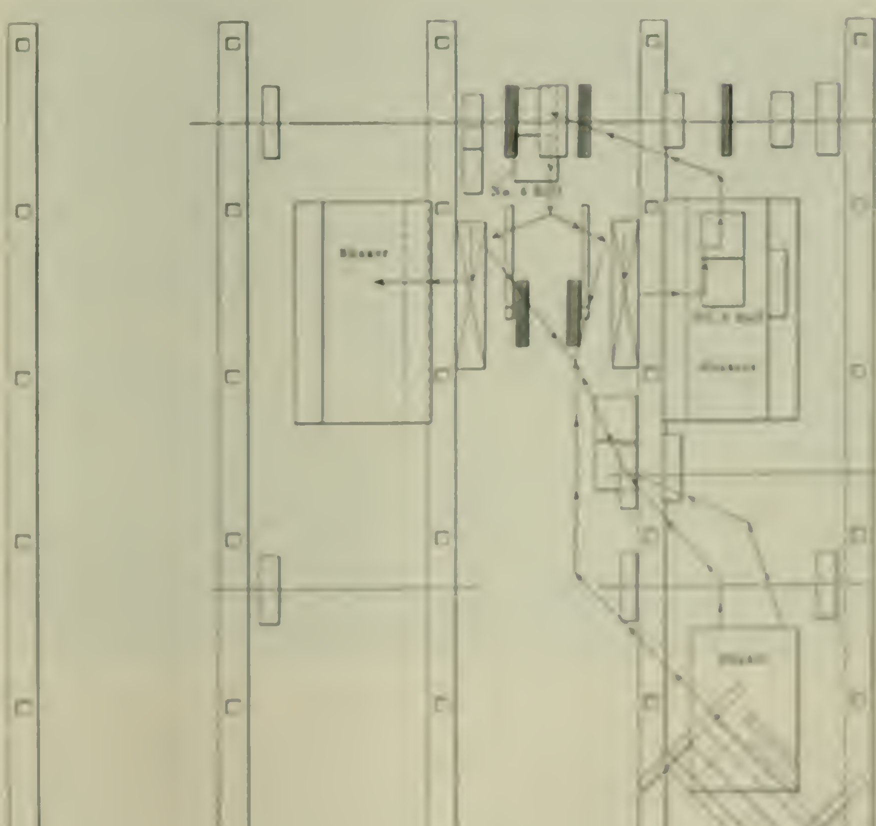

FIG. 6. PLAN VIEW OF NO. 2 WASHERY

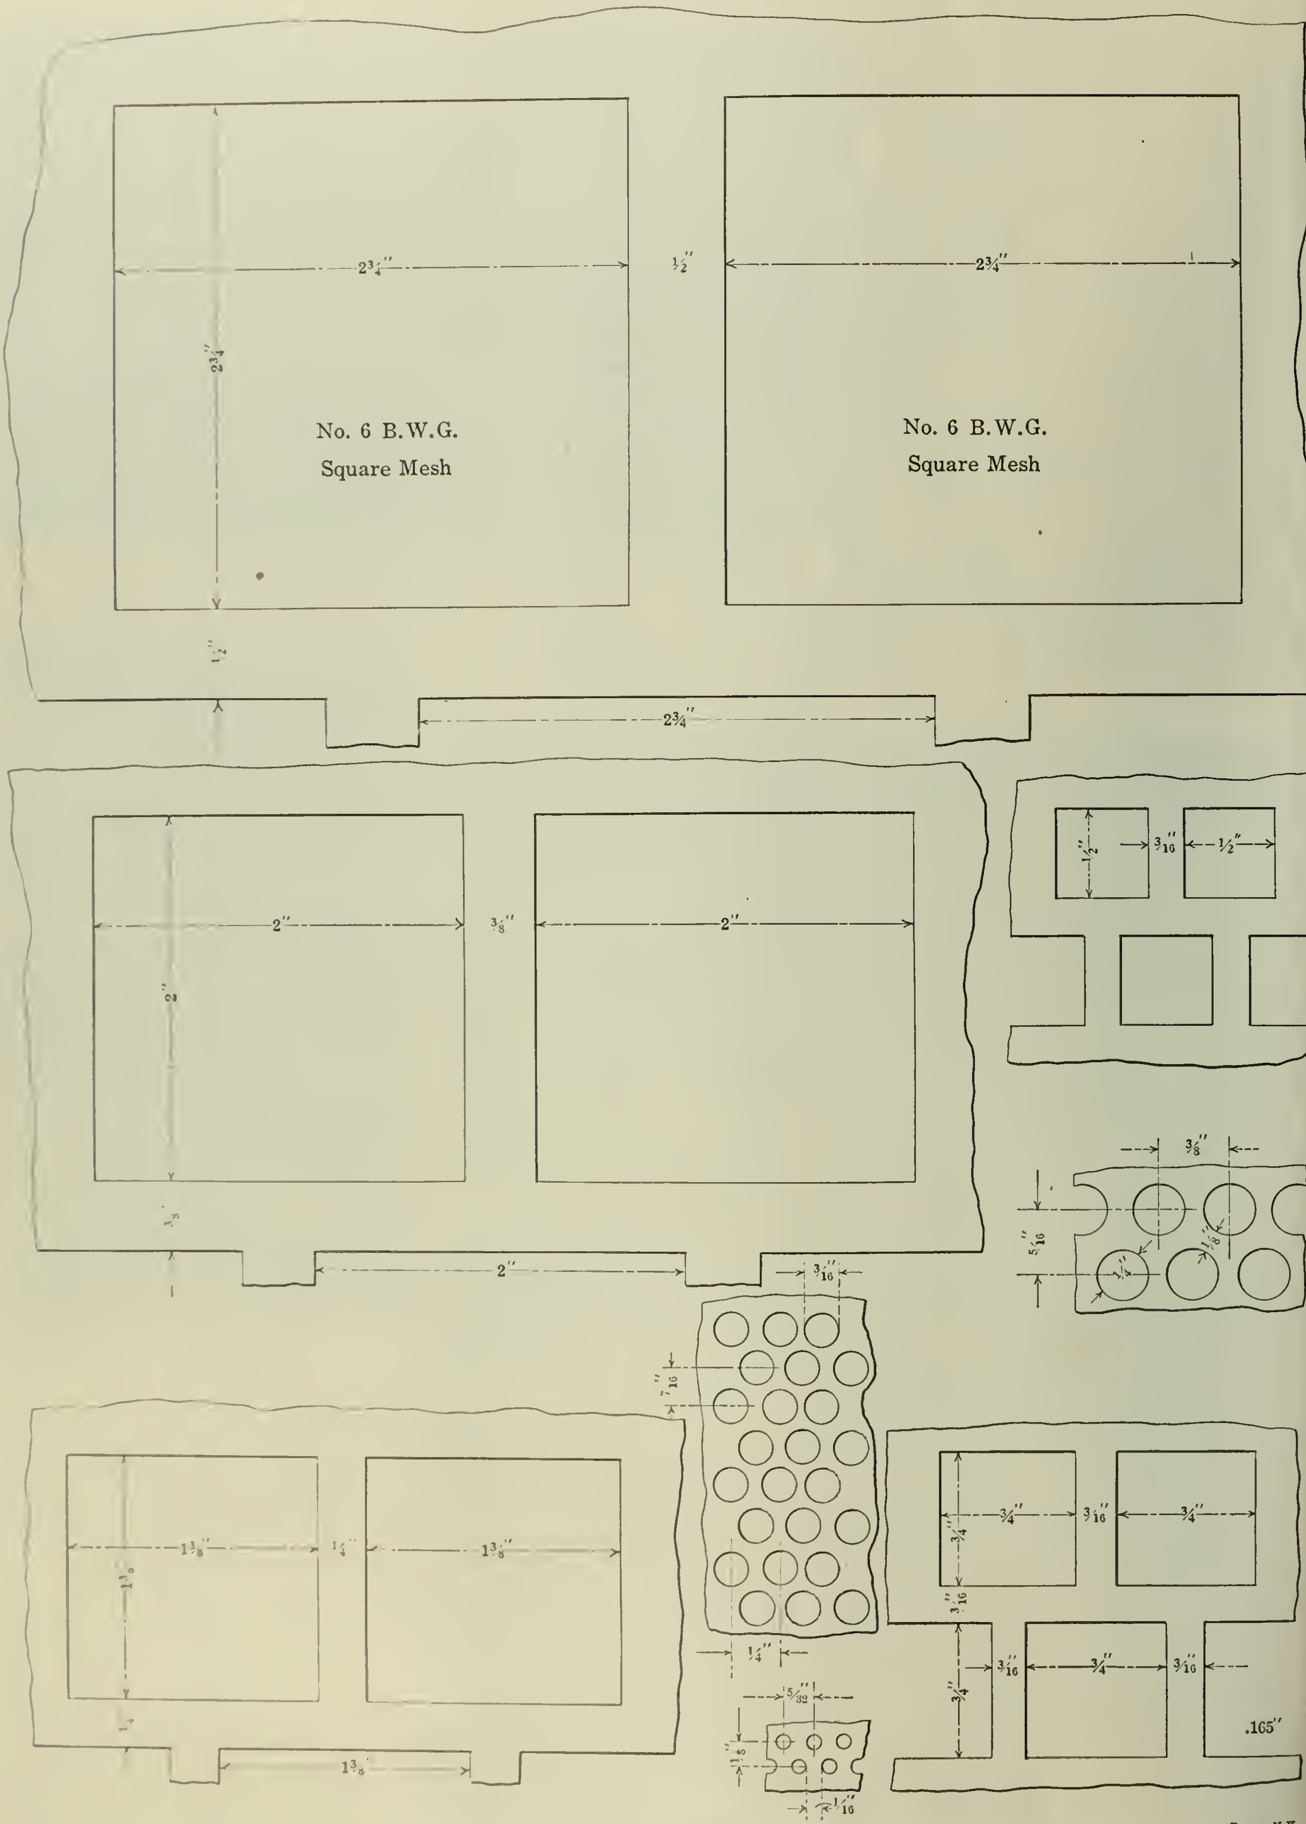

FIG. 7. ACTUAL SIZE OF SCREENS

down into the conveyer, one man reaching the highest portion of the pile, while the other directs the stream lower down, in order to maintain a constant supply to the conveyer system. The conveyers are kept as close to the foot of the bank as safety of the men will allow, as the bank frequently changes and slides out

FIG. 8. CRUSHING ROLLS

some distance at the bottom. Although there have been a number of men killed at different times and places, none has been injured at the Kingston company's works by being caught under the caving culm bank. It requires good judgment and care to keep the conveyers close enough to handle the culm economically and at the same time make it safe for the men who are handling the hose.

In this installation the conveyers carry the culm about half way to the top of the washery, as shown in Fig. 2, where it is discharged on a set of two-deck shaking screens, the top deck being jacketed with a 2½-inch square-mesh perforation. This carries over all pieces larger than egg-coal size. The bottom deck is jacketed with a 2-inch square mesh, which carries over the egg-coal size and drops through everything smaller, which goes to the main elevator, which in turn carries it to the top of the building by means of an elevator, Fig. 3, for further separation. The material which passes over the top deck is "grate" size, and larger, and is carried to a mechanical separator which takes out what coal there is in it, usually about 5 per cent. The balance, which is slate, goes to a Jeffrey swing-hammer crusher which pulverizes it, when it is carried away with the other refuse and silt to a bore hole and flushed into the old workings in the mine. The egg size is treated in the same manner. Fig. 4 shows a portion of the two-deck shaking screen, also the water used in washing the coal.

All of the large-sized coal taken out goes to No. 3 crushing rolls, Fig. 8, which grind it to stove size and smaller, whence it goes to the main elevator with the material which passes through the first set of shakers. The elevators each discharge on a bank of six decks of 6x15 foot shaking screens which size the coal into stove or 1¾-inch square mesh, chestnut or ¾ inch square mesh, pea or ½ inch square mesh, buckwheat or ¼-inch round mesh, rice or 1/8 inch round mesh and barley or 3/32 inch round mesh. A study of the plan and elevation of this washery, Figs. 5 and 6, will show clearly the paths

FIG. 9. SHAKING SCREEN FOR SMALLER SIZED COAL

of the culm and coal to their respective destinations, the path of the coal being shown by the direction of the arrows and that of the culm by the broken line. Fig. 7 shows the exact size of the various coal.

Stove and chestnut coal are handled in the same manner as the "grate" and egg, with the exception that the stove coal goes to a pair of crusher rolls similar to those shown in Fig. 8, which grind it to chestnut sizes, when it, with the chestnut from the separators, goes into another pair of rolls, No. 5, which grind it to pea and smaller sizes. The coal then goes to the elevator and is again taken to the top to be properly sized through the shaker shown in Fig. 9. All pea and buckwheat are put over mechanical separators which take out the slate and then go to the pocket ready to be loaded into railroad cars.

THE MECHANICAL PICKER AND THE SEPARATOR

In passing, it may be well to state that the mechanical pickers are fast displacing the breaker boys in the colliery breaker and many of the culm washeries. Although the breaker boy is a healthy-looking individual, as is apparent in Fig. 10, the indications are that he will soon be unnecessary for the economical operation of coal-mine breakers. The principal features of the mechanical picker are that no power is required to operate the machine; it requires but a small area of space, is lightweight and can be used on washed or dry material, giving three separate separations, that is, coal, bone and slate, or only two, coal and slate, as desired. It is also economical in first cost and in repair. The Farrel separator used by the Kingston Coal Company takes out the worst of the slate and rock of the larger sizes, and saves the good coal and bone to be ground into smaller sizes. On rice, pea and buckwheat coal the spiral separates the slate from the coal so as to make the coal clean enough for market.

Its operation is simple. The slate,

weighing more than the coal, has a greater friction, and therefore moves at a lesser speed than the coal. For this reason the coal works down through the separator at a higher velocity than the slate and, gaining sufficient momentum, flies off the outside edge of the runway, while the slate falls on the inside. The pea and buckwheat sizes are put over a mechanical separator which takes out the

FIG. 10. BREAKER BOY

slate in the same manner, and the coal then goes to the pocket ready to be loaded into railroad cars. The rice and barley coal goes direct from the shaker to the pocket, no preparation other than sizing being required. As the culm coal is thoroughly saturated with water during this process of separation while passing through the shakers, it comes out at the end ready for shipment in a thoroughly clean condition.

The washery foreman's troubles are not always ended when the coal is loaded in cars, because each car is subjected to a rigid inspection and, if not prepared to a fixed standard, must be dumped into elevators and taken back to the washery to be prepared over again. It must contain only a certain percentage of slate and bone; and it is also condemned if over or under size, or if not thoroughly washed.

Nothing of the culm pile is wasted and besides the benefit derived in reclaiming the coal by the washing industry, the surfaces are cleared of the unsightly culm piles and made available for other uses; and the flushing of the pulverized rock and silt into the old workings sustain their roofs, and also make it possible to remove more of the solid coal than could otherwise be done.

Throttles

By F. Webster

Wiley, the chief, went up into the switchboard gallery to do some stunts, and left Burns, the second engineer, at the throttle. It was not uncommon for them to have some entertainment when throwing in a 25-cycle three-phase unit to parallel the one that was getting overloaded. But the fun they had always experienced with the old engines was not a circumstance as compared with the "didoes" of the new cross-compound engine recently installed at the end of the power line farthest from the boiler room. Aside from the trouble of getting it right on the dot for synchronizing, it was often a case of either plunging or bucking after the start in parallel was made.

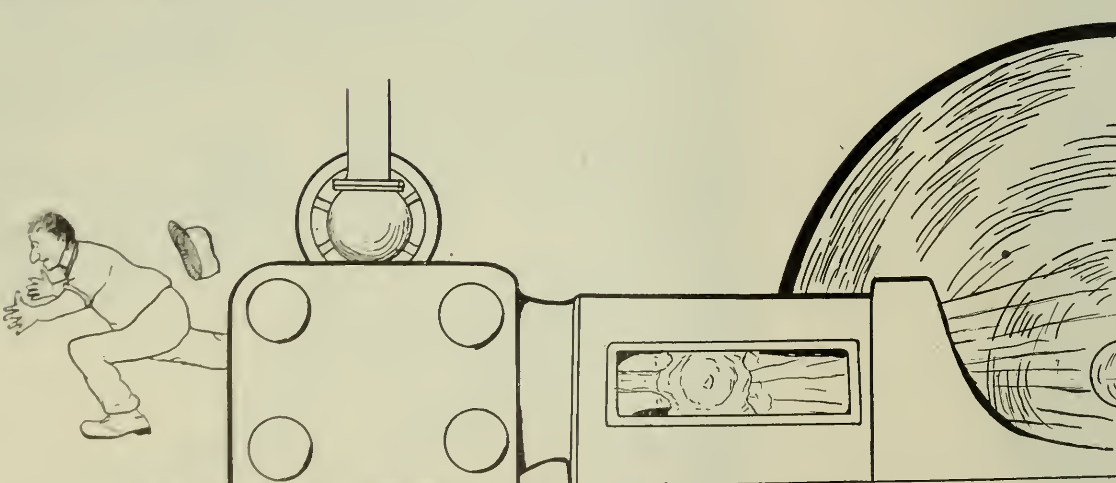
The engine acted very independent when it came to regulation, and neither coaxing nor argument had any effect in getting it to work in harmony with the other engines. Some of the station habitués said that the wild wail of the new generator-field cores made the engine daft. Those probably more capable of diagnosing engine diseases, however, believed that the eccentric straps and other reciprocating parts were so massive that the shaft governor was unable to drive the team at a steady gait. Sometimes the engine would plunge ahead and carry the whole station load, and then just as suddenly, maybe, take a notion to lie down and get pushed along as the generator motored.

In the meantime, before changes in the design of the eccentric straps and governor springs could be worked out and the new parts fitted, the big engine had to be operated a few hours each day; and our story opens on an occasion when all was in readiness for the testing out of the chief's new idea in engine regulation in connection with the synchronizing of three-phase 25-cycle generators.

Everything was running normally when some combination was made at the switchboard that caused the new engine to groan for a moment, and then it made a dash ahead at a record-breaking pace. No matter about the electrical connections that formed the combination for the shake-up, as the diagram will not be used again. There was a hair-raising clatter in the governor pulley as the parts concentric, eccentric and hyperbolic began to hit the stops, both a-coming and a-going. Burns let go of the throttle wheel and dropped into the condenser pit without touching the ladder. You see, the throttle wheel was located right in line with all the reciprocating and revolving combinations.

"Get back to your post!" yelled the chief.

"Stop chucking the engine, or else put the throttle where I won't get killed," piped Burns, as he stood on the ladder and peered over the edge of the floor.



"WHEN THE ENGINEER 'HIKES' FOR THE TALL TIMBER"

"All right, I'll stop," came from the switchboard; and as the engine seemed pacified, Burns went back to the throttle, but as cautiously as a rat making its first trip into the pantry.

Wiley came down from the gallery humming a Mother Goose melody with power-station variations.

"Oh, where should the throttle be,
The throttle be, the throttle be,

Oh, where should the throttle be-er
To save the life of the engin-e-er?"

Most any operating engineer can tell you of one or more of his experiences in the engine room—cases where he has been scared limp, and when he wished the throttle was located in a bomb-proof subway or over in some other voting precinct; anything in the world but to be compelled to stand up before belts or rope drives and that clacking aggregation on the engine shaft.

Illustrations have appeared frequently in POWER showing engine-room smashups in which flywheels and engineers were conspicuous by their absence.

SAFER IN THE BOILER ROOM THAN IN THE ENGINE ROOM

To most people, the statement may seem paradoxical that it is safer in the boiler room than in the engine room. Yet it is a fact that there is a greater loss ratio in the insurance of flywheels than there is on steam-boiler insurance. The applicant works out the boiler-seam problems with a flourish and gets a license to operate an engine. But how about the problem of the flywheel on his engine—its factor of safety against bursting or to prevent the arms from being ripped off the rim by a short-circuit?

This does not mean to imply that engineers are ignorant of flywheel theory, for they are not. For example, one enterprising engineer applied himself to the perfection of an engine safety stop that would be operated by the bulging effect of the flywheel rim between the arms when operating at a high speed. Surely this man knew what would happen, but he did not figure on furnishing a range finder and a field glass for observing the effectiveness of his invention.

The ancestors of steam-engine designers and of operating engineers came out of the same woods, yet the layout of some installations indicates a gap of several missing links between the two occupations. The designer becomes so absorbed in the weighty problems of first cost and of economy in operation that he fails to notice the spectacular gymnastics of the engineer as he leaps the loop on the flywheel to start the engine, or when he "takes" for the tall timber or the cave lands to escape a shower of power-house debris. It would be a joke were not the ending like that of a circus acrobat who dares perform without a net—six weeks in the hospital and two months on crutches.

A comparison of different makes of engine in the same service shows the throttle wheels located at all the cardinal points of the compass, with an occasional tendency on so-wester to spare. The location selected is often treated as a trivial matter worthy of only a few moments consideration, but for the engineer it is a lifetime.

There are branches of power-engineering service other than the power station where the convenience and safety of the operating engineer is not always considered, notwithstanding the fact that human life is more valuable than any kind of a power station. Recently a large order of switching locomotives was completed by a prominent builder. An examination of these locomotives showed that the engineer could neither stand nor sit except in positions of discomfort or danger, and more fatigue would be caused by his trying to get next to the work than in actually performing the running operations. If the history of these engines could be correctly written, no doubt it would be found that others besides the engineers were made to suffer on account of the poor work of the designer.

Cooling Gas Engine Jacket Water

By JOHN S. LEESE

As one of the chief reasons for installing gas engines instead of steam engines is often poor water supply at the desired locality, the repeated use of the circulating water is quite a live question. This applies especially to engines of small power, say up to 80 or 100 horsepower, since these are usually installed in out-of-the-way places.

The volume of the cooling water necessary for a 100-horsepower engine is considerable, and if it were simply run through to the sewer the water bill would be a large item in the running expenses. The usual provision for cooling the water so that it can be used again consists of tanks connected up so that thermo-siphon circulation can take place. These tanks take up considerable space and are often an eyesore to the neighborhood, and again they are often inadequate to cool the water sufficiently. The accompanying sketches illustrate a method of cooling jacket water, which is cheaper to install and gives less trouble in operation than any other method the writer knows of.

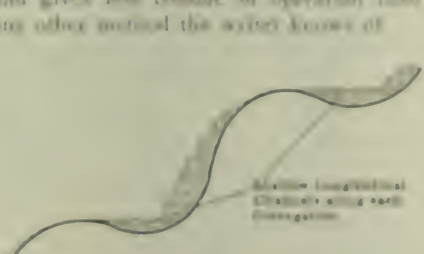


FIG. 2

In a corner of the yard, against a wall as near the engine room as possible (and, if possible, in a place where the sun never shines directly) put up a piece of ordinary corrugated iron, with not too shallow corrugations, as shown in Fig. 1. The slope should be determined by having it so that there is a longitudinal channel along each corrugation just sufficient to hold a shallow layer of water; this idea is indicated in Fig. 2. The object of these channels is further to cool the water as it flows down the sheet, by letting it flow into a channel full of cooler water at each corrugation.

The corrugated iron sheet must be kept as flat as possible to avoid the water flowing together toward a depression, thus lessening the cooling surface and reducing the efficiency. A good method of supporting it is to spike it to three stout timbers, as shown at A in Fig. 1. These timbers should stop about 9 inches from the bottom end of the sheet, which should be about 9 inches from the ground or floor level. The sides of the sheet should be bent up enough to prevent the water running off there, and the bottom corrugation should end with a downward curve or wave (Fig. 3), because if it ends with a level or upward part of the corrugation, the water will tend to creep round under the sheet, due to capillary action, and will not drop off in a square, clean sheet.

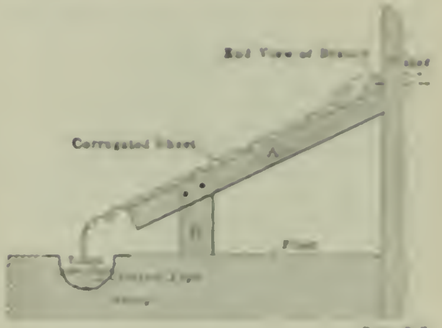

FIG. 1

A trough to receive the water at the floor or ground can be made in concrete or out of the old drain pipes. The trough should slope toward one end (that being more convenient to apply the outside pipe than the middle) and the water should drain into a sump where the pump suction intake is situated about 4 inches from the bottom. A strainer, made of brass-wire gauze wrapped around a perforated cylinder, should be used to keep extraneous matter out of the jackets. This completes the cooling plant.

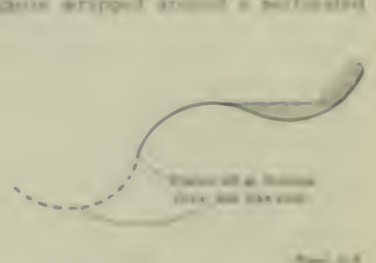

FIG. 3

If desired, the water can also be passed through a small storage tank, although if the cooler is designed properly for the engine horsepower and the jacket-water flow properly regulated, it is sufficient. I find that in a strong wind a piece of canvas suspended about 12 inches above the corrugated iron to shade it, and "doused" occasionally with a bucket of water, keeps the system in efficient condition.

As regards the feeding of the water onto the cooling surface, the outlet pipe is brought to a tee with the arms extending right and left along the top of the sheet

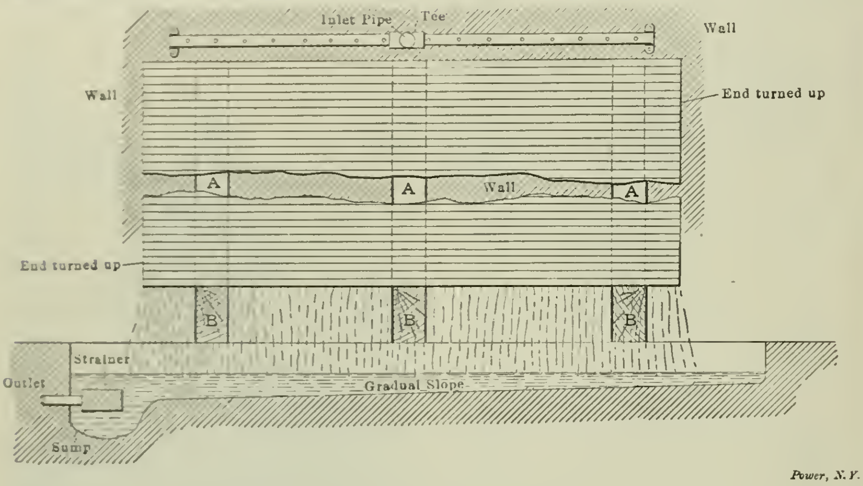

FIG. 4

an inch above the top. These arms are plugged at the ends and holes drilled in them with a total area equal to the area of the outlet pipe. This is shown in Fig. 4.

Catechism of Electricity

1066. *Illustrate and describe in detail the construction of the magnet poles.*

From Fig. 297, which shows one of the magnet poles before it is cast into the frame, it may be seen that the pole is built up of sheets (these are annealed steel) of two different widths *c* and *e*, assembled so as to form the size and shape of the pole pieces. The minute spaces between these laminations and the slight oxidization on the surface of each sheet tend to reduce eddy currents in the pole faces so as to decrease the iron loss and increase the efficiency of the machine.

The poles are slotted parallel with the shaft as shown at *n*, to prevent as far as possible the distortion of the magnetic field at heavy loads. The shape of the ends at *m* is such that when the molten metal is poured into the mold for the yoke, it grips the bases of the poles firmly and makes a good mechanical and magnetic joint.

1067. *Are direct-current generators ever built with more than two bearings?*

Large direct-current generators designed for belt drive are often built with three bearings. Fig. 298 shows a six-pole generator of this class built to supply current to a street railway system. It differs from the generator shown in Fig. 296 in that the bedplate, bearing pedestals and field magnet yoke are separate castings.

1068. *Illustrate and describe in detail the construction of the armature.*

Fig. 299 shows the armature partly wound; the core *a* is built of mild sheet-steel stampings which are japanned before assembling to reduce the eddy-current losses in the core. The armature-core disks are assembled under heavy pressure and held together by bolts passing through both halves of the armature spider, which are keyed to the shaft. Air ducts, *c*, extend from the inside up through the armature windings, and air is forced through them by the motion of the armature.

The armature coils are made of wire or bar copper, according to the capacity of the machine, the latter being employed when large currents are to be carried. These are form wound as shown at *s* to make all coils of the same shape. All coils are wrapped with linen tape, dipped in insulating varnish and baked. The slots of the armature core are also insulated as shown at *e* to afford additional protection to the coils. The coils are held at the ends of tinned-steel band wires beyond the ends of the core, where the cylindrical ribbed flanges *h* and *l* of the spider support the ends of the coils and secure ventilation around the ends of the coils from the interior of the core. Wooden wedges, in notched grooves in the slots below the surface of the core, hold the coils within the length of the core. The commutator segments *o* are assembled on a drum mounted on an extension of the armature hub. The segments are securely held on the drum by

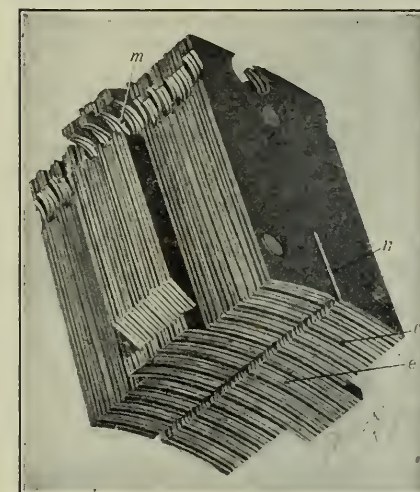

FIG. 297. LAMINATED POLE PIECE BEFORE BEING CAST-WELDED INTO THE FRAME OF THE FORT WAYNE GENERATOR, FIG. 296

end flanges at *b* and *r* which clamp over the beveled ends of the segments and draw them together.

Equalizer rings are placed between the commutator and the armature core and are connected to the armature winding at equipotential points as explained in a previous description.

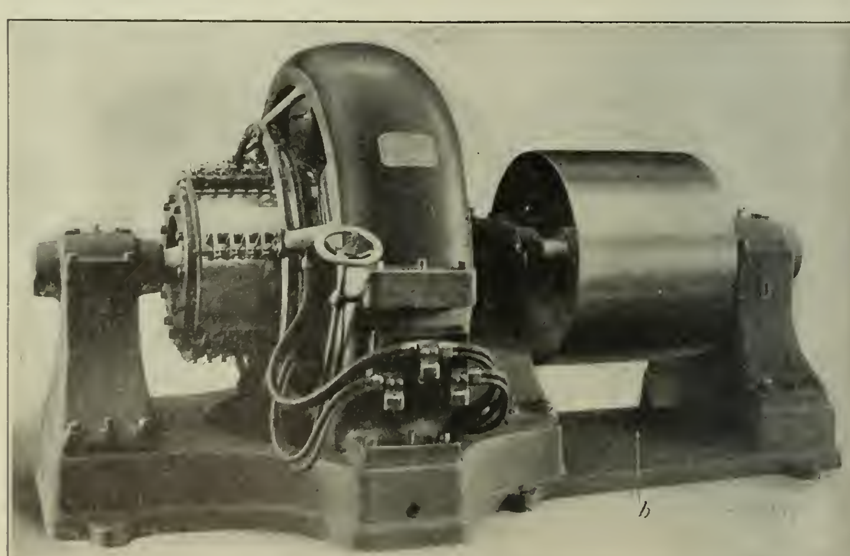

FIG. 298. FORT WAYNE THREE-BEARING MULTIPOLAR GENERATOR

1069. *Are solid field-magnet poles ever cast into the yoke?*

Yes; Fig. 300 shows the parts of a four-pole shunt-wound direct-current generator embodying this construction. The assembled machine is shown in Fig. 301.

1070. *Describe the construction of the generator shown in Figs. 300 and 301.*

The frame is of cast iron and the poles are of steel-circular in cross-section, and cast-welded into the frame. The armature core is built up of sheet-steel disks mounted directly on the shaft in the smaller sizes and on a cast-iron spider in the larger sizes. In both cases they are clamped together so that the pressure is applied near the slots. The coils are form-wound, taped and dipped in an insulating varnish; finally they are put in an oven to bake the varnish. There are longitudinal ventilating holes in both armature core and commutator, and through these, as well as between the commutator tails, air passes freely while the machine is in operation and assists in cooling the armature. The field-magnet coils are wound on circular forms, and are heavily insulated and protected by a tough, moisture-proof covering. They are held in place by pole-shoes fastened to the ends of the magnet poles.

The brushes slide in box holders and are pressed against the commutator by adjustable springs. The studs carrying the brush holders are attached to, but insulated from, a rocker arm by means of which all of the brushes may be shifted simultaneously around the commutator. The armature shaft is made of machinery steel, ground to size. It is made larger in the journals than in the projecting end, so that if worn or damaged from any cause the journal may be turned down without reducing its diameter below that of the projection. The leads from the field coils and brush holders are connected to the inner ends of brass studs which pass through the magnet at each side and are insulated therefrom by porcelain bushings. Although the dynamo selected for illustration is shunt-wound, this type of machine is also built either series or compound wound.

Pneumatic Oiling System

Herewith are an explanation and illustrations of an oiling system which is not advanced as anything new or original, except that the oil is all practically handled by compressed air, instead of by gravity feed or direct pump pressure.

Such a system has the advantage that the new oil in being drawn from barrels does not enter the power station at all, the barrels remaining outside of the building, as shown in Fig. 1. The vacuum in the oil tank is induced by the pipe running to a Conover independent condenser. There is no oil wasted nor spilled by this method. All filters, oil tanks, pumps, etc., are below the engine-room floor, where they can all be attended to by one attendant. There are no unsightly tanks on the wall of the engine room.

This system consists of five tanks, Fig. 2, arranged in a row; the first four receive the waste-oil drips from all the engines, which filter down through waste, and up through water in the bottom of the tank, flowing from the top of the water out into a header pipe common to the four filters, and discharging into a receptacle at the top of the tank *A*. This tank has five ½-inch pipes, with valves attached, arranged around the circumference of the receptacle at the bottom, and discharging through these into five wire-screen cylinders, closed at the bottom, and wrapped with toweling, through which all the oil filters.

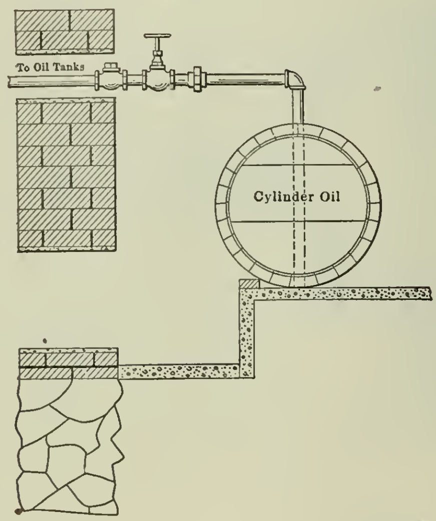

FIG. 1. METHOD OF GETTING OIL INTO STORAGE TANK

These cylinders are set on a perforated plate into which space the oil drips from the cylinders, through the toweling, and then runs through the suction pipe of the oil pump, which enters the bottom of the tank, and it is then pumped to the filtered oil-storage and feed tanks by the electrically driven pump.

These tanks have an air pressure of 15 pounds applied to the top of the oil. Enough oil is kept in the system to keep both tanks two-thirds full. An overflow pipe is attached to each tank two-thirds of the distance from the bottom, and these combine and discharge together through a safety valve into the filter tank *A*, as shown.

The pump is kept running continuously and if stopped for any cause, there is enough oil in the tanks to supply the engines for some three hours, the air pres-

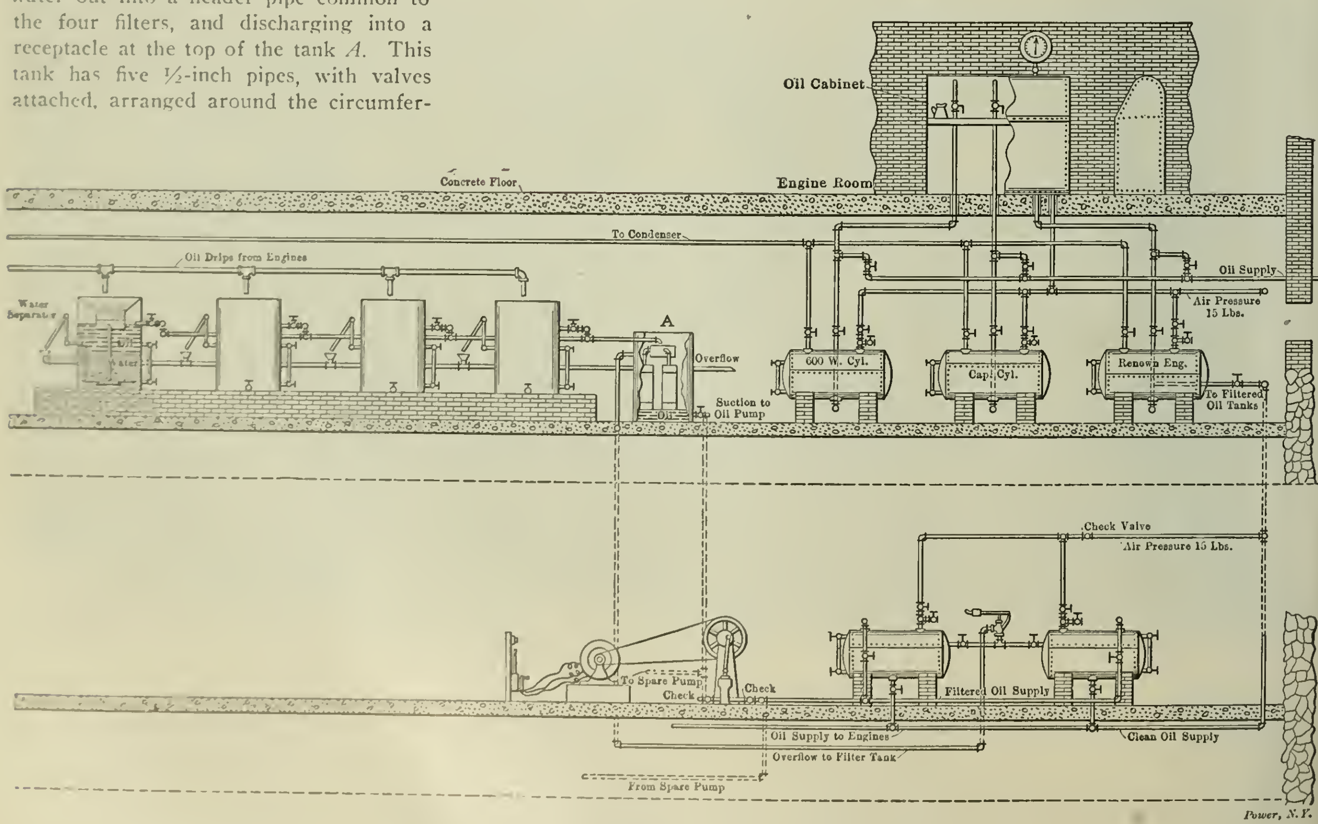

FIG. 2 LAYOUT OF PNEUMATIC OILING SYSTEM

sure supplying the necessary pressure to feed the oil.

When the pump is stopped, either by the circuit-breaker coming out or for any other reason, the handle of the motor-starting rheostat, in going to the off position, throws into circuit a red light which is placed in the engine room, thereby giving notice that the pump is off. The lamp continues to burn until the motor is again started.

We also have a spare pump attached to the end of the main shaft on the Conover condenser, which can be used as a spare pump.

To make up the natural loss of oil, and to keep the system at the required level, there is a pipe branching from the feed line on the new oil tank, through which new oil may be introduced into the filtered oil tanks by simply opening one valve.

New engine oil and two kinds of cylinder oil are drawn into three tanks arranged as shown in Fig. 2. The oil is drawn from barrels, outside of the engine room through a 1¼-inch pipe. The bungs are knocked out of the barrels and the pipe put in, the union made tight and a vacuum turned on. A barrel of engine oil will flow into the tank in about five minutes, cylinder oils take more time, depending on the temperature.

When there is sufficient oil in the tanks, as shown by the gages on the ends, the vacuum is shut off and an air pressure of 15 pounds is applied to the top of the oil and kept on at all times, except when filling the tanks.

Pipes from the bottom of the tanks lead to the oil cabinet in the engine room, and oil is measured out to the oilers from this cabinet and a record kept of it.

New engine oil is used on valve gears and in blowing-engine cylinders, and to make up loss in the filtered-oil systems; all other bearings are lubricated with filtered oil which is all returned to the filters from the drip pans of the engines.

A reducing valve on the high-pressure line reduces the pressure from 120 to 15 pounds. A safety valve is attached to the low-pressure line, in case the reducing valve should stick or leak.

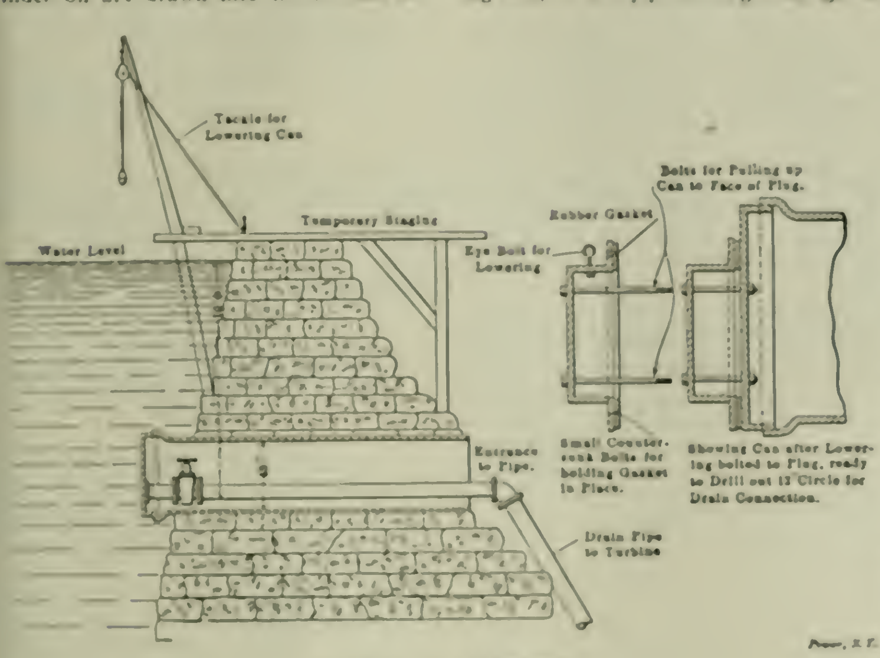
The installation operates very satisfactorily, and is a great saver of time, patience and oil and is reliable.

GEORGE L. FALLS.

Copperhill, Tenn.

Difficult Pipe Connection

The accompanying illustration shows an easy way of cutting a connection through the end of a plugged pipe that is under a head of water, without getting wet, if the pipe is large enough in diameter to permit a man to work inside. The case I refer to was a 48-inch cast-iron pipe.



DIFFICULT PIPE CONNECTION

I first made a water-tight can to conform with the diameter of the plug. I then put two drawbolts through the can to pull it up against the outside face of the plug, and bolted a soft rubber gasket to the flange face of the can with small countersunk bolts. Two holes were drilled through the plug in the end of the pipe, large enough to admit the bolts in the can, the center to be the same as the bolt center on the can. As the holes were drilled a soft wood plug was driven in each.

When both holes were complete a small ⅛" slot was cut along one side of a wood plug and a wire pushed out and fished up to the surface by a man on a platform overhanging the lake.

The can was slung in position for lowering and each wire fastened to its respective bolt.

When the can was near its proper position, the man inside the pipe guided the bolts into the holes with the aid of wire attached, and the can was bolted securely to the face of the plug.

A 12-inch circle was then cut out of the plug and a flange placed on it to which was attached a valve for shutting off at any future time when repairs would be needed on the drive line beyond.

The can was taken off after serving its purpose and the top cut out and a heavy screen put in to keep out fish and foreign matter, and then replaced in usual way.

This proved the simplest and best way after numerous suggestions by clever men. The water level in the lake could not be lowered to permit of work being done on the water side of the dam.

Montgomery, Ala.

Water Power

On page 686 of the April 13 number, Henry D. Jackson takes up the subject of water power and suggests the careful looking up of Government records for a long time. This must mean the record of rainfall.

This record is important, but there are other things that have a bearing on it that are not often enough taken into account, viz., the general nature of the soil and probable changes.

A country, or section, through which the stream passes that has a scrubby growth of trees that it pays to cut only for wood, and swamps that will not pay to drain, will have a good summer supply and not excessive in winter. This stream will last, as there is no probability of its ever being drained or any woodland destroyed for any length of time, as the roots will sprout and growth begin before erosion will take place.

Such a stream will need storage only for "lean years" and this will not be large. The "run off" on such a stream will be slow.

If we have a section made up of clay, rocks and woods consisting of large trees, with little undergrowth, we have the prospect of the trees being cut and a slow growth.

Clay and rocks do not hold water and a stream running through such a section will have extreme high and low water as the "run off" is rapid, and such a stream would need large storage capacity, as this storage would be called upon nearly every year. During the "lean years" the storage would have to supply the stream for six months.

A section made up chiefly of sand and gravel will be about midway between the foregoing, as, while there may not be many springs in such a section, the "run off" will be moderately slow, the soil having a fair capacity for retaining water. In looking up water powers, these considerations should enter into the account as well as cheap sites for storage. Storage is the important item, if the water proposition is to be a success. If possible, the dam site should be a gorge or narrow place so as to have a short dam.

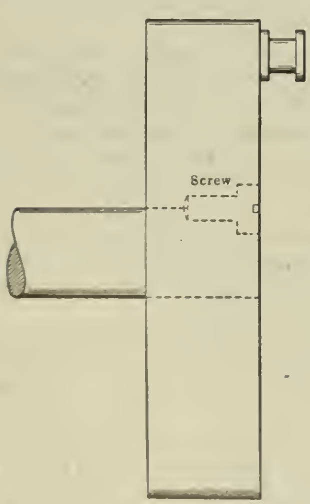
When we go through a drought, we claim that it is the worst that ever happened and the oldest inhabitant never saw anything like it. There will be more just like it, and if one goes into the water-power business he must provide for it.

W. E. Crane.

Broadalbin, N. Y.

Securing a Loose Crank Disk

In a recent issue I saw a method of repairing a loose crank disk by the use of tapered pins. I have a method which I have used in several cases that I think makes a better job. I drill and tap a hole, half in the disk and half in the shaft, the size varying according to the diameter of the shaft. Then I counterbore about ¼ inch deep and make a screw of tool steel with a slight amount of taper, enough to insure a tight fit, allowing the body to go in the counterbored hole so it may be finished nicely without showing.



SECURING A LOOSE CRANK DISK

For a stud I use a piece of stock about 7 or 8 inches long and screw it in with a pipe wrench as tight as it will go; I then saw it off, leaving just enough to rivet up.

I used this method in the case of a disk which worked off the shaft, and the engine is running yet and gives no trouble. The thread will hold the disk from slipping endwise.

Diagrams Explained

On page 686, of the April 13 number, C. K. Desai shows indicator diagrams and wants them explained. Diagrams like these can be obtained by tightening the drum spring and using a twisted cord that stretches. There are also braided cords that stretch too much for this purpose. The paper drum starts slowly and lags until some of the stretch is out, and its movement is never coincident with that of the piston.

W. E. Crane.

Air Receivers

Referring to the article on air receivers, by John B. Sperry, in the April 6 number, I note Mr. Sperry advises placing the outlet near the top of the air receiver. This was formerly the universal practice, but it is now being discarded to a considerable extent, as it is found more satisfactory to take the air at a point about one foot above the bottom. The advantage is that with a good sized receiver the air is fairly cool near the bottom, and if it contains much moisture on entering the receiver, it is found in practice that the air will be somewhat drier.

In air-drill work, mining, etc., we have found that there is somewhat less trouble from freezing where this plan is followed, and for the same reason vertical receivers are generally preferred where conditions will admit of their being installed to advantage. But as a general thing the air will be found to be a little cooler near the bottom of a vertical receiver than in a horizontal one.

G. A. Reichard.

Los Angeles, Cal.

In the April 6 number, John B. Sperry states that air compressors should be connected with the inlet at the bottom and the outlet at the top; with which I should like to take issue. I have made several experiments in that line and have convinced myself that the proper way to connect is with the inlet at the top and the outlet near the bottom.

The bottom opening of a receiver is always at least 6 inches from the bottom, so that there is no danger of drawing any water from it, and if the compressor is working at near its full capacity the top of the receiver will be very hot. It is my opinion that when the air is taken from the top it will contain a greater amount of moisture in suspension than at the bottom, while when taken from the bottom the air, being cooler, will have precipitated the greater part of it to the bottom. Even in wet weather and without draining the receiver for a week, I have never seen more than about enough water come out of the drain to cover the bottom of the receiver. Our pipe line always carries considerable dry air.

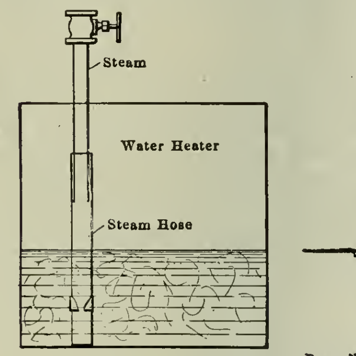
A Noiseless Water Heater

I have a noiseless water heater that is a good deal easier and quicker to make than any I have ever seen.

Take a piece of old steam hose 1½ or



A NOISELESS WATER HEATER

2 feet long and cut out about 6 inches from one end, as per the sketch, and stick the other end on the steam pipe.

Frank Gartmann.

Sheboygan, Wis.

Draining High Pressure Steam Lines

I read with much interest a letter by T. J. Bloss, in the February 9 number, and a later one by C. H. Beach, in the April 6 issue, regarding the drainage of high-pressure steam piping.

Mr. Bloss cited a case of a ¾-inch line piped direct from the boiler through 15 feet of horizontal pipe, then rising 96 feet vertically to a temporary bathroom.

As stated by Mr. Bloss, this vertical line stood full of cold water, except when a valve at the upper end of the line was opened, in which case the water backed down again into the boiler; the steam pressure carried was 100 pounds per square inch.

This ¾-inch pipe must have been trapped at some point in the horizontal line, which would account for the vertical line standing full of water when the upper valve is closed.

It would seem quite natural that any water of condensation which forms in a vertical steam pipe, where there is no flow, would tend to drain back to the boilers as fast as it forms, especially where the hight is as great as in the given case, unless the line were trapped. With 96 feet of water standing in a vertical pipe there would be exerted a pressure at its base of

$$0.434 \times 96 = 41.66$$

pounds per square inch. This water of condensation, even if formed into a solid column, should break up sufficiently to run down one side of the pipe while the steam rises on the other side to take its place, where it in turn is condensed.

If it is attempted to drain the water of condensation back against the steam flow, in large steam pipes, water hammer is almost sure to occur, or the water may collect until a "slug" is formed, which greatly reduces the area of the pipe, in which case a heavy flow of steam in the direction of the engines will very likely carry the "slug" of water over with it at high velocity, if not stopped by a separator.

Mr. Beach cites a case of a 75-horsepower Corliss engine connected to 200 feet of pipe with a separator placed just above the engine throttle valve. Still, in several instances, water has passed over in sufficient quantities to stall the engine.

The purpose of a separator is chiefly to prevent water going over in sufficient quantities with the steam flow to cause damage to the engine. If a separator passes a "slug" of water sufficient in quantity to stall an engine and throw it out of alinement it would seem that the so-called separator is not very efficient as a safety device.

There are separators on the market that not only separate or remove large "slugs" of water coming over with the steam flow, but they remove also a large percentage of the moisture held in suspension in the steam, which has a bad effect on the economy of the engine.

I agree with Mr. Beach that tapping a small pipe connection into the bottom of a line of pipe is a poor means of removing the condensation, as the flowing steam will undoubtedly sweep the water along with it past such a small opening. Drip pockets of large cubical capacity should be used, and may be placed in the steam line at the desired drainage points, and the water drained off by a trap or other suitable means.

When a steam header is divided into separate sections any one or more of which may be cut out of service, each section should be dripped, as the steam remaining in the dead section is bound to condense and should be well drained off before opening the dead section again to the live-steam pressure. This will prevent water hammer.

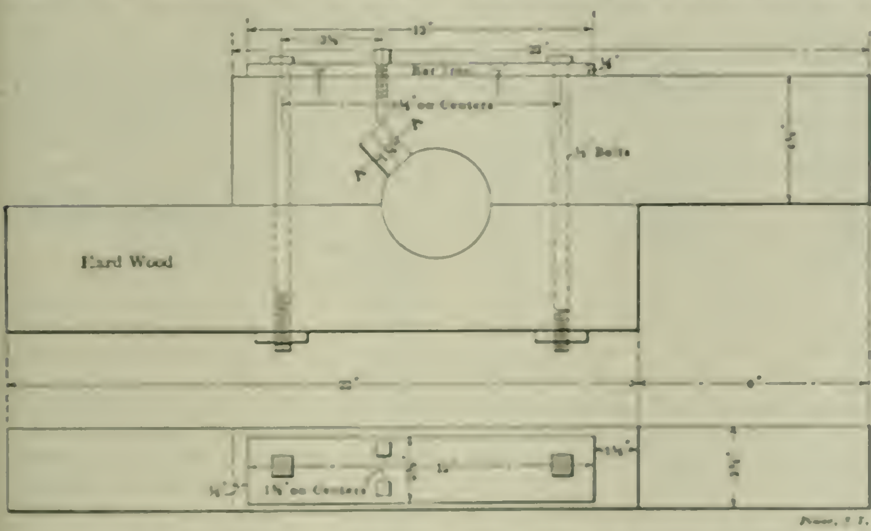
If all high-pressure drip lines are well covered with good-quality nonconductive pipe covering of proper thickness the condensing effect mentioned by Mr. Beach should not prove such a serious drawback.

WILLIAM F. FISCHER.

New York City.

Tool for Turning Pin on Center Crank Engine

The accompanying sketch illustrates a tool used to turn a crank pin on a center-crank engine. The pin was badly out of true, and to get the shaft out, and to the shop, meant a long hard job, so we made the following contrivance do the work.



SIDE ELEVATION AND PLAN VIEW OF APPARATUS FOR TURNING PIN ON CENTER-CRANK ENGINE

Two pieces of oak wood, 4½ inches wide and 3¼ inches thick by 2 feet 10 inches long, made parallel, were fastened together by two ½-inch bolts, a piece of ½-inch flat-iron stock being placed on the top with holes drilled for bolts and countersunk holes for wood screws to hold it. The rig was then taken to the shop and the hole made for the tool, the slot being wide enough to insert a wedge for holding the tool, which was made of common tool steel and flattened on the top to receive the set screw by which it was fed, as illustrated. The rig was first tried on a piece of stock known to be round and proved satisfactory. It was then bolted to the crank pin, and in two hours the pin was round. In making the tool, care must be taken to make a templet of the fillet of the pin to grind the tool by, and also to grind the tool on a very long bevel.

West Everett, Mass.

Gas Engine Valve Setting

Undoubtedly when Mr. Hellman wrote his article on the "Method of Setting Gas Engine Valves" he had no intention of creating the discussion that followed. He should be congratulated, however, upon awakening a few of the gas-engine men, for I do not think we hear from them as often as we should.

Gas-engine valve setting and ignition timing are largely matters of experience, but I think we will agree that the timing of ignition depends somewhat upon the size of the engine cylinders, the speed and fuel used. Herein lies the fact upon which I should base my criticism of preceding articles upon this subject (by Mr. Tilden, page 416, March 2, and Messrs. Burchman and Alegg, page 688, April 13), none of which was sufficiently explicit in giving these details.

It is evident that more time is required to burn the gases in a large cylinder than in a small one, and therefore it may be necessary to have the point of ignition earlier in the larger cylinder. In the same way, the speed of the engine will affect the point of ignition, for with the point of ignition the same, relative to crank angle, it is evident that more time is allowed before the crank passes the central position for the ignition of gases in a slow-speed than in a high-speed engine. The kind of fuel used is probably the most important factor, however. Some gases burn much more slowly than others. A mixture of producer gas, for instance, will not ignite as quickly as one of natural gas.

Regarding valve settings: When gas engines were first manufactured, it was the practice to have inlet and exhaust valves open and close when the crank was on the dead centers. Experience, however, taught that better results were obtainable by varying the valve settings considerably. By opening the exhaust valve 30 to 50 degrees earlier, the gases are allowed to expand nearly to atmospheric pressure before the piston commences the exhaust stroke. It is true that this arrangement sacrifices an appreciable area under the expansion curve, but at the same time back pressure on the exhaust stroke is avoided, and this more than compensates for the work lost on the expansion stroke. Another advantage is that less heat will be transferred to the cylinder walls by having this early opening of exhaust valves. The exact time of exhaust closure varies considerably in practice, but an average would probably be between 5 and 10 degrees past the inner center.

The time of opening of inlet valves also varies, some engineers having this event occur before the exhaust valve closes, while others defer it until afterward. The relation of this event to exhaust-valve closure depends upon the fuel burned. In the case of high-speed oil engines, where a comparatively large amount of the heavy hydrocarbons is found in the exhaust gases, the inlet valve is not opened usually until the exhaust valve has closed, in order to prevent back-firing. In cases where other fuels are used I do not think back-firing will be caused, generally, by having both inlet and exhaust valves open at the same time; for if this is a fact, why do not the exhaust gases contained in the clearance space ignite the incoming charge? Also, by having the inlet valve open before the exhaust valve closes, a more complete scavenging of the cylinder is effected.

The foregoing statement is verified by my own experience with three-cylinder single-acting natural-gas engines, which were rated at 360 horsepower, running at 200 revolutions per minute, with cylinders 18 inches in diameter by 22-inch stroke. The best results were obtained with the following timing of events: Ignition, about 24 degrees early; inlet valves opened about 10 degrees before the inner center; inlet valves closed about 30 degrees past the outer center; exhaust valves opened about 45 degrees before the outer center; exhaust valves closed about 10 degrees past the inner center.

The engines carried about three-quarter load and ran on an average fuel consumption of 21 cubic feet of gas per kilowatt-hour for six months, the gas having a heating value of from 950 to 1000 B.t.u. per cubic foot. Back-firing was very rare and never troublesome.

I regret that I have no data relative to other valve settings upon these engines and should like very much to hear from someone who has such data.

J. C. Parmely.

Urbana, Ill.

The communications from Messrs. Buschman and Abegg, set forth some ideas that fit the principles involved and some that, in my estimation, do not.

My letter, in reply to one from Mr. Hollman, reference to which is made, dealt with that type of gas engine used on standard automobiles, with which it is necessary to get right down to "brass tacks" or you don't make the hill on the high gear.

The point I aimed at was the definite necessity of getting a cylinder full of mixture to start with, and it has been my experience that closing the exhaust valve as nearly as possible on the dead center, is a prime requisite to that end.

If the correspondents named have found it necessary to release the expanding charge when the crank lacks some 40 degrees of having reached the end of the stroke, does it indicate that I have advanced a theory that won't hold water, or that the designer of these particular engines (wonder if they are both from the same shop) had peculiar ideas regarding the behavior of gases under pressure?

In considering the engine as a gas pump, the time of opening the exhaust valve has nothing to do with the question, provided the exhaust valve may be closed at the proper time; and Mr. Hollman's letter gave me the impression that the time of closing his exhaust depended on the time of opening it.

Regarding the theory that a column of air and gas will continue in motion after having been put in motion, due to its inertia, it is very easy to confuse the term "inertia" with that property of matter known as momentum.

No one will question that a column of gas and air has inertia, but I do dispute that it has momentum enough when in motion to overcome the resistance of mechanical friction. If the correspondents will spend some time with an indicator on a compound air compressor, where they will have an opportunity to experiment with gas at atmospheric pressure, with a spring to match that sort of work, and check their work by following it through the high-pressure cylinder, I think they will agree with me that while a column of gas at low pressure may be inert it won't "moment" for sour apples.

The last paragraph in Mr. Buschman's letter contains the statement that "the maximum explosion pressure is obtained when the volume of the mixture is the smallest, or in other words, the compression pressure is the highest at the instant the entire mass is ignited."

If the words "explosion" and "compression" were transposed the first proposition would be true, but the last would still lack something of full or exact truth, I believe. The burning of a charge of gas and air in an engine cylinder is not instantaneous as to time, but continues over an easily measurable portion of the crank-pin travel, and the time of the highest explosion pressure depends on the quality of the mixture, the amount of compression, the point of ignition and the speed of the engine. Varying any one of these elements will vary the time or point of the highest explosion pressure.

That part of gas-engine indicator diagram that connects the top of the compression curve with the commencement of the expansion line always has an inward slant, which is an index of the time consumed in burning the charge in the cylinder. If the burning of the charge was an instantaneous explosion, that line would obviously be perpendicular to the atmospheric line.

Mr. Abegg calls attention to two advantages resulting from releasing at 40 degrees ahead of the center, one of which is that the cylinder walls are cooled thereby, which "allows a more complete new charge." That is to say, he throws away part of his charge to facilitate acquiring a bigger charge than is needed for the next power stroke.

If the theory set forth, regarding the inertia of a column of gas in motion, was right, proof of that fact could be found by scrutinizing the exhaust line of an indicator diagram from a gas engine. The burned gases certainly leave the cylinder at a much higher velocity when first released by the opening exhaust valve than is possible when impelled by the comparatively slow-moving piston, and yet whoever heard of the piston being sucked out of the cylinder by the vacuum produced by the "inertia" of the outrushing column of burned gas?

Cost of Cleaning Boilers

The editorial entitled, "How Much Does It Cost to Clean Boilers?" is a step in the right direction. Power-plant owners and operators should know more than they do about what scale and impure water are costing them. They should keep a record of such costs, including all incidentals, and then at the end of the year they can tell how much they can afford to pay for some system of water treatment.

There is one statement, however, that may give rise to misconception. The editorial says: "How much better off would you be if you had absolutely pure feed water for your boilers, so pure that it would leave absolutely nothing behind it when it boiled away?" This is a commercial impossibility; at least, you cannot get such waters from natural supplies except by distilling, the cost of which would be, in most cases, prohibitive, even as compared with cleaning the boilers.

It is true that a condensing plant under certain conditions might afford to distill its make-up water, but even that is hardly probable. The distinction that is to be drawn is between water which forms scale in the boilers and water which does not, or at the most deposits only sludge, since boilers using the latter can be kept clean by regular blowing down with an occasional washing out with a hose.

Scale is responsible for most of the expense of boiler cleaning and maintenance, necessitating, as it does, the use of mechanical cleaners and causing frequent injuries to tubes, plates and seams through overheating.

By treating sulphates and carbonates you can keep the lime and magnesia out of the water, but a sodium or some similar highly soluble salt will pass on into the boiler and its accumulation there must be prevented by blowing down. At the same time, a certain amount of fine sludge will get through any practical form of filter, and the boilers should be blown down to remove this also.

The foregoing statement applies to every form of treatment, hot or cold, or boiler compound, that I know about, with the exception of barium carbonate, which is not in use in this country on account of its high price.

George H. Gibson.

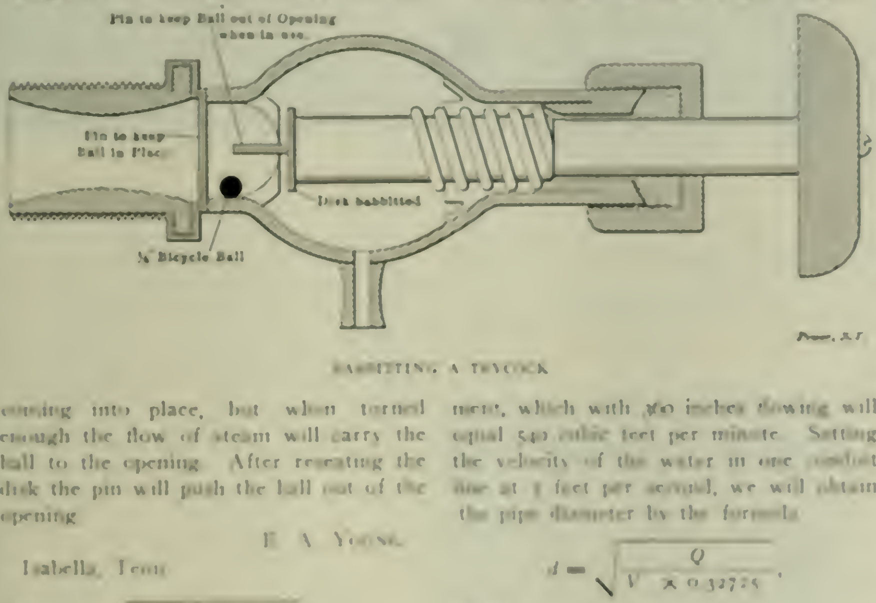
New York City.

Babbitting a Trycock

The accompanying sketch is of a trycock, and shows the way I fixed it so I could take the stem out and put in a new babbitt seat while steam was on the boiler.

I had but one boiler to run five miles of electric railroad and some lighting. We had to run 20 hours a day seven days a week, so we did not have any time to get steam off the boiler for repairs.

It will be noticed that the pin is long enough so that the cock can be opened enough to try the water without the ball coming into place, but when turned enough the flow of steam will carry the ball to the opening. After reseating the disk the pin will push the ball out of the opening.



BABBITTING A TRYCOCK

Trap Won't Work

On page 600 of the March 30 number, a steam trap is illustrated and explained by H. C. Williamson. In looking at the sketch, it appears that the arrangement shown will not operate. For instance, when the float rises on the rod until it hits the top stopper, then the trap is full of water, but as the float rises, lifting the rod with it, the bell crank will close the outlet valve instead of opening it, as should be the case. On the other hand, the outlet valve is opened by the float falling, which means that if it were possible the outlet valve would open only when the trap was empty and would close only when it was full. The cure would be to attach the bell crank to the inside of the trap on the opposite side from the outlet valve, which would reverse the movement of the outlet valve with relation to the movements of the float and thus render the trap operative.

Hydraulic Information

Mr. Piper does not state whether the 360 inches of water delivered is in cubic inches or in miner's inches. There is a great difference in the two terms and calculations made for one would be wholly wrong for the other.

The miner's inch is equal to 1.5 cubic feet of water flowing per minute (approximately), which would make the available power with a head of 140 feet, at 85 per cent. efficiency, about 120 horsepower when 360 inches is flowing. If we take it to mean 360 cubic inches discharge per second, which equals 12.5 cubic feet per minute, we will get with the 140 feet head, at 85 per cent. efficiency, about 2.8 horsepower.

We will take the miner's inch measurement, which with 360 inches flowing will equal 540 cubic feet per minute. Setting the velocity of the water in one conduit line at 3 feet per second, we will obtain the pipe diameter by the formula

$$d = \sqrt{\frac{Q}{V \times 0.32725}},$$

where

d = Diameter of pipe,

Q = Quantity of water discharged per minute,

V = Velocity of water in feet per second.

$$d = \sqrt{\frac{540}{3 \times 0.32725}} = \sqrt{550} = 23.45 +$$

inches. A 24-inch riveted steel pipe should be used, made of 12-gage material, which will weigh about 32 pounds per linear foot. This will give a velocity a trifle less than 3 feet per second, but the writer favors keeping the velocity low, and receiving full benefit of the low pipe friction. The loss by friction in this case is calculated by the formula

$$H = \frac{L}{d} \times \frac{4V^2 + 5V - 2}{1200} = 0.83 +$$

foot head loss, where

H = Head loss,

L = Length of pipe line,

d = Diameter of pipe,

V = Velocity of water flowing in feet per second.

This will give 139.17 feet of effective head.

A water wheel of the pelton impulse type, 6 feet in diameter, taking water with a spouting velocity of about 5600 feet per minute and operating at 150 revolutions per minute, should be installed if the dynamo is to be a belted machine. This would deliver approximately 115 horsepower which, after allowing for necessary losses, both mechanical and electrical, would easily supply one thousand two hundred 16-candlepower lamps of the carbon filament type, or about three thousand two hundred 20-candlepower tungsten lamps.

If the electrical distribution is to be over a large area an alternating-current generator of a suitable phase, cycle and voltage should be installed, but if the load is to be entirely local the low-voltage direct-current system will fill all requirements. The above speed of the wheel could be used only for a belted generator, as the cost of slow-speed electrical machinery is high, which would in this case very likely prohibit its use for direct coupling. If a direct-connected set is desired a higher-speeded wheel can be used, say, 600 revolutions per minute. A good speed regulator should be installed. This point is often overlooked, and results far from pleasing are obtained.

If this hydraulic development was for the smaller power mentioned, using 360 cubic inches of water per second or 12.5 cubic feet per minute, 4-inch iron pipe should be installed and an 18-inch pelton impulse-type wheel used, which will give about 2.5 horsepower, supplying thirty 16-candlepower lamps. If this smaller power was installed there would be no necessity for installing a regulator for the water wheel, the speed being governed by hand as required, or by a small motor connected with a voltage regulator.

Bennington, N. H.

Standard Pipe Fittings

The recent article regarding architects and "standard pipe fittings" brought to mind the following:

I was employed as a steamfitter in a certain building and an 11-inch pipe was specified. After writing all the leading supply houses, causing a two weeks' delay, we received word they were unable to furnish 11-inch fittings, so the architect was notified, and we were told to install 12-inch pipe, which increased the cost. I afterward figured the piping and was satisfied that a 10-inch pipe would have been amply large.

Vacuum Ash Conveyer at Armour Glue Works

An Installation Serving 4435 Boiler Horsepower Perfected by Experiment to Handle 7 Tons of Ash per Hour at Cost of 7 Cents per Ton

BY GEORGE B. HESS

The vacuum ash-conveying system at this works, which was perfected only after a great deal of experimentation, consists primarily of a positive blower, a storage tank and conveying pipes. The blower exhausts the air from the storage tank into which the ashes are drawn by suction through the pipes leading from the boiler ashpits. The closed storage tank has a capacity of 1640 cubic feet and is elevated about 33 feet above the level of the boiler-room floor. Just above the storage tank is a smaller tank about 7 feet high by 5 feet in diameter, designed to act as a settling chamber. The small tank is connected to the storage tank by a 12-inch pipe leading from the bottom directly into the storage tank and also by two 12-inch bypass pipes that lead from opposite sides and near the top of the chamber down into the storage tank. Leading out of the top of the settling chamber to the inlet side of the blower is a 22-inch galvanized-iron suction pipe and a similar pipe leads from the other side of the blower up into the smoke stack.

As there are two separate boiler rooms, there are also two separate ash-conveying pipes, one for each boiler room. These pipes, which are 10 inches in diameter extend the entire length of the boiler pits and discharge the ashes into the top of the storage tank. The elbow of each pipe, where it leads into the storage tank, is tapped for an ½-inch water pipe for settling the dust and cooling the ashes, and that part of the piping extending along the front of the boiler pits is provided with 6-inch holes on the upper side, the holes being placed at distances to correspond with the doors opening into the ashpit directly beneath the furnaces. When not in use, these holes are covered by caps with handles attached for convenience in handling. When it is desired to pull the ashes from the pit into the conveying pipes, a small portable hopper is used. This has been made with a 6-inch outlet and can readily be placed over any of the openings. The conveyer successfully handles an average of 47 tons of ash every 24 hours, during which time it is in operation only 6 hours and 45 minutes. An outline of the system and some details are shown in Fig. 1 and in Table 1 are given some data on the plant and ash-conveying system, for the perfection of which much credit is due to C. W. Brown, chief engineer of The Armour Glue Works.

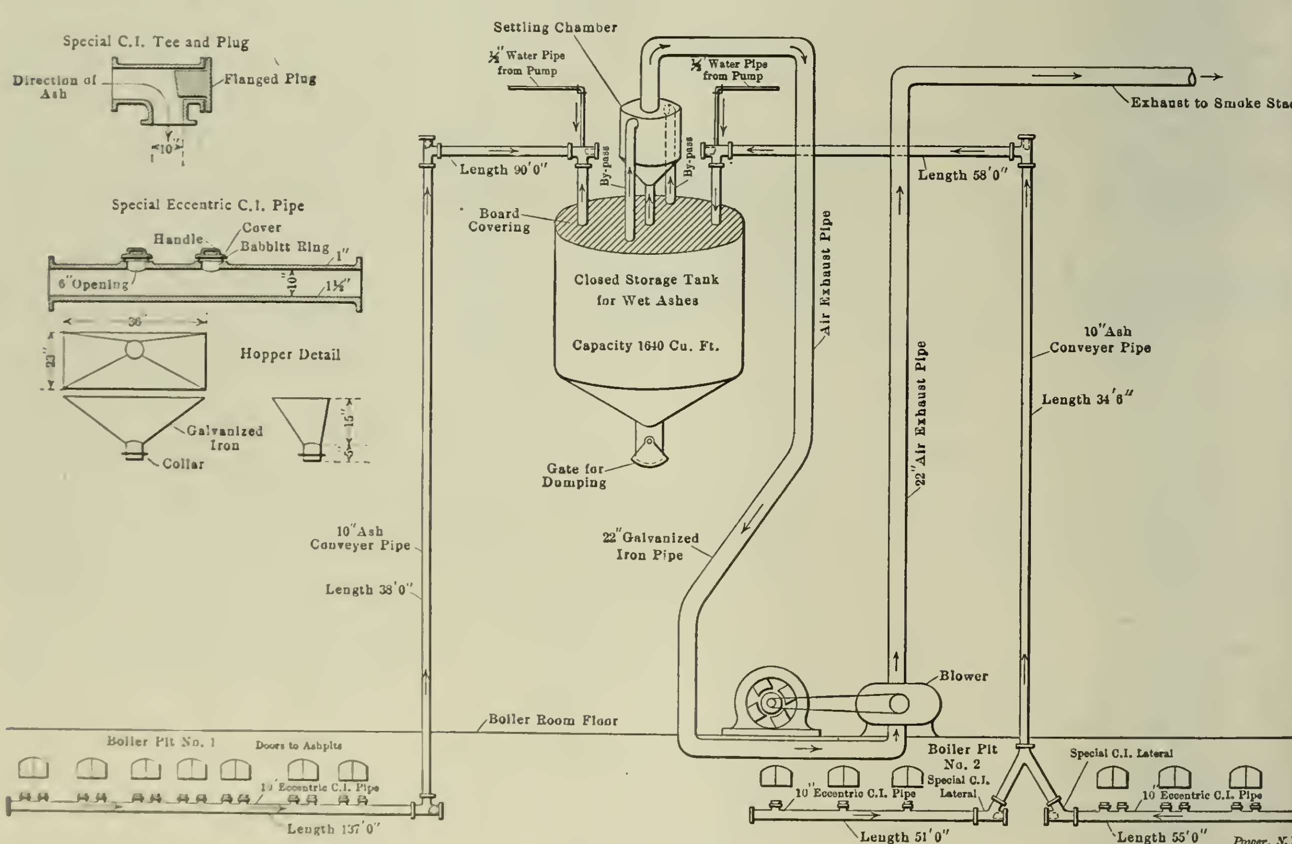

FIG. 1. OUTLINE OF VACUUM ASH-CONVEYING SYSTEM AND DETAIL OF PIPING

As the building of the conveyer was entirely along experimental lines, a successful application was hardly to be expected at the first attempt. The device, however, was installed along lines which it was thought would most nearly meet the requirements, but the result was a failure in almost every respect, and practically the only feature of the original installation which is now made use of is the application of the water in settling the dust and cooling the ashes. It will be necessary to go a little into detail in regard to the original apparatus, the difficulties that were met with and the methods of overcoming them in order to see just why the system has been arranged as it now is.

A Change of Blowers

The exhauster first used was not adapted to this work, and no end of trouble was experienced with this part of the apparatus. It was geared to a 75-horsepower motor, and this in itself was very unsatisfactory. The blower was not only incapable of meeting the demands made upon it, but it was constantly getting out of balance to an extent that might at any time prove serious, and in spite of all the attention that was given to it, the blower finally burst into hundreds of small pieces. The continual tendency to unbalance could be accounted for only in one way, and that was by the wearing away of the fan blades by the small particles of ash which were carried along in the air as it was exhausted from the system. The original blower was then replaced by a 24 [illegible] Root positive blower, Fig. 2, running at [illegible] revolutions per minute and driven by belt from the 75-horsepower 500-volt direct-current motor. This blower has been in service a little over one year and appears to successfully meet all requirements. It steadily maintains a vacuum of 2½ inches of mercury at the inlet side under all working conditions.

The Ash-storage Tank

Originally the large ash-storage tank, Fig. 3, was used only for the purpose of storing the ashes until they could be dumped into cars and was in no way connected with the exhauster. The present tank or settling chamber directly above the storage tank was designed to act as a cyclone produced by causing a violent whirling of the ashes around the inside of the chamber and permitting the heavier particles to drop to the bottom. The exhauster was connected with the top of the chamber and the two ash-conveying pipes led into opposite sides near the top where the two bypasses are now attached. As the ashes settled in this chamber they were allowed to pass out continuously through the 12-inch pipe extending from the cone-shaped bottom of the chamber into the storage tank. This had to be done without letting any air into the chamber, so a rotating valve, operated by a one-horsepower motor, was placed in the ash pipe below the cyclone chamber. This arrangement did serve to act as a seal to the cyclone chamber, yet it was not entirely satisfactory, as the conditions under which the motor had to operate were not such as to secure the best results, and the valve itself had to be repaired very frequently. For these reasons it was thought best to dispense entirely with the cyclone chamber and the rotating valve, if the desired results could possibly be obtained otherwise. A radical [illegible]

parture from the original scheme was now devised. The top of the storage tank was boarded over and the two ash-conveying pipes, which led into the sides of the cyclone chamber, were now led directly into the top of the storage tank and the cyclone chamber was made simply an enlarged section of the exhaust pipe. As the upper side of this chamber was connected to the exhauster by a 22-inch pipe and the lower side to the storage tank by a 12-inch pipe, it was evident that nothing was to be gained from the use of the large exhaust pipe unless the area of the opening in the storage tank was correspondingly as large. To offset this drawback two 12-inch bypass pipes were led from the openings in the chamber where the two conveying pipes previously entered, down into the top of the storage tank. This served to reduce the velocity of the air as it left the storage tank and the tendency of the particles of ash or dust as they passed through the old cyclone chamber, where there was a considerably lower velocity, was to settle and fall back into the storage tank. This is the present arrangement of what is now called the settling chamber.

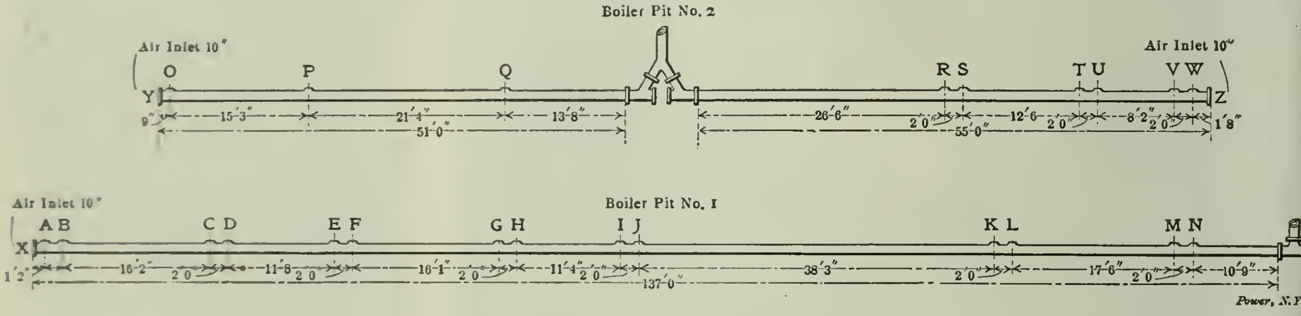

FIG. 5. DETAIL OF ASH-CONVEYING PIPES IN BOILER PITS

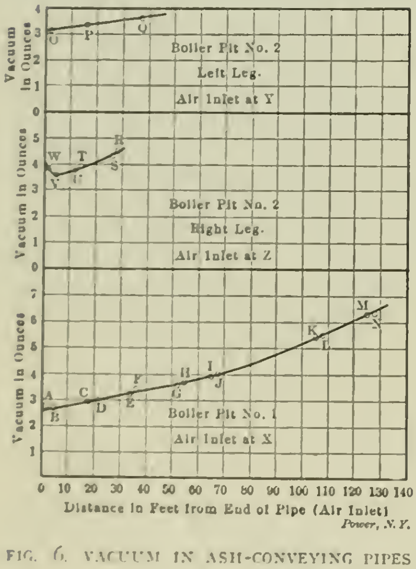

FIG. 6. VACUUM IN ASH-CONVEYING PIPES

Ash-conveyer Piping

The ash-conveying pipes, Figs. 4 and 5, which extend the entire length of the boiler pits and convey the ashes into the storage tank, were made first of 10-inch extra-heavy wrought-iron pipe with 6-inch holes spaced along the top in front of each ashpit. The proper construction of these pipes was a hard matter to decide without experimenting. It was thought that the ash in traveling through the horizontal legs would naturally hug the lower surface of the pipe, but prominent engineers who were consulted in regard to this matter advanced the theory that the air in passing through the pipe with a high velocity would acquire a whirling motion and this same motion would be imparted to the ashes, with the result that a uniform wear of the inner surface of the pipe would take place. Assuming that this theory was correct, the 10-inch extra-heavy wrought-iron pipe with a standard threaded coupling was put in place. It was but a short time before this arrangement showed decided wear. This was first noticeable at the couplings where the thickness of the pipe had been reduced by the cutting of the thread, and shortly after it was apparent that the bottom of the pipe was also affected in the same way. Sections of this pipe as fast as they wore out, were replaced by new pipe, but its life was so short that the wrought-iron pipe was discarded for another and more substantial one of cast iron with flanged joints. For the horizontal lines, where the greatest wear occurred at the bottom, a special eccentric cast-iron pipe was designed, having a thickness of metal of 1 inch on the upper side and 1½ inches on the lower side.

For those sections which were to be placed in front of the ashpits and in which it was necessary to provide openings for the hopper, a boss about 9 inches in diameter was cast at the top of the pipe. This boss, having a 6-inch hole in the center for the hopper, was faced to present a perfectly flat and smooth surface. The caps which were provided to cover these holes when not in use were simply flat circular castings with handles on top. The lower side of the cap was cast with a V-shaped groove about 7½ inches in diameter, which was afterward babbitted and machined, thus making a fairly good air-tight joint when in place on the boss. The areas of the hopper openings in the conveying pipes bear a definite relation to the area of the pipe itself, and this point cannot be overlooked in the construction of a conveyer of this kind. Several attempts to adapt this apparatus to other plants have resulted in failure simply because engineers have not realized the importance of this feature. The ratio of the area of the hopper opening to the area of the pipe, as determined by experiment, is practically 1 to 3. A ratio of 1 to 2.77 has been used in the case of the Armour conveyer with very good results. It is important also that the air inlet at the end of the conveying pipe shall be at the end of the pipe and not on the side. This opening should in no case be less than the full diameter of the pipe, and a bell-shaped opening would seem to be preferable to the flanged end of the pipe as it would permit of a higher velocity of the air at the inlet. That the size and shape of the inlet exert considerable influence over the action of the air at this point has been experimentally shown. For the present installation the vacuum in ounces at the various openings lettered in Fig. 5. are given in the curves of Fig. 6, and the velocity of the air for the various

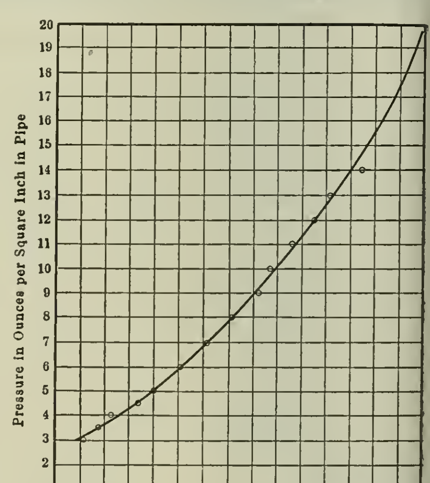

FIG. 7. PRESSURE-VELOCITY CURVE

pressures given may be determined from Fig. 7.

Special Tee Preferred to Elbow

Another difficulty that was overcome only after considerable experimenting was the construction of the elbows for these pipe lines, and as each conveyer pipe had practically three 90-degree elbows, all of which were subject to severe usage, it will be seen that this was a matter requiring early attention. The 10-inch standard wrought iron tee which was first tried was expected to form a sort of pocket, always retaining a certain amount of ash as long as the blower was in operation and thus protecting itself from wear, but no such results were obtained, and an elbow of long sweep was substituted in the hope that it might prove more satisfactory. The elbow did not give any better service and was thrown out to be replaced by a specially designed cast-iron tee and flanged plug. This tee was designed with one side of the run shorter than the other, and it was placed in the position of the old elbow with the longer side of the run attached to the ashpit side of the pipe. To the shorter side of the run of this tee was bolted the flanged plug of cast iron. The plug, which was of solid metal, 7 inches long, was slightly smaller than the inside diameter of the tee, and when placed in position with its flange bolted to the flange of the tee it extended about 1 inch beyond the neck of the outlet. With this arrangement practically all of the wear on the tee, except that which would normally take place in the straight pipe, was now received entirely by the plug inserted in the shorter side of the run.

Besides preventing excessive wear of the pipe, this type of tee also assists in breaking up clinkers. In drawing ashes into the hoppers on the conveying pipe, clinkers almost as large as the 6-inch opening often fall into the pipe. The velocity of the air in the pipe is always sufficient to carry along these large clinkers until they strike the vertical leg, or the point at which the tee and flanged plug are located. By the time these clinkers have reached this point they have acquired considerable momentum and in striking the flanged plug are broken into many small pieces. As the ashes on their way to the storage tank are required to pass through three of these tees, it is evident that by the time they reach the storage tank they will be in a finely divided state. The condition of the ash as drawn from the storage tank is sufficient to prove that this is what actually does happen.

So far as protecting the pipe from wear was concerned this proved to be an ideal arrangement, but whatever effect it produced upon the action of the air due to the increased friction has not yet been determined. The tee undoubtedly offers greater resistance to the air than a long-sweep elbow would, but when the small number of these elbows and the capacity of the apparatus are considered, it appears to be a matter of only minor importance. Frequent inspection of these plugs show that they wear away quite rapidly, while the tee itself shows comparatively little wear. When worn out, it is a simple matter to replace the plugs at slight expense.

For packing the flanged joints of the pipe line, a piece of 1/2-inch asbestos having a diameter slightly less than that of the bolt hole circle was used instead of any of the ordinary packing materials. Small pressure was applied to these joints by the flange bolts, and while the blower was in operation a heavy paint was poured between the flanges. The suction created by the blower drew this paint into any crevices which might have remained after the bolts had been tightened and it soon hardened there, leaving a perfectly air-tight joint at small expense.

Reinforced Concrete for Storage Tank

The original storage tank is still in service, but chemical action caused by the mixture of the ash and water has eaten away the steel until in places nothing but a very thin piece of metal remains. One drawback to a riveted tank of this kind is that the wet ashes are constantly adhering to the joints and rivets, especially to the latter, and they gradually pile up to such an extent that it is necessary to send a man inside to knock them off with a sledge. It will be necessary to replace this tank in the near future, and it is probable that a reinforced-concrete or at least a cement-lined tank, and one having no corners nor projections on the inside, will be substituted in place of steel.

System Cheapens Ash Removal

Application of this conveying system to power plants is dependent upon several factors, of which the first and most important is the coal, with the amount and character of the ash produced. The coal used in connection with the conveyer just described is the ordinary run of Illinois screenings; the ash produced averages practically 20 per cent. of the total coal and the clinkers formed seldom exceed 6 to 8 inches in diameter, and these are of such a nature that they can be easily broken up when pulled into the hopper. With a coal forming a large, hard clinker some means would have to be provided for breaking up the clinker to a size adapted to the openings in the conveying pipe.

The second and next important factor would be the cost of installation, and this should not be considered only from the standpoint of first cost and maintenance, but should take into consideration the yearly saving effected. That the latter is the deciding factor, especially in large plants, has been proved in the case of the conveyer under discussion by actual results, the saving in cost of the yearly disposal of ash amounting to about 55 per cent. of that of the preceding year when the conveyer was not in use.

For each separate power station there will naturally be some obstacles to be overcome, peculiar to that station itself, but there seems to be no reason, however, why this system could not be adapted to fit the conditions, providing that the ash does not form too large a clinker.

If this type of conveyer is so well adapted to the economical handling of ash, the question naturally arises, why should it not be just as well suited to the handling of coal or other materials of a similar nature? A conveyer of this kind has recently been built for the handling of coal, but either because of the nature of the coal or improper design, the device has not produced the excellent results expected of it. This probably can be accounted for by the fact that coal contains a large percentage of moisture which would cause it to stick to the inner surface of the conveying pipe, where it would quickly build up to such an extent as to completely clog the pipe. It would then be necessary to shut down the blower and rod out the pipe before operation could be resumed. It is self-evident that under these conditions no economy can be expected when the whole outfit should require no more than one man to operate it.

International Association for the Prevention of Smoke

The program for the fourth annual convention of the International Association for the Prevention of Smoke, to be held in Syracuse, N. Y., June 23, 24 and 25, is practically complete. The speakers include Dr. Thomas Darlington, health officer, New York City; Prof. H. M. Wilson, chief engineer United States Geological Survey; Paul P. Bird, chief smoke inspector, Chicago; L. M. Booth, D. T. Randall, D. Raymond Cobb, Prof. J. R. Fackler Jr., Syracuse University; O. M. Dean, of New York, and others. The idea has been to make the program short and leave time for the thorough discussion of each paper.

A theater party, an afternoon at the greatest fishing grounds in New York, with a dinner to follow it, are some of the things that are down on the program. The headquarters will be at the Vanderbilt hotel.

At the monthly meeting of the Polytechnic Institute (Brooklyn) student section of the A. S. M. E., held Saturday evening, June 5, James A. Nelson spoke on "Hydraulic Machinery," the lecture being illustrated with stereopticon views.

A New Transmission Dynamometer*

A Compact, Rigid, Coupling-like Instrument That Can Be Used for Either Rotation of the Shaft and Can Be Read at a Distance

BY WM. H. KENERSON

I have received from time to time many requests for a simple transmission dynamometer, and have often felt the need of one which would be more generally applicable than those now in use. These continued requests, together with the requirements of a definite problem whose solution demanded a rigid transmission dynamometer in the form of a coupling, led to the design and construction of the instrument described herewith. The accompanying illustrations show the construction of the dynamometer and its method of application and use. In Figs. 2 and 4 the corresponding parts of the dynamometer are given the same letters and are referred to in the text.

The couplings A and B, each keyed to its respective shaft, are held together loosely by the stud bolts C. The holes in the flange A are larger than the studs C, so that these studs have no part in transmitting power from one shaft to the other. The power is transmitted from A to B through the agency of the latches L, four of which are arranged around the circumference of the flange B. These latches are mounted and are free to turn on the studs E. The two fingers of the latches engage the studs F on the flange A. On the ends of each latch are knife edges parallel to the stud about which the latch turns. For either direction of rotation of the flange A the latches L, which are in effect double bell-crank levers, will exert a pressure on the disk G, tending to force it axially along the hub of the coupling B, and this pressure, it will be seen, is proportional to the torque.

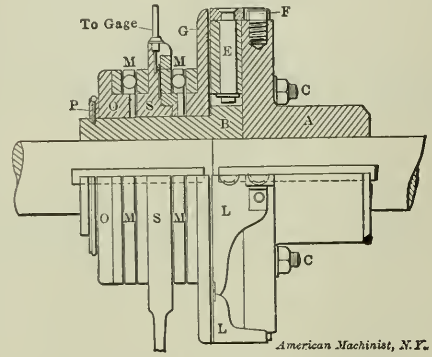

FIG. 2. TRANSMISSION DYNAMOMETER SHOWN IN SECTION

Between the end-thrust ball, or roller, bearings M M is held the stationary ring S, which is the weighing member. O is a thrust collar screwed on the hub of B, and P is its check nut, which is ordinarily pinned to the hub when in position. The stationary member S, in the form of a ring surrounding the shaft, is prevented from rotating by fastening to some fixed object the attached arm shown in the view, Fig. 1, of the assembled instrument. In the ring is an annular cavity covered by a thin, flexible copper diaphragm D, against which the ball race of one of the thrust bearings presses. The edge of this ball race is slightly chamfered to allow some motion to the diaphragm. The cavity is filled with a fluid, such as oil, and connected by means of a tube to a gage. The oil pressure measured by the gage is proportional to the pressure between the thrust bearings, which in turn is proportional to the torque.

The instrument may be calibrated in the torsion-testing machine, or by means of a sensitive friction brake. Fig. 6 is an actual calibration curve for a small instrument, obtained by hanging standard weights at proper distances from the shaft on a horizontal lever attached to the shaft, and reading the pressures indicated by the gage for the various torques shown

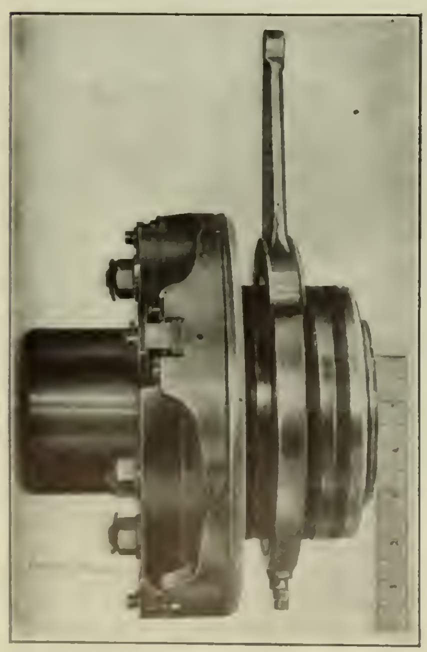

FIG. 1. TRANSMISSION DYNAMOMETER FOR 2-INCH SHAFT—WEIGHT 60 POUNDS

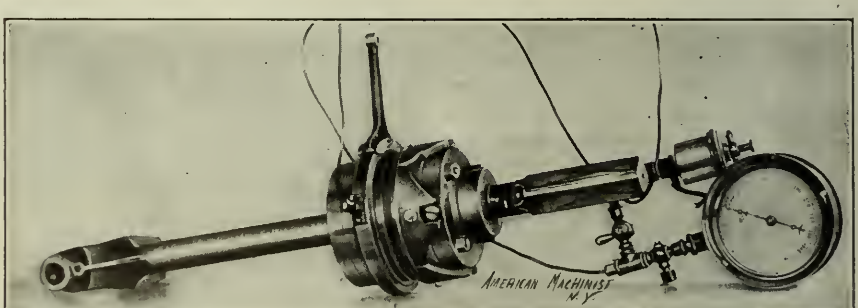

FIG. 3. TRANSMISSION DYNAMOMETER IN AUTOMOBILE PROPELLER SHAFT

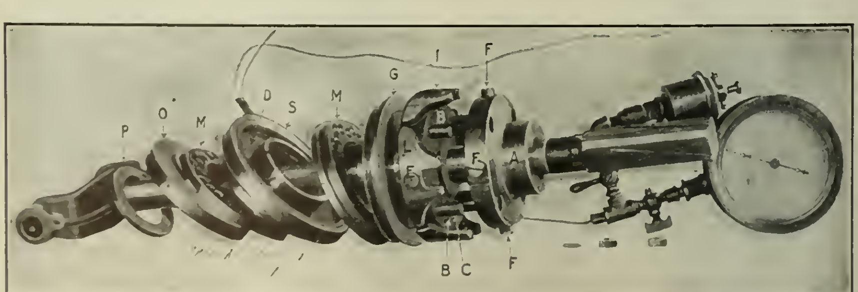

FIG. 4. TRANSMISSION DYNAMOMETER DISASSEMBLED TO SHOW CONSTRUCTION

*Slightly condensed from the *Journal* of the American Society of Mechanical Engineers.

in the diagram. For ordinary purposes, however, it is not necessary to calibrate the instrument by actual trial, since computations of the oil pressures for the various torques from the lengths of the lever arms and diaphragm area check very closely those thus obtained.

It will be seen that the weighing means is similar to that employed in the Emery testing machine, which is recognized as being extremely accurate. It will be possible to employ the Emery flexible steel knife edges on the levers, if desired, but this has been found in practice an unnecessary refinement.

The construction makes the coupling as nearly rigid as materials will permit, the movement of the diaphragm being extremely small. The only flow of oil through the copper connecting pipe is that sufficient to alter the shape of the bourdon tube, if that is the form of gage employed. As soon as the normal position of the gage is reached this flow ceases, hence there can be no fluid friction. It is possible, therefore, to use as long and as small a tube as desired, without introducing error. Where the gage is placed at a distance above or below the coupling, correction should, of course, be made for the static head.

Other means than the gage shown may be employed to measure the fluid pressure. Where extreme accuracy is desired it will be well to employ the weighing device used with the Emery testing machine. The manograph has been used in this connection to measure variations in torque too rapid for indication by the ordinary gage. For example, the variations in torque in a single revolution of the shaft of a three-cylinder gasolene engine have been recorded with its aid.

Where the rate of rotation of the shaft is variable and it is desired to indicate the horsepower direct, the combination of gage and tachometer shown in Fig. 7 is employed. The hydraulic gage is connected to the coupling described, its pointer, therefore, indicating torque. The pointer of the tachometer shows the number of revolutions per minute. Being a function of the revolutions per minute and the torque, the horsepower will be indicated by the intersection of the two pointers and suitable curves on the dial, as shown. Arrangements for recording or integrating the work done may also be attached to the coupling.

A summary of some of the more important characteristics of the instrument follows:

The instrument is compact. The example shown in Figs. 3 and 4, which is designed to transmit 30 horsepower at 500 revolutions per minute, is about 5¼ inches in diameter and weighs about 25 pounds. That shown in Fig. 5 driving a 3-inch shaft is about 11 inches in diameter and weighs about 100 pounds.

It is as rigid as an ordinary flange coupling.

It may be made in the form of a coupling, and will then occupy about the same space as the usual flange coupling, or it may be made in the form of a quill on which a pulley is mounted. This form may be made in halves for application to a continuous shaft.

It will indicate for either direction of rotation of the shaft.

The torque may be read and recorded or the work integrated at a considerable distance from the coupling.

The readings do not require correction for different speeds of rotation. All parts containing oil are stationary, hence are unaffected by variation in speed. Other parts are likewise unaffected by centrifugal action.

It may be made very sensitive and accurate. The construction lends itself very easily to variation of range of application and to varying degrees of sensitiveness, since the oil pressure, and hence the sensitiveness of the instrument, depend upon the area of the diaphragm, the relative lengths of the arms of the latches L, and the diameter of flanges. Its accuracy is dependent mainly on the degree of accuracy of the means employed to measure the fluid pressure, of which a number of forms, other than the usual pressure-gage, are available.

The only power absorbed is the small amount due to the friction of the belt, or pulley bearings, and this can be determined from the pull of the whirling arm. It is unnecessary to make correction for this, however, since the amount is so small as to be negligible.

FIG. 5. DYNAMOMETER IN A LINE SHAFT IN A MACHINE SHOP. SHAFT 3 INCHES IN DIAMETER

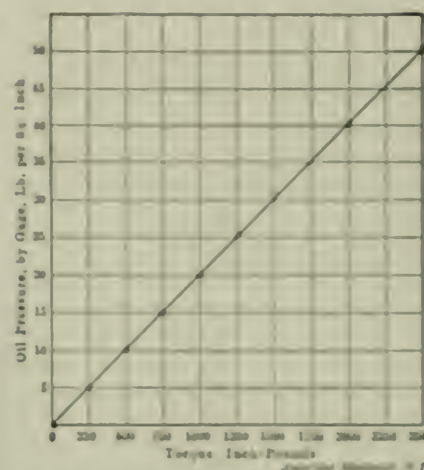

FIG. 6. CALIBRATION CURVE FOR [illegible] DYNAMOMETER

FIG. 7. COMBINATION PRESSURE GAGE AND TACHOMETER INDICATING TORQUE, REVOLUTIONS PER MINUTE AND HORSEPOWER

Since the only wearing parts are the ball, or roller, bearings, which may be lightly loaded, the instrument should not be deranged easily. Because of the very small volume of oil contained in the weighing chamber, ordinary temperature changes do not affect the calibration. All parts containing oil are stationary, hence all joints may be soldered and leakage entirely prevented.

With suitable material and ordinary workmanship, it is believed that there is little likelihood of failure of any part of the instrument. It is conceivable, however, that the balls, or rollers, although lightly loaded might crush; the diaphragm might shear; or the stationary member, although bearing only its own weight and lubricated, might seize to the hub. Remote as are any of these possibilities, should any or all of them occur, the worst that could happen would be the tearing off of the oil pipe and retaining arm, when the whole would revolve as a solid coupling. In no case can the coupling fail to drive the shaft because of its variation from the standard form, since, in addition to the driving latches employed to carry the load normally, the same number of connecting bolts may be employed as in the ordinary coupling, which will still hold the coupling together should the latches fail. Since, however, these latches are farther from the shaft, they should, if properly constructed, be less likely to fail than the connecting bolts usually employed.

Pennsylvania N. A. S. E. Convention

The tenth annual convention of the Pennsylvania State Association of the National Association of Stationary Engineers, was held at Erie, Penn., June 4, 5 and 6, with headquarters at the Liebel house. There were about sixty delegates in attendance. Sessions were held on Friday and Saturday mornings.

The delegates were called to order at 10 a.m. on Friday by John M. Lynch, chairman of the local committee, who assured the visitors that every attention would be given them during their stay in the city. Mr. Lynch then introduced Hon. Michael Liebel, mayor of Erie, who extended to the delegates and guests a warm-hearted welcome; hoped that their stay would be pleasant, and wished they would pay a return visit in the near future. In behalf of the engineers, Charles H. Garlick, past National president of the N. A. S. E., made an earnest response.

The convention was then formally turned over to John G. Lewis, State president, who presented National Treasurer, Samuel B. Forse, who urged that every delegate and guest give the closest attention and inspection to the fine exhibit of the manufacturers. Henry Sims, who followed, emphasized the good resulting to all from a higher appreciation and a closer attention to the display of the supplymen. President Lewis then appointed the several committees, after which the meeting adjourned.

The exhibit hall was then formally opened by Samuel B. Forse.

At the session on Saturday morning, considerable important business was transacted and the following officers were elected: John M. Lynch, president; F. A. Zimmerman, vice-president; D. E. Seeley, secretary; Richard Pope, treasurer; Charles Flint, conductor; John D. Dallas, doorkeeper.

The feature of the entertainment arrangements was a banquet on Friday evening, to which the ladies were invited. After a most appetizing repast, Samuel B. Forse, the genial toastmaster, introduced the following speakers, who made crisp and interesting addresses: G. F. Duemler, John M. Lynch, John A. Kerley, Mayor Liebel, F. R. Low, J. G. Gregory, George Brownhill and Charles Garlick. Jack Armour entertained with song, story and recital.

During the evening, Mrs. George Bowers and her daughter gave several instrumental selections.

Other entertainment features included a sail on Lake Erie, visits to various large plants, a trip to Four-Mile creek and a trolley ride to Waldameer. Great praise was given to the local committee for its very efficient work.

A room for the manufacturers' exhibits was arranged so that the delegates and visitors passed through it on the way to the convention hall. The following exhibited: Garlock Packing Company; Quaker City Rubber Company; Sims Company; Crandall Packing Company; Excelsior Boiler Compound Company; Atlantic Refining Company; Northwestern Pipe and Supply Company; H. W. Johns-Manville Company; Home Rubber Company; United States Asbestos Company; Mechanical Rubber Company; Erie Manufacturing and Supply Company; V. D. Anderson Company; Trill Indicator Company; William Powell Company; Greene, Tweed & Company; Jenkins Brothers; Jarecki Manufacturing Company; Lunkenheimer Company.

Leaky gasolene tanks can be temporarily repaired by the use of common yellow soap. Gasolene will not affect soap and if the latter merely is pressed into a leak the opening will effectually be stopped up. In the absence of shellac, soap is an excellent article to use in making up gasolene-pipe joints.—*Nautical Gazette.*

From March 15 to May 10, inclusive, the Fidelity and Casualty Company reported 38 boiler explosions in the United States, exclusive of railroad locomotive boilers. The loss of life approximated 20 persons.

A Cracked Flywheel Rejected

In looking over and inspecting a large flywheel for installation in your plant would you reject a wheel containing numerous, although not serious, blowholes and a small crack in the lug joining the two halves of the rim together? Would you accept a wheel from the manufacturer and take the responsibility for the destruction to property and the loss of life that might ensue if the defect should prove serious and the flywheel explode during some period of its operation? A conservative engineer who wished to take no chances would undoubtedly reject a wheel of this character and turn it back to the manufacturer. This is what actually happened in a case tried before the supreme court in New York City. A certain works in Massachusetts required 1000 horsepower to drive its new mill, which was to be supplied by a twin gas engine designed for producer gas. The wheel, which was to be mounted between the two engines of this unit, was to be a combination flywheel and rope drive. Flywheels of this special type were not made by the gas-engine company, and the contract for the wheel was let to a prominent builder in this line. The wheel was to be 17 feet in diameter on the pitch circle and have a maximum diameter of 17 feet 3 inches. Its weight was to be about 50,000 pounds and it was to deliver 1000 horsepower at 100 revolutions per minute. In reality it was a double wheel with one of the wheels split horizontally, and the other vertically, so that it contained four sections. On its 5-foot face were 24 grooves for 1¾-inch rope. The two wheels were bolted together at the rim and also bolted at the joints of the rim and hub, and in addition tie rods joined the hub and rim at the joints. The general construction and the section of the rim at the joints will be apparent from Fig. 1, which is only approximate and was sketched from models used in court. For convenience the maker of the flywheel will be called the plaintiff and the gas-engine company the defendant.

In due course of time the wheel was ready for inspection and the defendant sent its representative to examine the wheel, which was completely erected on the pit lathe of the plaintiff. After a careful inspection three of the castings were pronounced good, but the fourth casting contained as many as 19 scab spots in various parts of the rim and hub, the maximum depth being ¾ inch. These spots were not considered serious enough for the rejection of the wheel, and upon provision that these spots should be filled, the wheel was virtually accepted and was shipped for its destination in Massachusetts.

It was not until the wheel was being unloaded that the engineer of the Massachusetts company detected the crack in the lug at the rim joint. This was clearly evident upon the machined surface of the lug, but on the exterior could hardly be detected on account of the paint and dirt covering the casting. As shown in the sketch, Fig. 2, the crack ran through the lug parallel with the bolt holes and apparently continued for 4 inches from the edge of the lug on the machined side and about 2 inches on the exterior. These dimensions for the visible crack are probably correct, as they were determined by the use of a magnifying glass, but there was much discussion on this point, and it was claimed by the plaintiff that the crack extended only 2 inches on the machined side and about 1 inch on the exterior. The crack was at once reported, and as the two manufacturing companies were not able to reach an amicable settlement the lawsuit followed in an attempt by the plaintiff to collect the money for the wheel.

tensile strength of 20,000 pounds per square inch was taken for the iron in the wheel, and no internal stress was assumed, and by the use of these formulas, which were all based on Hooke's law, numerous factors of safety for different parts of the wheel were determined.

The results obtained and given in the evidence are reproduced in the following table

Weight of whole rim, lb	28,400
Weight of rim, lugs, lb	1,900
Complete weight of rim, lb	30,300
Centrifugal force of ½ of rim or half of one section, lb	219,640
Rim speed in feet per minute	5,341
R.p.m. of wheel	100
Area of 12 parting bolts, sq in	42
Breaking load of bolts at 40,000 lb. per sq in., lb	1,680,000
Factor of safety	7.6
Area of five arms at rim, sq in	102
Breaking load of arms at rim at 20,000 lb. per sq in., lb	2,040,000
Factor of safety	9
Complete weight of arms, lb	12,000
Centrifugal force of five arms, lb	41,180

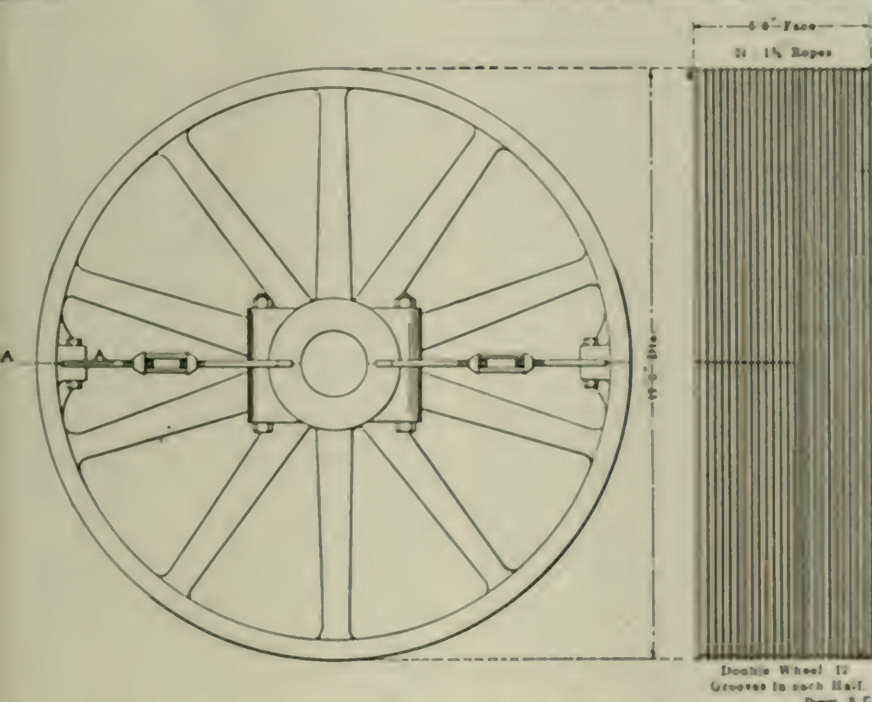

FIG. 1 GENERAL CONSTRUCTION AND SECTION OF RIM

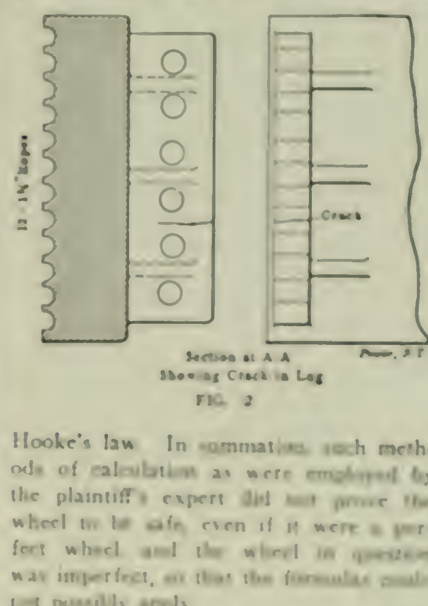
After the wheel had been placed on the flat cars ready for shipment, it was claimed by the plaintiff that its responsibility ended, and this, of course, would have been the case if the crack had been visible during the inspection of the defendant. The crack was not visible, however, as during this inspection the wheel was assembled, and according to law the plaintiff was still responsible for any defect that was hidden or concealed.

Secondly, the plaintiff claimed that it did not make any difference, anyway, for the crack was not dangerous and was not at all a serious defect, and an attempt was made to show that the wheel was perfectly safe, by the usual formulas for centrifugal stress applied to a free rim, then to a spoke, and to the hub, or, in general, to different parts of the wheel considered free of the other parts. A

Centrifugal force of ½ of rim or ½ of one section, including centrifugal force of arms, lb	[illegible]
Area of section of web, reduced by scab hollows in wheels, sq in	[illegible]
Area of reduced sections of arms at hub due to scab hollows, sq in	[illegible]
Present factor of safety at reduced web to take centrifugal force of arms and rim with iron at 20,000 lb per sq in	[illegible]
Present factor of safety of arms at reduced web to take centrifugal force of arms and rim with iron at 20,000 lb per sq in	15
Weight of cantilever formed by overhang of rim at parting line from first arm one side, one section, lb	[illegible]
Centrifugal force of above section, lb	[illegible]
Breaking load of section of above portion of rim at arm, assuming hub and tension rod, in lb	[illegible]
Bending moment, in lb	[illegible]
Factor of safety	[illegible]
Deflection, in	[illegible]
Considering the portion of rim between arms at parting for one section only with improved tension rod. Centrifugal force between arms at parting, lb	[illegible]
Area of tension bolts, sq in	[illegible]
Breaking load of tension bolts at 40,000 lb. per sq in., lb	152,400
Factor of safety, neglecting bending moment of rim at arms and the bolts	3
Factor of safety to hold rim between arms at parting, neglecting the bolts	6

In reply the defendant stated that there must have been internal stress, as the wheel evidently had a shrinkage crack, and if this was the case 20,000 pounds tensile strength was much too high for exterior loading in addition to the internal stresses. It was also contended that the formulas used did not show anything, as they did not apply to a complete wheel with the restraints of one part figured over the others. The rim instead of being a free rim was a continuous girder, undergoing tension in addition to its bending, and it was a special girder because it was wider than its support, the spoke, and had two chances of bending; that is, when the wheel was in motion the metal near the two edges of the rim would tend to bend outward. There was no formula to take account of this unusual bending, and for that matter any of the formulas used in the case were true only to the elastic limit, and not to the breaking point, because all were derived from



Section at A A
Showing Crack in Lug
FIG. 2

Hooke's law. In summation, such methods of calculation as were employed by the plaintiff's expert did not prove the wheel to be safe, even if it were a perfect wheel, and the wheel in question was imperfect, so that the formulas could not possibly apply.

It was practically admitted that the defect was a shrinkage crack, and it was the claim of the defendant that there was no way of telling how deep it was, how far it would go, or in what direction. The plaintiff offered to cut out the crack, but the same objection still remained. If the crack should go through the flange and across part of the rim, the wheel would surely break, as the velocity of the rim was 89 feet per second. The defendant did not know whether the wheel would explode or not, but it had a crack, and as this crack was in cast iron, the chances were good that it would break, and any conservative engineer, in spite of any calculations to the contrary, must reject the wheel. These views of the case were upheld by the jury.

The Principles of Steam Condensers*

Some of the Essential Features Which Make for Efficiency and Economy, Both as Regards Design and Operation of the Apparatus

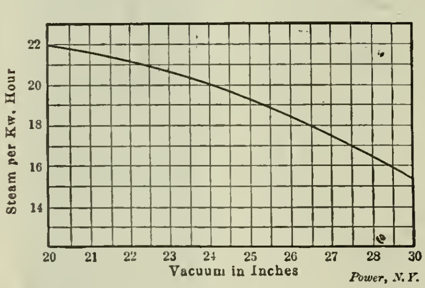
BY M. R. BUMP

The fundamental principle of design and operation of steam condensers is to secure a maximum transfer of heat from steam to water at a minimum of expense for fixed charges; that is, minimum first cost plus operating expenses. The choice of this apparatus depends in greatest measure upon the vacuum obtainable under different atmospheric and weather conditions, and when cooling towers are to be used in the design of apparatus allowance must be made for these conditions and apparatus selected which averages best under all conditions.

The cost of pumping the circulating water depends directly upon the amount of heat imparted to each pound of water in the condenser. Therefore, for a minimum of pumping cost, the water should leave the condenser exactly at the temperature of the steam entering the condenser, for in this case each pound of water carries from the condenser the maximum possible amount of heat and the amount of water required is therefore reduced to a minimum. In practical design, therefore, the condenser should be laid out with a view of obtaining this result as nearly as practical conditions will permit. In the surface-type condenser, where the heat is transferred through metallic tubes, it is necessary to allow for a certain differential of temperature between the steam and water, and the amount of heat transferred is directly proportional to the differential temperature allowed. If the differential temperature is 5 degrees, the surface required will be twice as great as in a case where 10 degrees differential temperature is allowed. The selection of proper amount of surface for any given location may be determined upon the basis of balancing fixed charges on additional surface against fixed charges and operating expenses of pumping apparatus. As the amount of surface is increased the cost will increase in definite proportion, while the differential temperature required will decrease. The decrease in differential temperature permits of a reduction in the quantity of water to be pumped, and therefore reduces both the size and first cost of the pumps and also the power required to operate the pumps.

The problem is a special one for each installation and should be so considered.

With the jet condenser it should be possible to reduce the differential temperature to a very few degrees, yet it is more common to find the difference greater than in the surface condenser. It is common to see a jet condenser taking water at 75 degrees and discharging at or below 90 degrees when the temperature of the steam is at least 110 degrees. Under this condition the discharge water should be raised to at least 105 degrees, in which case just half of the amount used would be required. The greatest inherent advantage of the jet condenser is wasted by operating in that manner. The writer has seen tests on jet condensers where the differential temperature between entering steam and escaping water was less than two degrees over a wide range in load. When operating on a fluctuating load it may be advisable to allow a somewhat greater differential temperature, but there seems to be no good reason why greater than five degrees differential should ever be allowed in a properly designed condenser. The poor results ordinarily reported are due in large measure to carelessness on the part of the engineer, who simply starts the pump and then lets it run at constant speed.



WATER-RATE CURVE OF STANDARD 1000-KILOWATT TURBINE WITH VARIATION OF VACUUM, STEAM PRESSURE 175 POUNDS, SUPERHEAT 100 DEGREES

In selecting a condenser for any given location, the consideration of weather and climatic conditions, of quantity temperature and quality of cooling water, at all times of the year, the variation in steam results on the unit for varying vacua, and the load conditions of the unit to be operated, are all of importance. The question of floor space has an effect upon the size and cost of buildings, and the ground space is often a most important item where ground is very valuable, as in the large cities.

The weather and climatic conditions are particularly important where cooling towers are to be used, as will be discussed later. The consideration of the water supply is of greatest importance. The quality of the water must be carefully considered. If the water is inclined to scale or to deposit solids when heated, the jet condenser is better suited to its use. If, on the other hand, it does not give trouble from this source at the temperatures employed in condensers but does cause scaling or pitting in the boilers, it is a distinct advantage to use a surface condenser and save the condensation for use in the boilers. In this connection, however, it is interesting to note that if the water being used over and over again is not allowed to come in contact with the air, there is a chance for it to become a very pure distilled water, which would very rapidly eat out iron pipe and would attack the iron in the boilers if it were still very free from all impurities when it entered the boilers. It is a well-known fact that pure distilled water will attack more or less any metal, and has an especially harmful effect on iron and steel. Under ordinary conditions, where the water is discharged into an open pump and then pumped into the heater, very little trouble should be occasioned from this source.

The temperature and quantity of water available are important factors. Where the quantity is at all limited it is desirable that the condenser should be designed with a view to imparting to each pound of water the greatest possible amount of heat. The maximum temperature of the water is the most important factor in determining the size of pumps. Where condensers draw their water supply from sources in which the temperature runs very high during summer months it is again very important to impart the greatest possible amount of heat to each pound of water in order to avoid the necessity for installing and operating an excessively large pumping installation. Having given the maximum temperature of the water, it is a matter of considerable work to figure out the best installation. It is often necessary to operate at lower vacua during summer months, and it is often found that many plants do operate on lower vacua than would be necessary if the condensers were properly designed and operated. In order to determine the size and best operating conditions the effect of a reduced vacuum on the steam results of the unit during those weeks or

*Read before the National Electric Light Association convention, Atlantic City, N. J., June 1, 2, 3 and 4, 1909.

months when the temperature of water is high must be considered.

The accompanying water-rate curve reading shows the effect of reduction of vacuum upon the economy of a standard steam turbine of 1000 kilowatts capacity, with 175 pounds steam and 100 degrees superheat.

These data are also summarized as follows:

Vacuum, Inches.	Steam per Hour at Full Rated Load Pounds.	Increase Over Consumption on 29-Inch Vacuum.	Increase, Per Cent.	Approx. Temperature Exhaust Steam, Degrees.
29	15,350	....	....	77
28	16,550	1,200	7.8	100
27	17,500	2,150	14	116
26	18,550	3,200	20.8	124
25	19,350	4,000	26	132
24	20,000	4,650	30.3	140
23	20,600	5,250	34.2	146
22	21,100	5,750	37.5	151
21	21,600	6,250	40.8	157

Allowing for the differential temperatures required in condenser and tower and for the temperature of the water, the amount of water required for any given vacuum over that of the next lesser vacuum can be determined and the benefits compared with the costs of obtaining it.

It is often possible to effect a very material saving in cost and size of condensers by allowing for a reduced vacuum when the temperature of the water is high. It becomes then a problem of balancing the added cost of fuel, and the like, against the fixed and operating charges on the condensing equipment to determine the most economical installation. If the water rate of the unit is carefully determined by test or can be accurately forecasted by manufacturer's guarantee, the cost of fuel to generate the additional steam required can be estimated easily. Then by plotting the temperature curve of the water supply and allowing for a fair differential temperature, the quantity of water required to condense the steam for full load of the unit can be figured for each season of the year. By comparing this with the fuel costs noted above, the final selection can be properly determined after securing estimates or proposals on various sizes of condensers and pumps.

Since the introduction of the steam turbine, the condensing problem has become doubly important. With engines the gain in economy by the last one or two inches of vacuum is relatively very much smaller than with the turbine. Furthermore, the reduction in first cost, floor space, and the like have demanded different types of condenser. The introduction of the low-pressure turbine also emphasizes the importance of high vacua essential to their successful operation.

The daily and annual load factor on the unit also have an important bearing on the condenser. Where the unit is to be operated continuously at or near full load the conditions noted above will apply, but where the load is fluctuating and averages considerably below the rated capacity, the effect on economy of the unit has important bearing only at hours of full or heavy load and should be considered only for these hours, because the water supply will be ample at other times.

The design of an air pump or dry-vacuum pump involves the general features of the air compressor. The variation in intake and discharge pressure is not great, but the volumes to be handled are enormous, owing to the low pressures. The important items outside the pump itself are, first, to keep the piping system from the point where the pressure goes below atmosphere to and including the condenser and its auxiliaries as nearly bottle-tight as possible, and, second, to cool the air entering the pump and remove from it as much of the water vapor as possible. The first question is one of careful attention and inspection, and is often a very greatly neglected point in plant operation. If the engineer properly inspects the system daily and watches the mercury column or gage closely, he can very quickly detect any unusual amount of air leakage. Yet it is common to note the falling off of one to three inches in vacuum before any attention is paid to the matter, when a fraction of an inch should be an indication that something is wrong and requires immediate attention.

The second essential, namely, the cooling of the air and separation of the moisture, is a matter that must be considered in the design of the condenser itself.

In the jet condenser, particular attention should be given to the air offtake, which should be so designed that all the air must pass in intimate contact with the cold water entering the condenser chamber. In the surface condenser, attention should be paid to the proper distribution of baffle plates in order to accomplish this result as nearly as possible. The writer is of the opinion that in many cases the air should be drawn off through a separate chamber, in which it is cooled as nearly as possible to that of the entering water. This would reduce the volume of the air itself and would greatly reduce the volume of water vapor, and would enable a considerable reduction to be made both in the size of air pump and in the work the pump does.

The compression in the air pump should approach as nearly as possible a true isothermal, in order to reduce the power required for its operation to a minimum.

In operating an air pump many engineers start the pump, set it at its normal speed and let it run regardless of the load. The result is that the air pump does a great deal of unnecessary work, and at times it is pumping steam to a greater extent than air. This can often be quickly checked by slowing down the air pump materially without any effect upon the vacuum.

The surface condenser is used almost exclusively on all the large turbine installations, and has given better results than jet condensers ordinarily show. There seems to be no inherent advantage that would justify any appreciable difference between the two types of condenser. With the large turbine units the steam consumption per unit of output is as low as 14 pounds per kilowatt-hour, and upon this basis the amount of surface per kilowatt of capacity required is very much less than in smaller units. With small units the ordinary installation requires 4 to 5 square feet of tube surface per kilowatt capacity, while on the large turbines the surface required varies from 1.75 to 2.5 square feet. The reduction in first cost per kilowatt of capacity in large-sized units is therefore as great as 50 per cent. The surface-condensing equipments installed at some of the largest stations produce continuously vacua in excess of 28 inches and have reached 29 inches.

There seems to be no reason why a jet condenser should not produce equally good results if properly designed. It is true that the work required of the air pump on a jet condenser installation is in excess of that required on a surface condenser, but the decreased amount of cooling water necessary should more than offset the disadvantage of the extra quantity of air. The first cost of jet condensing equipment would not exceed 50 to 60 per cent. of the cost of surface condensing equipment, and the repairs and maintenance should be much smaller. The surface condenser requires more attention, the surface must be kept clean and the tubes tight, and the best results can only be secured by constant attention.

A condenser of novel features has recently been introduced in this country from European practice. In this condenser the design of the chamber in a measure resembles the ordinary barometric condenser, the chief novelty being in the pump unit. The water pump and rotary air pump are both mounted on the same shaft and can be directly connected to steam turbine or motor, as desired, making a very compact and simple unit. Tests on this condenser have shown frequently that the discharge temperature of the water can be maintained between one and three degrees of the temperature of steam.

The selection of the pump-driving unit for any condensing installation must depend largely upon the other plant conditions. If the exhaust from these units can be advantageously used to heat the boiler feed water, the steam-driven pumps will invariably figure as the most desirable. Where the exhaust from other plant auxiliaries is sufficient for feed-water heating, or where economizers are used, the selection depends upon a comparison of cost of motor and steam-driven pumps and of the expenses for operating them. The general features of the newly-discussed motor- versus steam-driven auxiliaries enters into the problem.

A Standard of Excellence

We sigh for the days of the arts and crafts, when artsmen and craftsmen labored for the love of it and produced for the pleasure of producing; when each man strove for excellence and each master for reputation, and the incentive was to turn out the best that could be made.

It is more than likely that there never was such a time, but we like to think that there was; to admire the workmanship of the old things which have come down to us because they were made in this way; and to say: "In those days they knew how to do a good job."

As a matter of fact, though, are not things done in this way now if one insists upon and is willing to pay for it?

You want a job of steam fitting or plumbing done. The bids vary widely and you give it to the lowest bidder. The cheapest kind of labor and material that will satisfy the specifications are used. The "solid nickel" caps and sheaths are about as heavy as wrapping paper, and crumple up when one goes to polish them; the wiped joints leak; the fixtures won't stay fixed, and you are at a continual expense which would pay the interest on enough money to have done the job in gilt-edged style so that you could have been proud of it and not constantly fretted and annoyed by it.

It is the same way with everything else. Ask for prices on leather belting and the bids will vary as much as one hundred per cent., but it is foolish to suppose that the low price will procure the same kind of a belt as the high one. For any but the most trivial and transient use the higher-priced belt made from the center of selected hides, properly tanned by a full-time process, is the cheaper to buy.

Most purchasers realize this and are willing to pay the extra price for the all-wool, sterling, high-grade article, but they want to be sure that they are getting it. Put a Dunlap label into a new one-dollar hat and not one man in fifty will tell the difference. Give ten ordinary purchasers a half dozen samples of rubber hose and it is doubtful, if they are not experienced buyers of this class of goods, if the majority of them would select the same sample for the best. The price of cylinder oil is no gage of its quality or cost of production. Of two boilers which look the same to the casual observer one may have rivet joints of high efficiency and be built with carefully rolled sheets, reamed rivet holes and ample bracing, while the other may have a joint copied from another boiler, and not efficient for this one, put into a sheet tortured by battering, drawn together with drift pins and braced as came handiest. It costs less to make a boiler the last way; the boiler made the first way is worth additionally much more than the difference; but how is the ordinary purchaser going to tell whether, when he pays the higher price, he is getting the superior quality?

This subject was considered by the American Supply and Machinery Manufacturers' Association and the National Supply and Machinery Dealers' Association at their recent joint meeting in Pittsburg, a vigorous campaign having been instituted by Charles F. Aaron, of the New York Leather Belting Company and president of the manufacturers' association. After an extended consideration of the subject in the course of which the idea received many warm commendations, it was decided to appoint a committee, equally divided in its membership between the two societies, to investigate the subject.

The discussion developed the opinion that it would be entirely practicable to fix certain specifications setting the standard for first-quality goods in certain lines and that manufacturers of goods made to these specifications might stamp them, with a distinguishing mark authorized by the association, in the same way that the trade name "Naco" is used by the confederated supply associations in the plumbing-supply trade. Such a practice, if the mark were protected against unwarranted use, if all manufacturers who conformed to the specifications were free to use it, and if adherence to the specifications were strictly enforced, would encourage manufacturers to make honest goods out of honest material, and guarantee the purchaser who was looking for real merit that he was getting the superior article for which he was willing to pay. The one thing which must be guarded against is that there shall be any warrant for the impression which the non-users of the mark will seek to create that its use is restricted to a privileged few and not open to everybody who makes goods of the required grade of excellence.

The Electric Light Convention

The annual convention of the National Electric Light Association just held at Atlantic City was phenomenally successful. This is not the customary platitude inspired by a desire to be complimentary; it is a bald statement of fact. The attendance was gratifyingly large, the interest in the sessions was unusually widespread and the quality of the program excellent. Impartial consideration of the program prior to the convention, however, disclosed a serious flaw, and attendance upon the sessions confirmed the prognosis. There were too many papers for the length of time available for their consideration. Two of the morning programs of the general and technical sessions provided seven papers each and the third one contained eight. Now, it is absolutely impossible to devote anything like intelligent consideration and discussion to such a number of papers within the allotted space of three hours. Every paper and committee report presented at this convention was of high merit and real importance, but many of them had to be railroaded through—read in skimpy abstract and undiscussed—because there was no time left for adequate treatment. While it may seem deplorable to omit or postpone the presentation of some good material, that would be far better than congesting the program to such an extent as to neutralize a large proportion of it.

The report of the committee on gas engines, while of undoubted value to many of the delegates, was disappointing to those who were already familiar with the general status of gas-power engineering. Some operating records from gas-power plants, which the committee had collected by much hard work, and which constituted by far the most valuable feature of their work, were transferred from the regular report to a supplementary confidential report presented to the executive committee of the association. Of course we have no knowledge of the character of the suppressed records, but we cannot conceive any good reason why the data from any properly operated gas-power plant should be treated with such uncanny secrecy. Whether the records would have caused apprehension in the ranks of steam-engine builders or consternation on the part of gas-engine and producer men we have not the remotest idea; but having been secured for the information of the association at large, they should have been presented to the association at large and not restricted to the executive committee.

Mr. Smart's paper on turbines, to be printed in next week's issue, deals very frankly with the characteristic features of the several types of steam turbine, and offered excellent opportunity for a lively discussion which might have served to put on record a fairly complete summary of the turbine situation. Apparently the advocates of turbines other than the Rateau were out sailing or fishing and couldn't get back in time. At any rate the discussion was not enlightening.

This brings to mind another point wherein the sessions of this association (and several others) are sometimes weak. No effort seems to be devoted to securing the presence of men especially qualified and willing to discuss important papers. It is easier to advise than to achieve, of course, in all cases, and we appreciate the difficulty of assuring the attendance of busy engineers; but we feel impelled to emphasize the fact that the quality of the proceedings would be greatly enhanced if some means could be devised to procure the coöperation of more of the right men in the matter of discussing the papers. The real usefulness of these meetings depends very largely upon the discussions, which should bring out valuable information not otherwise obtainable.

Gumption

At a time when the results of the late depression are still felt and many a steady, capable engineer is looking for a job, there is a cry abroad in all the wide land for men with "gumption."

The man who knows the joy of a task well done, the man who does not believe that there is just as much in getting rid of a job as there is in doing it, the man who takes an intelligent interest in what is going on about him; the man who sees what has to be done and tries harder to help to do it than to frame up an excuse for not doing so—that is the man with "gumption." Oh, that there were more of him.

Give the man with gumption a job and you can forget it in the confidence that it will be done. Give the other fellow the same job and six weeks afterward, upon a casual inquiry as to the progress of the work, you will find in all probability that the job has never been started. Some trifling difficulty, which the man of gumption would have gone ahead and solved, has stood in the way, or perhaps your question will receive the answer so common with a man of this type, "I have not got around to it yet." "Tomorrow" is his favorite expression, and so often the tomorrow referred to never comes. Then again there are men with just a little more activity. The job will be started, but done in the easiest way. Thoroughness and good workmanship are not incorporated in their code of morals, and the result is a slovenly piece of work or a temporary makeshift when repairs are necessary.

To operate a power plant with economy requires men of gumption. There is no room for the slothful, lazy ones or the put-it-off type. When a boiler bags or the safety valve sticks, it is necessary to correct the evil, not in a day or two, but at once, if the cost of repairs or the safety of the plant are given due consideration. Watch the water level and fire frequently in small amounts. Do not do like the lazy but most ingenious fireman who dozed on his easy chair and the coziest place in the boiler room. An electrical connection to the steam gage and a bell on the bottom of his chair notified him when the pressure had dropped to a certain point and thus served to space the intervals of firing. The feed-water pump could run as it pleased, but was generally given some attention after the furnace was filled with coal. A half-hour's sleep was frequently obtained throughout the day, and what did the cost of fuel or the life and safety of the boiler amount to when compared with his comfort? Direct the same ingenuity to a better purpose, and if you know the safety stop on the engine will not work, take the necessary time to fix it, not within a week or perhaps a month, but at the earliest possible moment.

The man of quick wit or ready perception, the man who sees quickly what is to be done and has the energy to go ahead and do it, is the man who will make his way. There is always demand for men of quality and of gumption.

Give Boilers the Hydrostatic Test Often

While in the discharge of his duty, a boiler inspector applied hydrostatic pressure to a boiler which showed no signs of weakness or deterioration beyond a leaking rivet which repeated calking had failed to make tight. Slight leaks around rivets are not usually considered serious defects and when calking fails to stop the leak, new rivets are put in, as a matter of course, and the job considered as done.

In the case mentioned, pressure was applied before putting in new rivets, perhaps to determine if other rivets might need replacement, with the result that at three pounds above the working pressure a crack about two feet in length opened in the overlapping sheet, close to the line of the edge of the rivet heads.

Failing, as this boiler did, at a pressure of only three pounds above that at which the safety valve was set suggests that periodic applications of the hydrostatic test of boilers might not be bad practice. Like the man who took a bath once a month whether he needed it or not, would it not be a good plan to apply water pressure fifty per cent. in excess of the regular working pressure to all boilers once a year whether it is considered necessary or not?

It is generally understood that the development of cracks in the overlapping sheet is gradual and it is probable that a pressure fifty per cent. in excess of the regular working pressure would reveal a weakness in the sheet before it became dangerous. Where a factor of safety of four or five is chosen, the application of a pressure one-third of itself above the working pressure will probably not approach the elastic limit of the material of which the boiler is made and thus when applied permanently deform the boiler; and if this be true, it would do no harm and would in all likelihood be productive of much good.

In the case of the Harwood boiler at Lynn (Mass.), the engineer's attention was drawn to the crooked seam by pumping steam after the crack had gone clear through. Had a water pressure been put on the boiler six months or a year before then, it is probable that the crack, which had been slowly penetrating the sheet, would have yielded to the applied pressure and shown that a supposedly safe boiler was in reality in a seriously dangerous condition.

The Tower Gas Engine

The Tower Engineering Company, of Buffalo, N. Y., one of the latest additions to the list of gas-engine manufacturers, is building a line of multicylinder vertical engines of the general type illustrated by Fig. 1. The engines are all single-acting, with long trunk pistons, and operate on the four-stroke cycle. Contrary to the common practice in engines of the single-acting type, the valves are operated by means of eccentrics and wiping rockers instead of revolving cams and rollers. The valve-gear shaft is mounted in a housing alongside the cylinder tops, as indicated in Fig. 1 and shown more definitely in Fig. 2. The latter engraving also illustrates the construction of the water-cooled

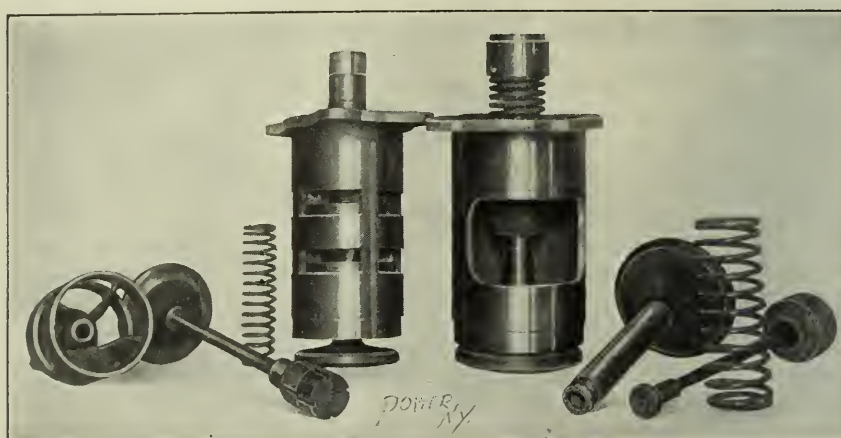

FIG. 3. INLET AND EXHAUST VALVES AND CAGES

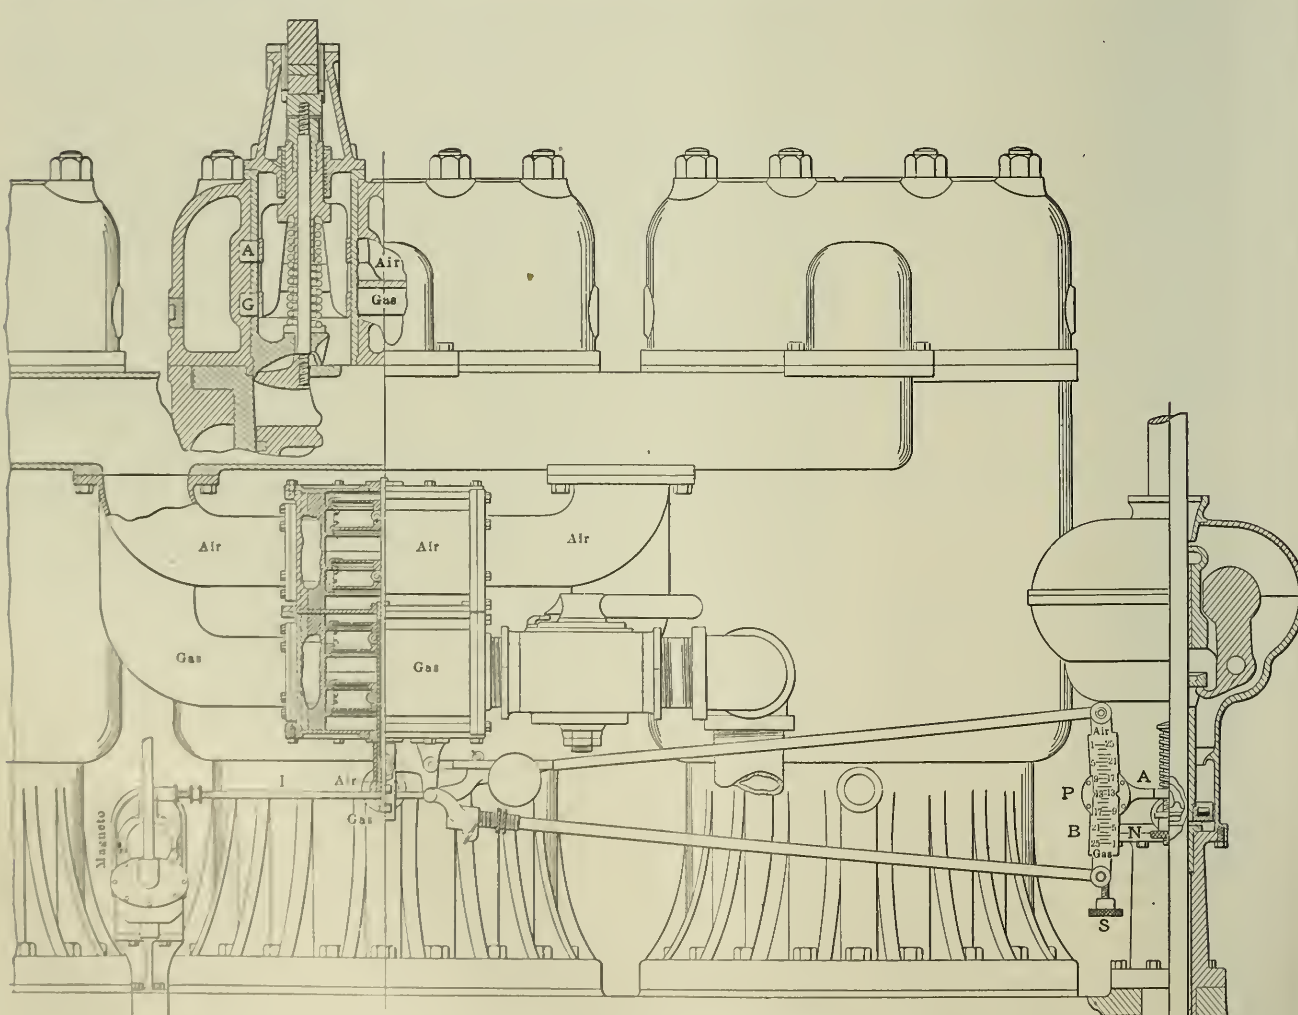

FIG. 5. GOVERNING MECHANISM

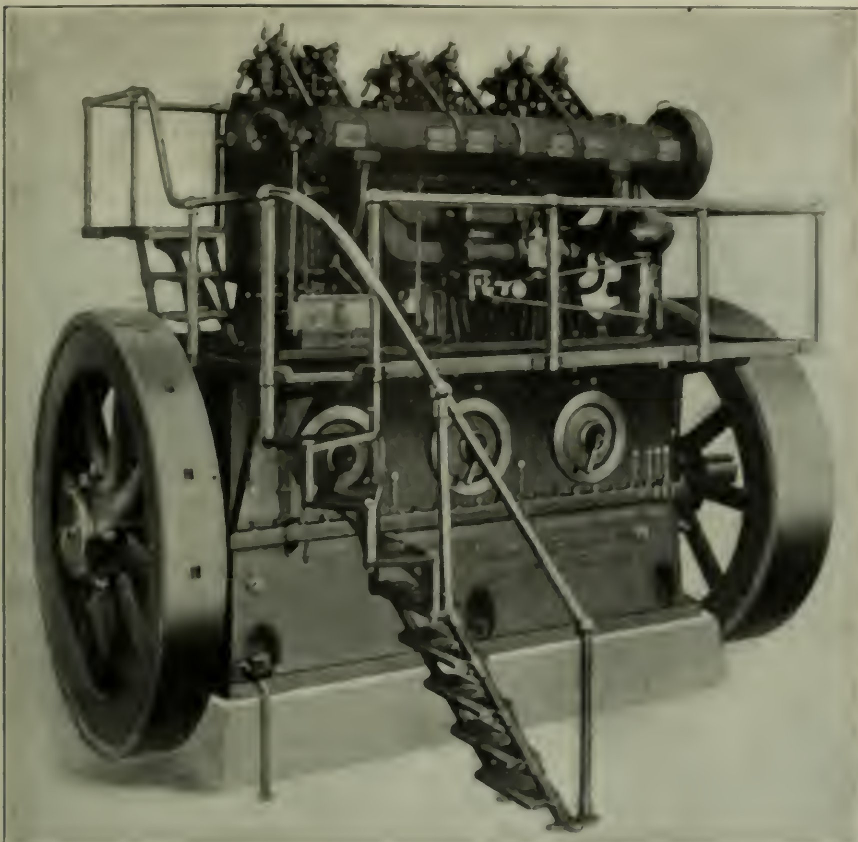

FIG. 1. TOWER GAS ENGINE

exhaust valve, the ribbing of the cylinder water jacket and some features of the lubricating system, referred to later.

The inlet valves are of the usual solid poppet type, set in removable cages, and the exhaust valves are of the hollow mushroom type. Each inlet-valve cage contains a piston mixing valve immediately above the main inlet valve, as illustrated at the left in Fig. 3, which shows an inlet valve, a mixing valve and an exhaust valve, removed from their cages, and also an inlet cage and exhaust cage complete with valves. The small stem with a piston-shaped block on the end, shown at the extreme right, is the water-inlet tube which fits into the stem of the exhaust valve as shown in Fig. 2; the block on the end is a head containing the water inlet and outlet channels, which are connected by flexible tubing with the stationary water pipes.

Speed regulation is obtained by altering the supply of gas and air in opposite directions; that is, when the load falls off, causing an increase in speed, the governor reduces the gas supply and increases the air supply. The compression is not maintained constant, however, as is customary with this general method of governing; when the gas supply is reduced the air supply is increased to a greater extent than that necessary to keep the total mixture constant, with the result that the compression pressure is actually higher at light loads than at full load. The object of this is to avoid "skipping" at light loads, due to the lean mixture. Fig. 5 illustrates the governor mechanism. The face-plate P is mounted on the end of a small shaft which is rocked by the inward and outward motion of the governor balls and is provided with an arm A which engages with a helical spring opposing the outward movement of the balls. This spring is adjustable by means of the thumb-nut N, to regulate the engine speed, and it is merely auxiliary to a pair of main governor springs inside the casing (see Fig. 2), which supply most of the opposition to the centrifugal force in the balls. Across the face-plate P is an under-cut slot in which is mounted a graduated bar B, the position of this bar is adjusted by means of the thumb screw S, and upon its position depends the relative motion of the gas- and air-control valves when the governor changes its position.

Pivotally attached to the ends of the bar B are two reach rods which actuate the air and gas valves in the two chambers marked "Air" and "Gas;" if the governor shifts the upper end of the bar B to the left (due to an increase in speed), the air valve will be opened wider and the gas valve partly closed; simultaneously, the point of ignition will be advanced by means of the supplementary reach rod I extending to the magneto. The air and

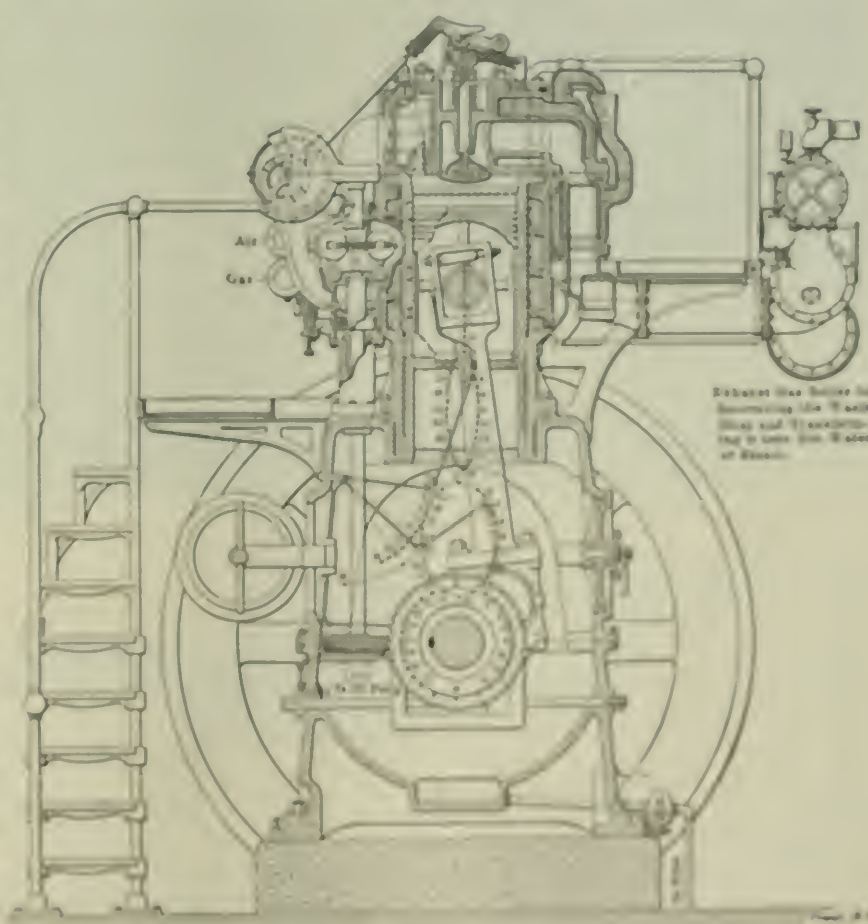

FIG. 2. SECTIONAL ELEVATION OF TOWER GAS ENGINE

gas-control valves are of the spool type, as indicated by the view through the broken-away casing. The air and gas do not mix until reaching the inlet-valve cage, separate headers being provided along the cylinder heads. At the cage, the gas enters through the ports *A* and the air through the lower ports *G*. The mixing valve is provided with spiral ribs on the interior, which give the air and gas a whirling motion conducive to thorough mixing.

Another unusual feature embodied in the Tower engine is the spark-plug mounting. The make-and-break system is employed, with electromagnetic plugs, and two plugs are provided in each cylinder. Both plugs are mounted in a single flanged disk which is set into a cage bolted to the cylinder head, as indicated in Fig. 6. The terminal of the ignition circuit is fixed on the igniter cage and the disk containing the two plugs may be

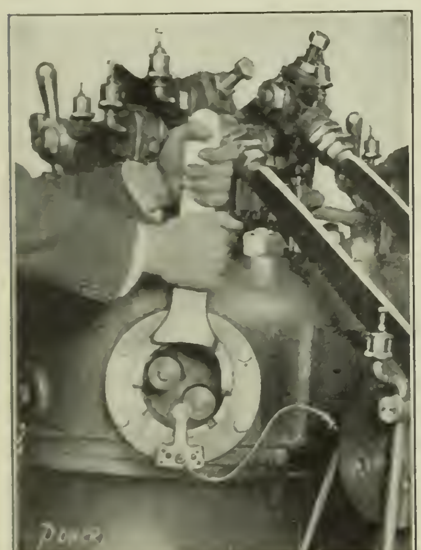

FIG. 6. IGNITER-PLUG MOUNTING

rotated in the cage so as to bring either plug into contact with the terminal. Should a plug become fouled or inactive from any cause, the other plug may be at once put into service by rotating the disk 180 degrees. Low-tension current is used, of course.

Fig. 7 shows a piston and top and bottom views of a cylinder head; in the latter, the gas- and air-inlet channels and the exhaust channel are clearly shown.

The connecting rod is of the marine type, as shown in Fig. 2, with the "big end" divided and bolted together and the upper end slotted out of the solid piece. The adjustments for wear are obvious.

The water jacket carries a spiral rib on the inside to compel thorough circulation of the cooling water. The cylinder barrel proper is a liner having a flange at the upper end which is clamped between the head and the main casting forming the jacket wall; the latter, of course, takes the stresses of operation, and is bolted to the crank case by a large number of nickel-steel studs.

Lubrication is positive throughout the engine. Oil pipes extend from a force-feed pump to the gudgeon pin, the crank-pin, the cylinder walls, the main bearings and the governor bearings.

The engine is equipped with a distributing air valve for controlling the compressed starting air. This valve is actuated by special cams carried on a sliding sleeve that can be thrown into and out of commission by a small lever that simultaneously opens or closes a master valve in the main air supply pipe, located in the head of each cylinder in a check valve; and when the master air valve is opened and the distributing

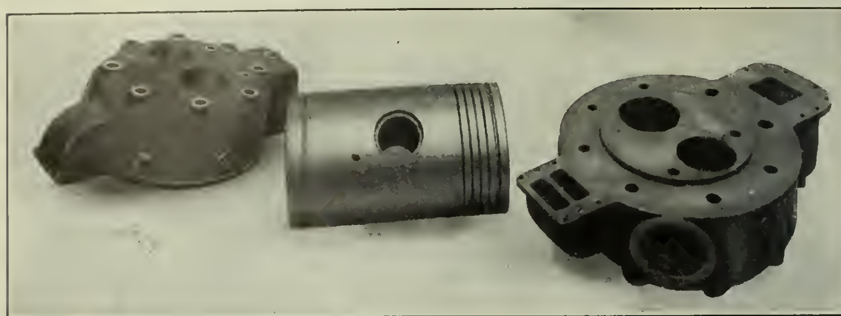

FIG. 7. PISTON AND CYLINDER HEAD

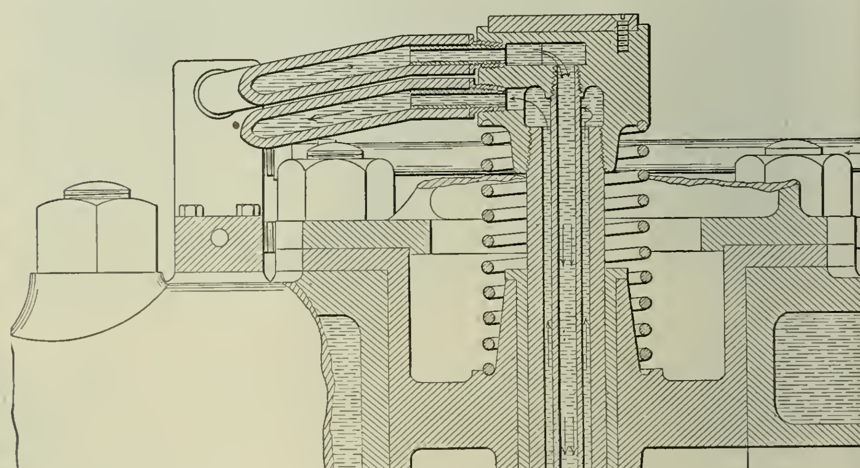

FIG. 4. ARRANGEMENT OF EXHAUST VALVE

valve thrown into position, the cylinder that is on its working stroke receives the starting air just after passing the latest ignition point; and when a cylinder picks up an explosion cycle the higher pressure of the explosion holds the check valve shut against the starting air pressure.

Boiler Explosion at Dowagiac, Michigan

A disastrous boiler explosion occurred at the hoop mill of Geesey Brothers & Coble, Dowagiac, Mich., on the afternoon of May 26, instantly killing five men, two of whom were brothers and proprietors of the mill, and seriously injuring one more, besides making a total wreck of the building. Another brother of the proprietors, who, by a strange coincidence was the nearest man to the boiler when it exploded, escaped with only minor injuries, and it is from him that an account of the events leading up to the catastrophe were obtained, the engineer being among the killed.

It appears that the plant was running along under ordinary load when the belt to a planer ran off and one of the proprietors shouted to the engineer to shut down. He ran to the engine and quickly closed the throttle, when immediately, before the engine had ceased turning over from its own momentum, the explosion occurred. The boiler was equipped with a high- and low-water alarm and a pop safety valve, the latter being screwed directly into the shell of the boiler in front of the dome. It was positively stated that neither the high- nor low-water alarm nor safety valve was blowing at the time of the explosion.

It was a horizontal return-tubular boiler, 36 inches in diameter, by 12 feet long, with double-riveted lap seams, installed in an ordinary brick setting. It went up in the air, scattering brick in all directions, turned over and came down through the roof of the plant about 50 feet distant, landing directly upside down on its steam dome. The age of the boiler was given as nine years. Examination showed that it was not badly scaled, and that the general condition of the metal was good. It happened that the young man in charge at the time, and who was killed, was not the regular engineer, the latter being laid off temporarily. When seen, in regard to the accident, the engineer, who had operated the plant for the past two years, stated that he had never been able to find any defects in the boiler, that the sheets were not burned or blistered, and that the high- and low-water alarm and safety valve had always worked satisfactorily for him, the safety valve blowing at 120 pounds, 100 pounds being the working pressure.

It seems reasonable to assume on the evidence that the boiler had a defect, not easily apparent, presumably in one of the seams, and that the additional strain caused by the sudden stopping of the engine was sufficient to disrupt it, as had the boiler been perfectly sound it should have been able, with its small diameter, easily to have withstood this treatment without injury.

BOILER EXPLOSION AT DOWAGIAC, MICH.

Indiana N. A. S. E. Convention Changed

The Indiana State N. A. S. E. convention, which was announced to be held at Indianapolis, will be held at Evansville, Ind., June 18, 19 and 20. Coincident with this meeting the annual outing of Evansville No. 2 N. A. S. E., will take place on June 20 at West Heights park.

New Jersey N. A. S. E. Convention

The eighteenth annual convention of the New Jersey State Association of the National Association of Stationary Engineers was held at Odd Fellows' hall, Hoboken, Saturday and Sunday, June 5 and 6, beginning at noon on Saturday. There were present delegates from Jersey City, Hoboken, Elizabeth, Perth Amboy, Plainfield, Newark, Passaic, Trenton and Paterson.

Mayor Steil welcomed the delegates to the city, and gave them the freedom of the municipality, while Recorder John J. McGovern cordially seconded the mayor's remarks.

National Vice-President William J. Reynolds, of Hoboken, answered on behalf of the delegates, and the committee on credentials prepared its report.

Dinner was enjoyed at 2 p.m., after which officers were elected, as follows: President, C. L. Case, of Plainfield No. 12; vice-president, Edward Sears, of Newark No. 3; treasurer, James J. Durkin, of Hoboken No. 5; secretary, John J. Reddy, of Jersey City No. 10; conductor, Edward De Groot, of Elizabeth No. 14; doorkeeper, P. J. Mooney, of Jersey City No. 10.

Unfinished business was transacted at the 10 a.m. session on Sunday; at 1 p.m. a banquet was served, and at 2:30 p.m., the delegates went in a body to inspect the North German Lloyd liner "Kronprinz Wilhelm II."

The State association was organized in 1891, and from a handful of members it is now one of the most powerful organizations in New Jersey, having locals in every prominent city.

Hundreds of delegates were present at the opening session and there was considerable enthusiasm over the reports of the secretary and treasurer, showing the progress made during the past year. Jersey City was chosen for next year.

Naval Architects and Marine Engineers

The summer convention of the Society of Naval Architects and Marine Engineers will be held at Detroit, June 24, 25 and 26. Registration will be at the Hotel Ponchartrain, and the professional sessions will be held in the rooms of the Employers' Association, Stevens building.

"Creole's" Turbines to Come Out

Press reports state that the Curtis turbines in the Southern Pacific liner "Creole" are to be taken out and reciprocating engines substituted. It is understood that the Fore River Shipbuilding Company is preparing a statement for publication regarding the "Creole's" turbines, and those of the scout cruiser "Salem."

Personal

J. R. Bibbins has resigned as publicity engineer for the Westinghouse Machine Company, to become associated with B. J. Arnold, director of appraisers of the Public Service Commission, of New York.

J. N. Oswald, formerly of Buffalo and at present connected with the Nagle Corliss Engine Company, of Erie, has been elected a director and appointed manager of the Rapid River Light Power and Transit Company, with plant at Rapid City, S. D., but with offices at Washington, Penn. He will leave for the West the middle of June and would like to get into communication with those supplying material for hydroelectric plants.

Business Items

The Ball & Wood Company, Elizabethport, N. J., has just issued a 22-page booklet, 6x9 inches, describing and illustrating the Rateau-Smoot turbo-generator outfits about which so much has been published in recent issues of Power. The booklet, which is handsomely printed and illustrated, describes these turbines and generators in detail and may be had on application.

The Macbeth Iron Company, of Cleveland, engineers, founders and machinists, builder of blowing engines, etc., and the Bruce-Meriam-Abbott Company, also of Cleveland, builder of gas engines, were consolidated on June 1, the name of the new company being the Bruce-Macbeth Engine Company. Both of the above companies have been long established in Cleveland, and their amalgamation makes one of the largest and strongest companies of its kind. The Macbeth Iron Company dates from the year 1870, having been known until late years as Macbeth & Company; The Meriam-Abbott Company, predecessor of the Bruce-Meriam-Abbott Company, was organized in 1890, and has been one of the pioneers in the manufacture of the commercial gas engine and its development to the present standard of perfection. It is the purpose of the Bruce-Macbeth Engine Company to continue the business of both of the former companies on a much larger scale than before. The manufacture and development of the gas engine will be continued and the former line of work of the Macbeth Iron Company, building of blowing engines and general machine and foundry work, will be conducted as heretofore. It is the intention of the new company to concentrate the two present plants at the former plant of the Macbeth Iron Company, on Center street, northwest Cleveland. Alterations to the present buildings will be made and several new buildings will be erected to accommodate the enlarged business, and the combined equipment of the two companies in one plant will make a very complete and modern shop. The officers of the company are as follows: President, W. C. Bruce; vice-president, C. W. Kelly; secretary and treasurer, C. J. Snow; manager, C. E. Curtiss. The above, with A. D. Macbeth, J. B. Meriam and F. A. Abbott, constitute the board of directors. Mr. Bruce, president, was formerly president of the Bruce-Meriam-Abbott Company; Messrs. Kelly, Snow and Curtiss retain the same positions formerly held in the Macbeth Iron Company.

Help Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

SELLING ENGINEER wanted for steam condensers. Schutte & Koerting Co., Philadelphia, Pa.

WANTED—Thoroughly competent steam specialty salesman; one that can sell high-grade goods. Address "M. M. Co.," Power.

AN ENGINEER in each town to sell the best rocking grate for steam boilers. Write Martin Grate Co., 281 Dearborn St., Chicago.

EXPERIENCED steam engineers to sell Detroit tilting steam traps to users. Address, stating experience, American Blower Company, Detroit, Mich.

Situations Wanted

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

WANTED—Position as stationary engineer. Am proficient; twenty years' practice with Buckeye, Brown and Corliss engines; have own tools and indicators; a thorough pipefitter and good repairer; temperate and industrious. Am N. A. S. E. man in good standing. Box 61, Power.

POSITION as constructing or chief engineer, or superintendent of building or buildings; New Jersey preferred. Best of references as to character and ability. Box 60, Power.

YOUNG MAN, age 25, desires position as engineer in charge of office or loft building. A. H. Perna, 422 6th Ave., New York.

POSITION—Single man, eight years' experience, steam-electric plants as chief and assistant. Good references, speak Spanish, prefer Mexico, Hawaii or Spanish country. Employed steam turbo-electric plant in Mexico. Address "R," Box 184, Seneca, Kans.

Miscellaneous

Advertisements under this head are inserted for 25 cents per line. About six words make a line.

WANTED—From 500 to 1500 horsepower of B. & W. water tube boilers in units of 250 horsepower each. Must be in A-1 condition. Inquire of J. F. Cargill, Room 1630, Frick Building, Pittsburg, Pa.

PATENTS secured promptly in the United States and foreign countries. Pamphlet of instructions sent free upon request. C. L. Parker, Ex-examiner, U. S. Patent Office, McGill Bldg., Washington, D. C.

WANTED—Any concern having a small Corliss engine, say, from 75 to 125 horsepower, that anticipates taking this engine out for a larger unit within the next few months, may

Sioux Falls Hydroelectric Development

Vertical Spiral Case Turbines Designed for a 70-foot Head Installed in a Plant Arranged to Take Care of Extremely High Flood Water

BY SIMPSON RICE

The development of the Sioux Falls Light and Power Company, Sioux Falls, S. D., comprising an installation of single-runner vertical-shaft turbines in plate-steel spiral castings, direct-connected to alternating-current generators, is of considerable engineering interest on account of the provisions made to take care of occasional extremely high flood water, also from the point of view of the arrangement and construction of the power house and because of the use of spiral, instead of cylindrical-case turbines, as has hitherto been customary for developments of this character. The plant as a whole represents an excellent example of modern design.

The power house is located on the Big Sioux river about a mile from the center of the city of Sioux Falls, S. D. The river rises in the northeastern part of the State, about 100 miles from the plant, flows in a general southeasterly direction to a point a few miles below Sioux Falls, where it makes a wide semicircular turn eastward, and runs to the north through the city. From its source to the dam at Sioux Falls, the river drains an area of about 1100 square miles and has an average flow of about 1000 cubic feet per second, with a minimum in freezing weather of only 120 cubic feet per second.

Special Features

The principal condition determining the design and arrangement of the power station and its location was that of the extremely high flood water which occasionally obtains at this point. For this reason it was considered inadvisable to place the power house below the old dam at the Coughran reservoir, Fig. 1, where a plant had been carried away by a flood some years before. Several hundred feet above the old dam there is a high rock bank which provides good protection, and at this point the site for the new building was chosen. It was decided that the generators and other electrical apparatus should be placed above the highest flood level (elevation 37), and, in order to do this, vertical turbines had to be adopted, since the difference in elevation between the lowest tail water and flood level is about 33 feet, which exceeds the practical draft head. The selection of vertical direct-connected turbines enabled the foundations to be built so high that they are never completely submerged.

FIG. 2. EXTERIOR OF POWER HOUSE

The location of the station within a mile of the city's center was a prominent factor in reducing the initial investment, as well as the operation and maintenance costs, by eliminating the necessity of step-up and step-down transformers and an expensive distributing system. The design had further to provide for close commercial regulation and large temporary overloads, due to the character of the service, which consists partly of lighting and partly of street railway and power load. The street railway service imposes severe conditions on account of the comparatively small number of cars and consequent sudden changes of load from minimum to maximum, or vice versa. That the design of this plant and the apparatus installed have successfully fulfilled the conditions is demonstrated by the fact that the generating units and auxiliaries have been in continuous and successful operation since first taking load.

FIG. 1. HYDROELECTRIC DEVELOPMENT AT SIOUX FALLS, S. D.

Turbines

There are in this plant three 850-boiler-horsepower, single vertical Allis-Chalmers, type FVF turbines in plate-steel spiral casings, designed for operating under a normal head of 70 feet and at 300 revolutions per minute. The present head is 60 feet, which will be increased to 70 feet by the installation of longer draft tubes. As has already been stated, these turbines were built with spiral instead of cylindrical casings. The better efficiencies to be obtained from the former constituted the chief factor in determining their adoption in this plant, as they represent the most efficient and modern arrangement for medium-head developments of this character. These machines, which are indicated in Fig. 3, are of the reaction type, direct-connected to revolving-field generators, the weight of the rotating parts being carried on thrust bearings.

The turbine gates are of the swivel pattern, operated through regulating shafts and connections. The advantage claimed for swivel gates over cylinder gates for this type of turbine are as follows:

Swivel gates give good efficiency with small, as well as with large gate openings, while the efficiency of cylinder gates is low except in wide open positions, due to excessive hydraulic disturbances.

With the use of swivel gates, the increase or decrease in power resulting from opening or closing the gates occurs uniformly throughout the stroke from wide-open to closed position, which char-

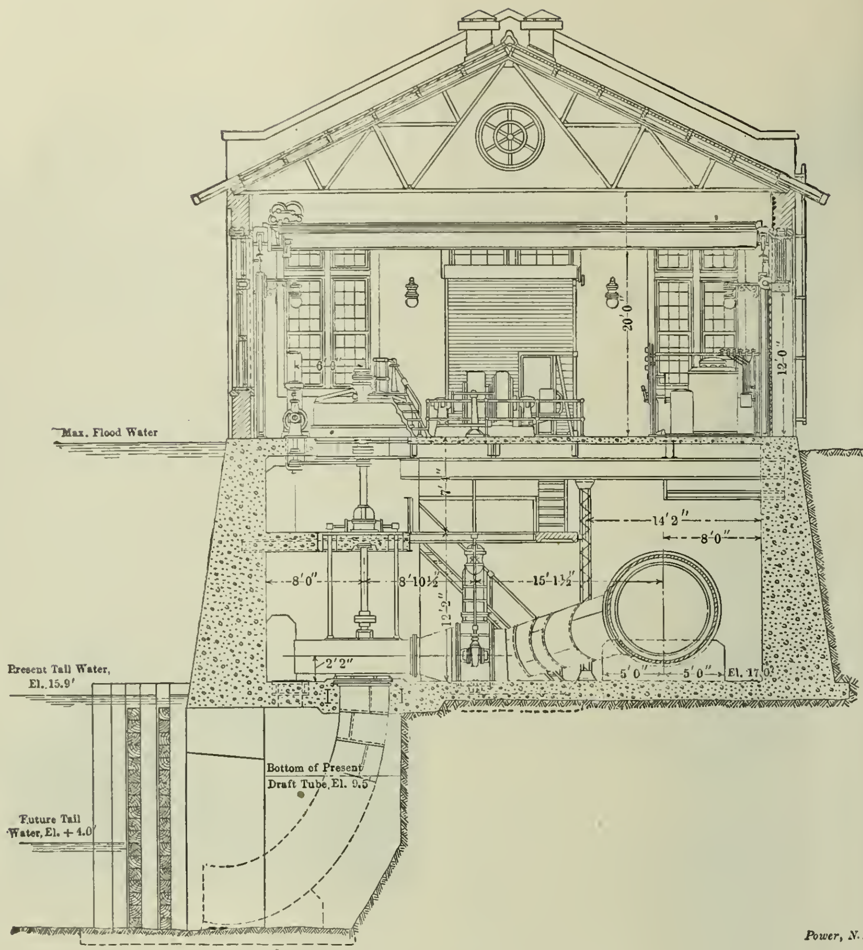

FIG. 3. END ELEVATION THROUGH PLANT

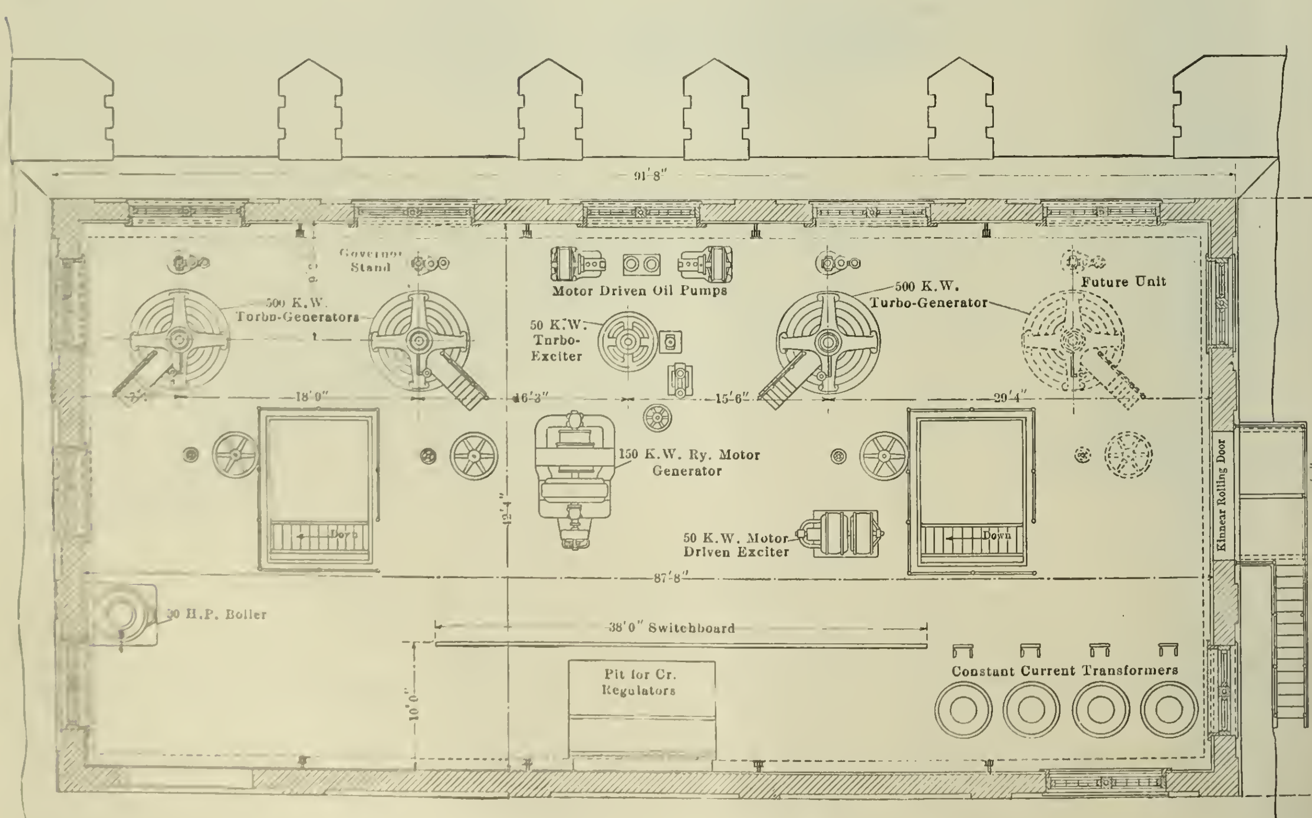

FIG. 5. PLAN OF GENERATOR ROOM

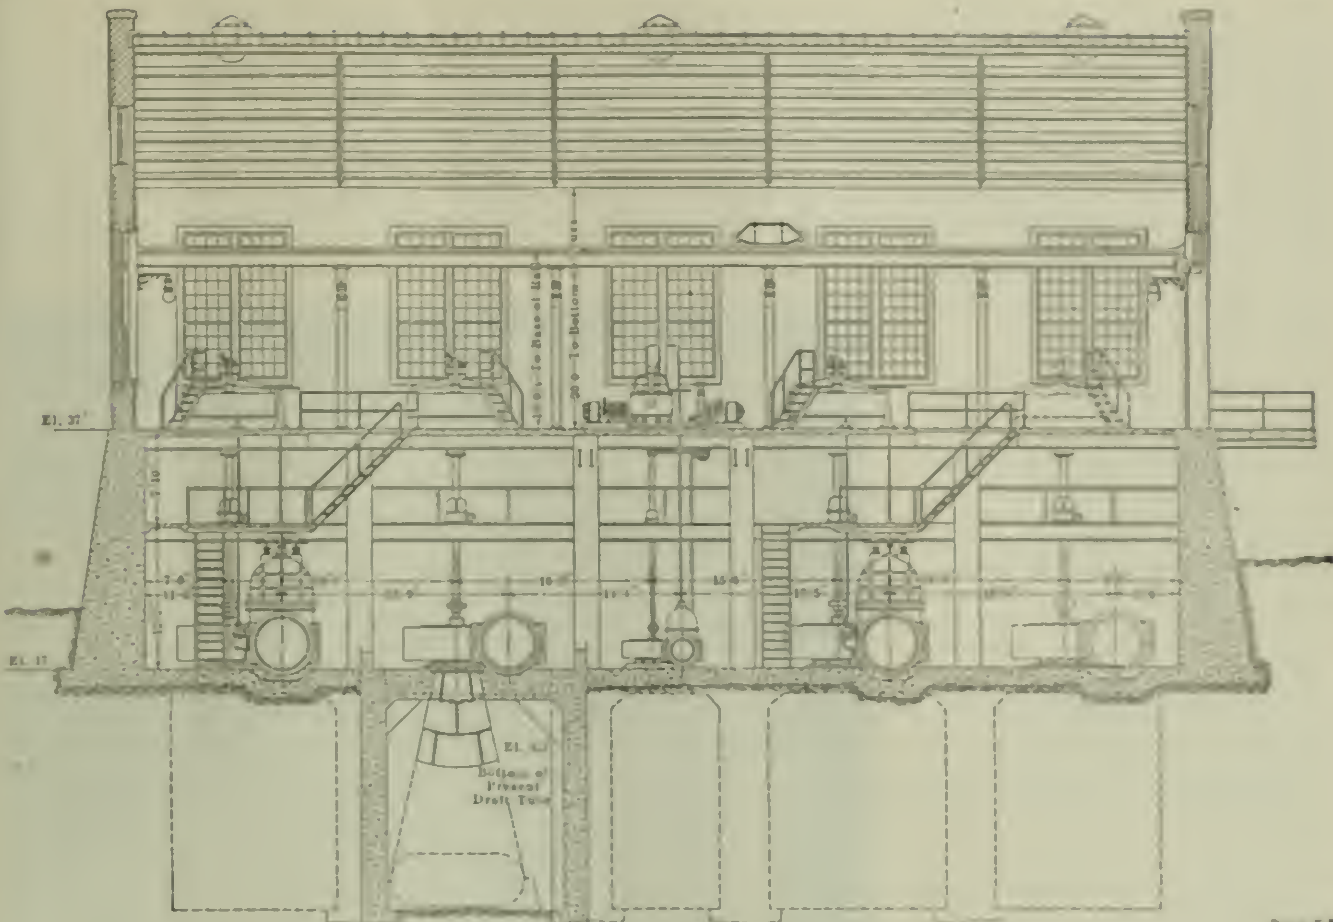

FIG. 4. SIDE ELEVATION OF POWER PLANT

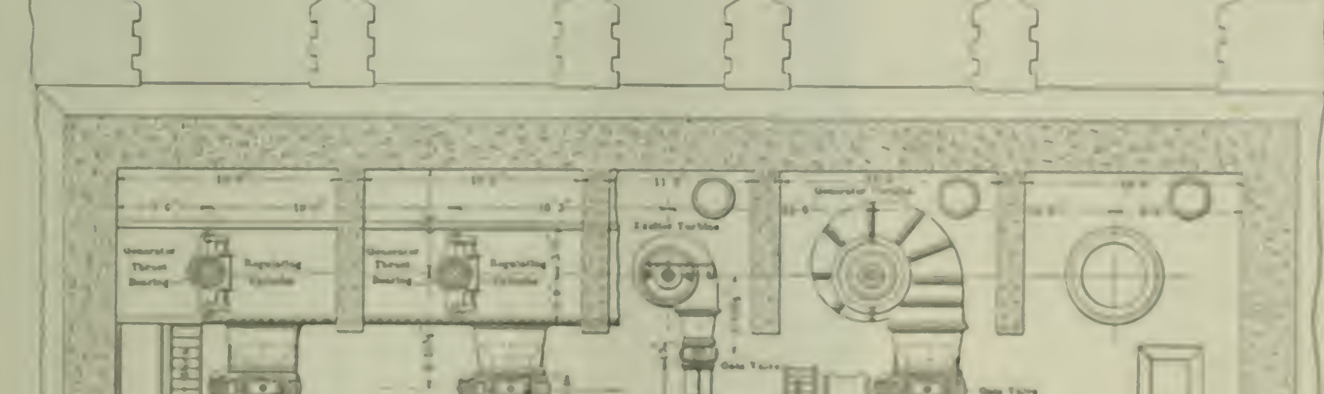

FIG. 5. PLAN OF TURBINE FLOOR

acteristic is necessary for uniformly sensitive regulation from no load to full load. With the cylinder type, a considerable closing of the gates from wide-open position is necessary before any reduction in power is effected. Moreover, at every small gate opening (required for friction load) the friction, eddies, etc., of the water are so great, as it passes through the gates, that no power whatever is developed in the wheel. This, of course, results in poor regulation at full gate and friction load gate opening.

The runners are constructed with cast-iron hubs and discharge flanges into which plate-steel buckets are cast. The efficiencies at 72, 70, 66, 62, 60 and 55-foot heads, were guaranteed as shown by the curves in Fig. 9. The characteristics of these runners enable normal speed to be maintained under a reduction of normal head with but slight loss in efficiency, thus making them particularly desirable for variable head developments. The speed rings made of cast iron are designed gradually to bring the velocity of the water in the casing to that attained in the guide vanes. The plate-steel casings are stiffened by means of angle irons, as shown in Fig. 7. They are built on the speed ring in the form of an evolutionary spiral.

Governors of the oil-pressure type were supplied with the turbines. This governor, which was described in detail, both as to construction and operation, in Power and The Engineer for September 15, 1908, consists of three distinct elements; namely, a source of energy, a means of applying the energy, and a device to regulate the time element during application of the energy.

The source of energy consists of a duplicate central-pressure oil system, as shown in Fig. 8. Each pumping unit is self-contained. The base supporting the pressure tank is of cast iron and contains a receiving tank in which a rotary oil pump of large capacity is driven continuously by a geared motor, and discharges into the pressure tank. It is of ample capacity to operate all the governors in the station, so that one pumping unit may be held in reserve.

The oil pressure from the pressure tank is transmitted to a regulating cylinder containing a piston, which is connected through a piston rod and short link direct to the regulating shaft. The oil acting on either side of the piston, as required, causes the piston to move forward or back, thus operating the gates in accordance with the changes in load.

Regulation of energy is performed by the governor proper, which is driven from the turbine shaft by means of a horizontal belt. The governor consists of a stand upon which are mounted the flyballs, floating lever, compensating dashpot, synchronizing attachment and relay device. The type of governor head used is an extremely sensitive, but absolutely static apparatus. The location of these governors is shown in Fig. 8.

Fig. 12 is a reproduction of a typical chart taken from the recording voltmeter, which shows the regulation effected by the governors in this station. During the period covered by this chart violent fluctuations of load, caused by operations of the street railway, were of constant occurrence.

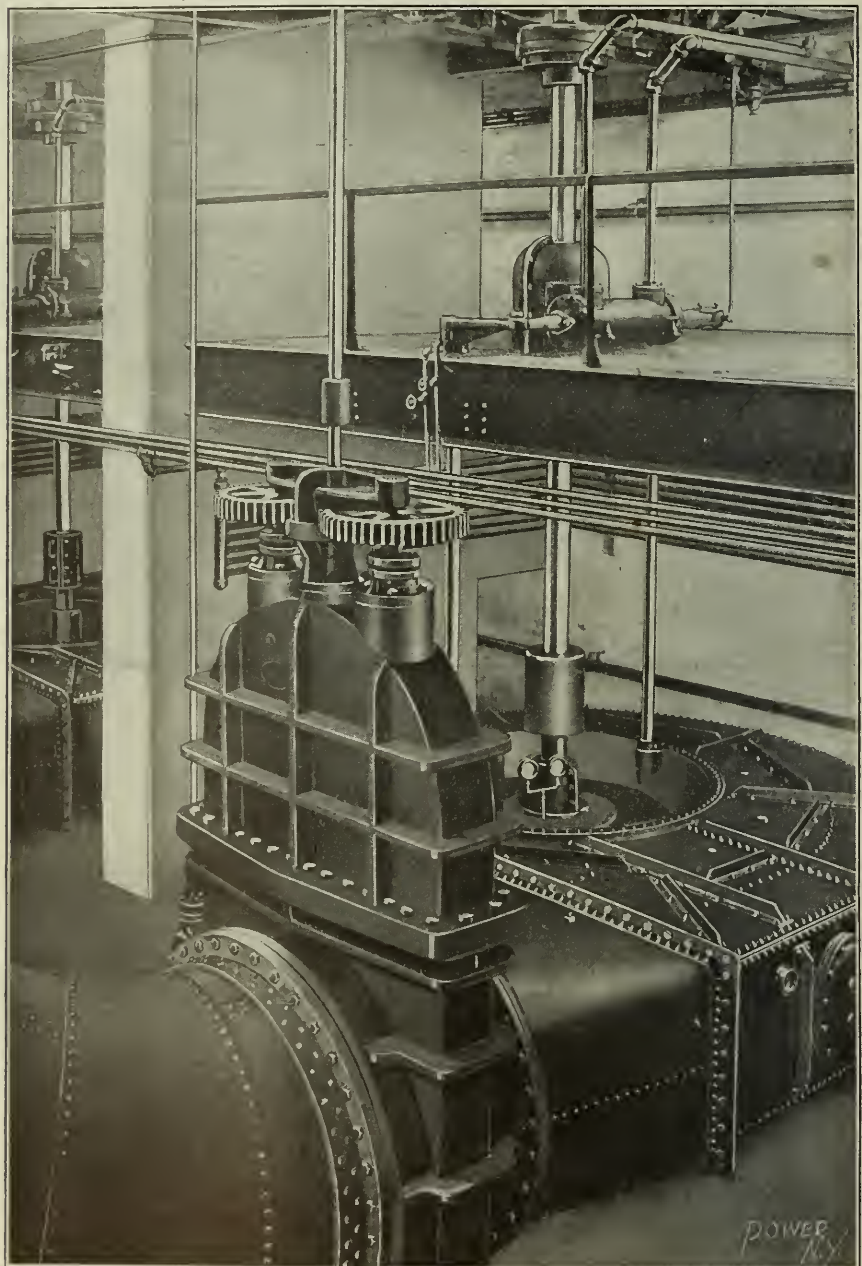

FIG. 7. ONE OF THE 850-HORSEPOWER TURBINES

At present the turbines are furnished with short steel draft tubes indicated in the power-house elevations, Figs. 3 and 4. These draft tubes are to be extended as shown by the dotted lines, and will lead the water from the turbines and discharge it at nearly the velocity of the tail race. This arrangement will effect an increase of over 10 feet in effective head, as well as a material increase in efficiency.

Thrust bearings of the oil-bath, self-contained type are furnished. A view of the outside casing, located on the thrust-bearing floor, with the regulating cylinder, is shown in Fig. 7. Self-oiling babbitted steady bearings of heavy construction are placed on top of the turbine crown plates and another babbitted steady bearing is carried on the bedplates supporting the thrust bearings. The generator shafts, which are coupled to the turbine shafts above the thrust bearings, are also supplied with two steady bearings, one of which is carried by the generator stator at the upper end of the shaft, and the other by a spider supported from the generator base ring.

Exciter Turbine and Governor

The exciter turbine is of the same general design and construction as the main turbines. It is designed for 100 boiler horsepower at 600 revolutions per minute and 60-foot head. The governor of the exciter unit is the standard Allis-Chalmers oil pressure type, Size 1. The principle of operation of this governor is identical with that of the main turbine governors, Size 2, with the exception that the compensating dashpot is omitted, as the variations in load on the exciter turbine do volt, revolving field Allis-Chalmers generators operating at a speed of 300 revolutions per minute. The general construction of these generators is similar to that of the same builder's standard waterwheel type. The stator of each generator is built with laminated armature cores mounted in a cast-iron yoke which rests on a heavy cast-iron base ring bolted to the reinforced concrete floor, as shown in Figs. 3 and 11. The spider carrying the upper steady bearing and brush holders is bolted to the top of the yoke, and the is proposed to install at some future time.

The second exciter unit is a 50-kilowatt, 125-volt, compound-wound, direct-current generator, direct-connected to a three-phase, 60-cycle induction motor of sufficient capacity to take care of the maximum load of the former. This unit is to be used to excite the main generators in case it is desired to use it in place of the turbine-driven unit.

The switchboard is of natural slate about 38 feet in length mounted upon

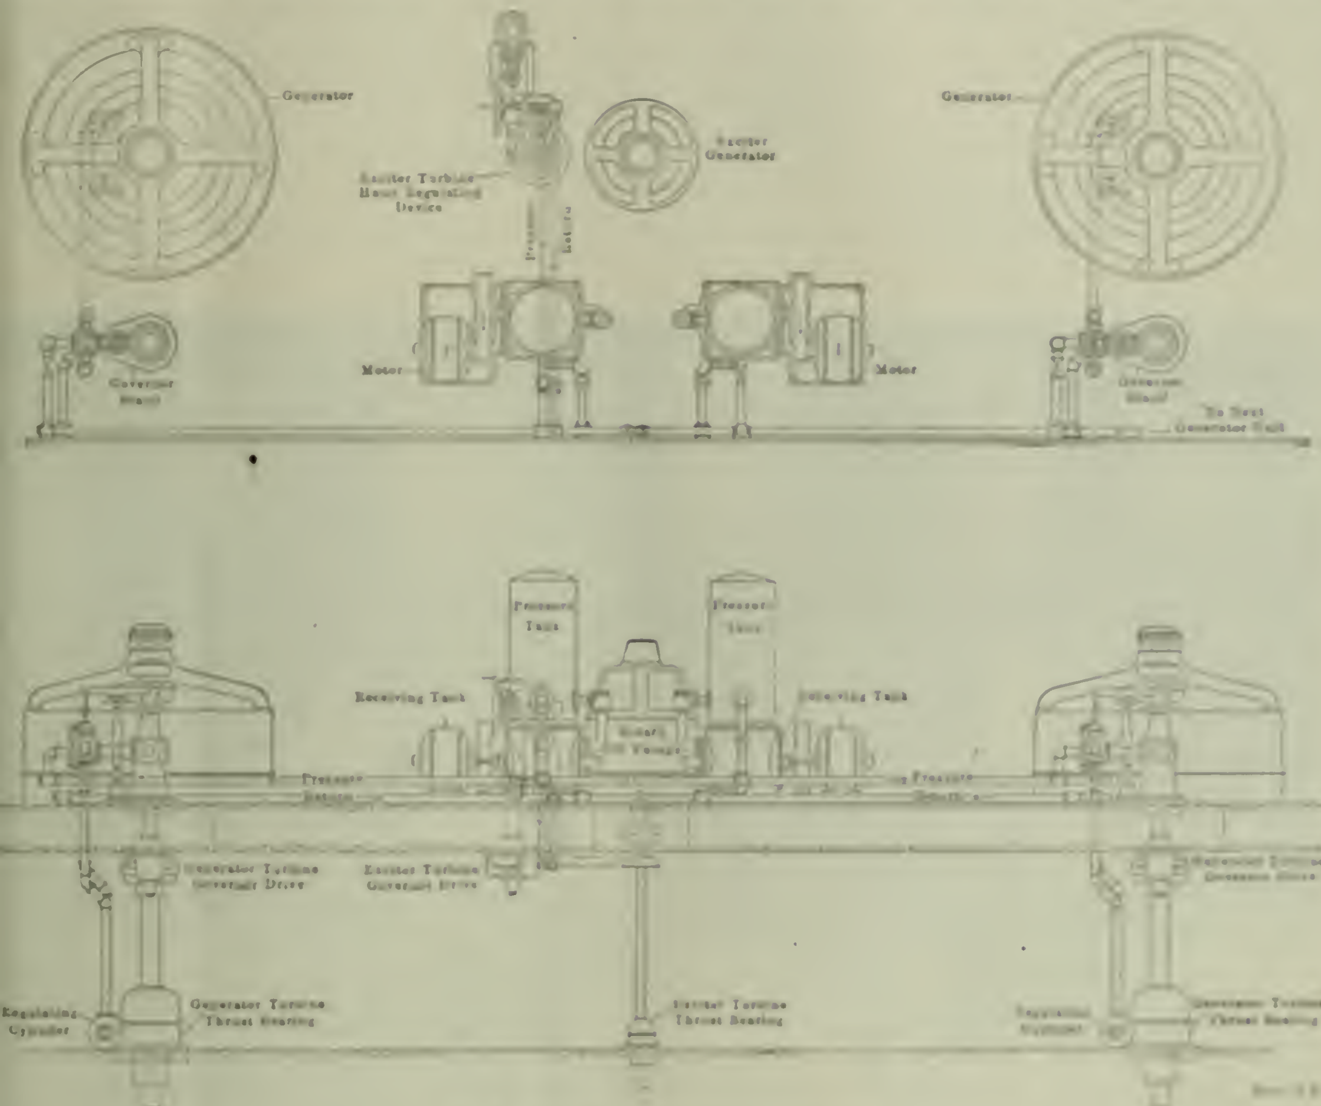

FIG. 8. DIAGRAM OF GOVERNOR CONNECTIONS

not require this auxiliary device. The construction of this governor differs from the main turbine governors in that the governor stand and regulating cylinder are in one piece, making these two elements self-contained. The efficiencies guaranteed with the exciter turbine are shown by the curves in Fig. 12.

Electrical Apparatus

There are three 500-kilowatt alternating-current, three-phase, 60-cycle, 2300- spider carrying the lower steady bearing is supported from the generator base ring. The rotating field has laminated poles, mounted on the spiders which are keyed on the shaft.

For excitation there are two units. One is a 50-kilowatt, 125-volt, compound-wound, direct-current vertical generator, direct-connected to the exciter turbine previously described. This generator is of ample capacity to furnish the necessary exciting current for the three main generators and a fourth generator which it pipe supports 3 feet from the wall. It is composed of: One swinging-bracket synchronism indicator, one double exciter panel, one induction-motor and regulator panel, three alternating-current generator panels, one blank generator panel, two three-phase feeder panels, one blank feeder panel, three 125-volt single-phase feeder panels, one three-phase synchronous motor panel, one blank motor panel, one exciter generator panel, one 125-volt lighting feeder panel, one blank feeder panel and one power feeder panel. The general construction may be seen in Fig. 11. Back of the switchboard is a pit for the regulators. On the walls are lightning arresters for single-phase lines and for three-phase regulators.

Additional installations consist of a 150-kilowatt motor-generator railway set, the synchronous motor being wound for three-phase, 60-cycle, 2300-volt and the generator for 500- to 550-volt direct current; also a motor-generator set consisting of a 2300-volt, three-phase, 60-cycle, alternating-current induction motor, direct-connected to a 50-kilowatt, 500- to 550-volt direct-current generator. Both units are placed on the generator floor.

General Construction and Development

A brief summary of several points of engineering interest in connection with the general development of this water power may be of interest. These can be more readily understood by reference to the plan of the general layout, Fig. 1, and to the drawings and photographs showing the station and apparatus. The substructure of the power house is of reinforced concrete, including walls, foundations and basement. The station foundations are built high enough so that the top will be above the highest flood-water level. The dimensions of the building are 92x46 by 55 feet high, including the basement. The superstructure is composed of red jasper stone quarried in that vicinity, and presents an unusually handsome appearance. The upper floor of concrete is supported by steel beams resting upon steel columns and concrete piers, and carries the three main generators, exciter generator, governors, motor-generator sets, oil-pressure system, switchboard, rotary converters and other electrical apparatus. The gate-valve stands, bypass-valve stands and a small boiler for heating purposes, together with radiators, are also on this floor. The portion of the floor carrying the generators is supported by thick concrete walls forming partitions separating the turbines. See Figs. 6 and 7. A crane loaded on steel pilasters, supported by the station walls, runs the length of the power house, and light is furnished by incandescent lamps. The building is entered on this floor by two rolling doors of steel construction.

Space was allowed in the design of the building for the installation of another main unit at some future time of the same size as the three now installed. Two flights of stairs lead down to the

intermediate floor which carries the thrust bearings and regulating cylinders. This floor is of concrete carried on steel I-beams supported by the concrete piers, which also support the generators on the floor above. A view of the floor may be obtained in Figs. 4 and 7. The basement

designed for slow movement of the water to avoid ice difficulties. All water passing through the racks into the penstock is compelled to flow under an arch so that ice will be intercepted. This method of preventing the ice from entering the penstock has proven exceedingly satisfactory

along the penstock, provision has been made to allow for contraction and expansion due to varying temperature. This is done by means of three plate-steel expansion joints. It has been found that the movement of the penstock due to expansion and contraction amounts to several inches.

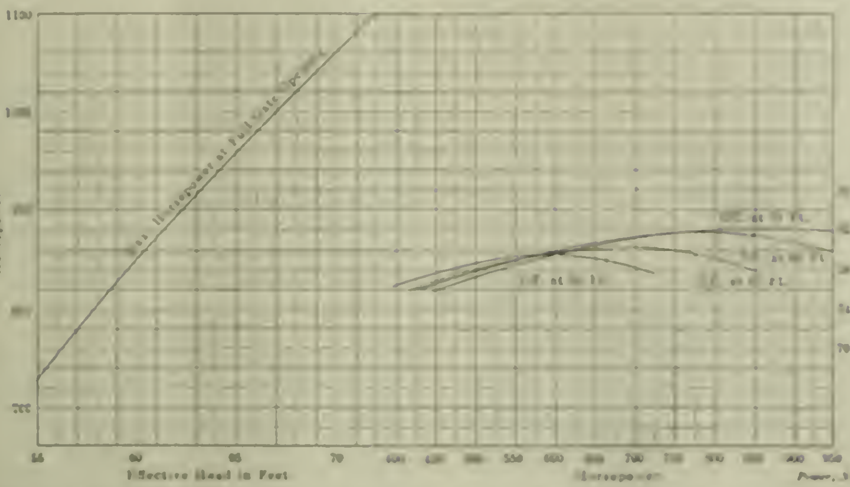

FIG. 10. POWER CURVE AND EFFICIENCY GUARANTEES OF MAIN TURBINE AT DIFFERENT HEADS

The Sioux Falls Light and Power Company was organized in 1903 for the purpose of furnishing power to the Sioux Falls Street Railway Company and other consumers, also to supply current for lighting the city and vicinity. The company commenced operations in 1905. The design and construction of the entire development was executed by the H. M. Byllesby Company, consulting engineers, of Chicago, under the direction of its chief engineer, O. E. Osthoff, and F. Y. Low, who was in entire charge of the construction work at Sandpoint.

The officials of the Sioux Falls Light and Power Company are: E. W. Congleton, president; W. G. Haley, vice-president; George B. Caldwell, treasurer; F. H. Reed, secretary; Arthur Huntington, general superintendent, and C. P. Frost, chief engineer.

floor carries the turbines, penstocks and gates. The penstock is supported on concrete piers resting upon the floor, and has a branch connection to the gate valve of each turbine, Fig. 3. That part of the basement floor supporting the turbine and discharge casing is reinforced by heavy I-beams. Provision is made for installing long draft tubes, as previously mentioned, which will extend down in long radius ells and will be supported by piers on bed rock. Ways are built just outside the foundations in the tail race for stop logs, with a space between for filling with sand bags, etc., so that the draft tube pits may be unwatered for examination when desired.

The dam and retaining walls were built of concrete and are located as shown in Fig. 1. The length of the dam at the crest is 250.4 feet, with a spillway extending the entire length. Its width at the crest is 6 feet and the depth varies from 5 to 8 feet, with a maximum width at the base of 18 feet. The base rests on bed rock. Provision is made for flashboards which increase the height of the dam 30 inches. By the construction of the dam and of about 2000 feet of retaining wall on both sides of the river, the water has been backed up forming a forebay with an area of 10 acres at the low-water line and 20 acres at the high-water line, thus providing a water storage of about 150 acre-feet. This, in addition to a reservoir of 30 acres formed by another dam farther up the river, gives this development ample storage facilities for handling peak loads.

Five sluice gates, 4x7 feet, are built into the dam at its northeastern end at the entrance to the intake. The intake was

in operation. Head gates are placed at the entrance to the intake forebay, so that the ice which is intercepted can be spilled. Two racks, each 12x21 feet, with 1-inch spacing, are built into the intake.

From the forebay the water is carried to the power house through 680 feet of steel penstock 7 feet in diameter. At the foot of the penstock there is a plate-steel standpipe, shown in the exterior view of the station, 16 feet in diameter and 62 feet high, of sufficient capacity to supply water for sudden fluctuations in

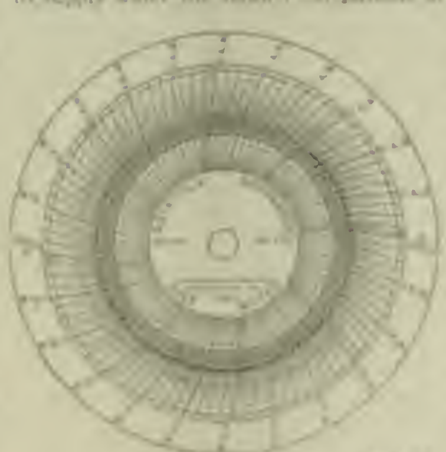

FIG. 12. TYPICAL CHART FROM RECORDING INDICATOR

the load without excessive pressure variations in the pipe line. During the operation of the plant heavy fluctuations on the street-railway load resulting from snow blockades have caused a maximum difference of water head in the standpipe of only 18 inches. At intervals

Scaling and Corroding Substances and Their Elimination from Water for Boilers*

By J. F. William Greth

The evaporation of water, and of water only, as expressed by the chemist's formula, H_2O, occurs in the generation of steam. Few of the natural water supplies are pure, since the carbonic acid absorbed by water when falling as rain enables it to dissolve certain salts of lime and magnesia. Other substances will be dissolved, depending upon the nature of the rocks, soil, vegetation, sewage and industrial waste with which it has come into contact. Among the substances in solution in waters are the following:

Calcium carbonate (carbonate of lime) which is but slightly soluble in chemically pure water, but when carbonic acid is present is dissolved in the water and forms the bicarbonate of lime, which is soluble. Carbonate of lime alone will not form a hard scale, but when present with other substances which cement it, it is apt to form a hard scale.

Calcium sulphate is also quite common in all natural water supplies, and is responsible for the hardest boiler scale. Further, this salt also acts as a cement, causing a hard scale formation with salts which ordinarily would form only sludge or a soft scale.

Calcium chloride is sometimes found in natural waters, but it is very soluble, and

*Abstract of a copyrighted paper read before the Western Railway Club, May 18, 1909.

in the absence of other scale-forming salts will not form scale unless after great concentration. It, however, can be classed among the corrosive substances found in water, as after concentration in the boiler it may be dissociated, liberating hydrochloric acid.

Calcium nitrate has practically the same characteristics as calcium chloride, but waters containing it are comparatively rare.

Magnesium carbonate is more soluble than calcium carbonate, but is ordinarily found in water as the bicarbonate. Bicarbonate of magnesia has all the characteristics of calcium bicarbonate.

Magnesium sulphate is common in natural waters, in which it is extremely soluble. Alone, it will not form scale, but it is broken up by the lime salts, from which scale is formed.

Magnesium chloride is very objectionable, since it not only forms scale but causes corrosion by liberating hydrochloric acid.

Magnesium nitrate has the same characteristics as magnesium chloride, but it is usually present only in very small quantities.

The sulphates of iron and alumina are present in water supplies contaminated with mine drainage, or the waste from galvanizing plants. These substances, when present, act in the boiler exactly like free sulphuric acid, inasmuch as they are dissociated by heat, the acid being set free and the iron and alumina precipitated as sludge or scale.

The oxides of iron and alumina are usually present in small quantities, and have little bearing on the formation of scale.

Silica is also present in small quantities in nearly all waters. It is a scale-forming substance, but since it is rarely present in large quantities, it is usually ignored.

Free sulphuric acid, like the iron and alumina sulphates, is introduced by drainage from mines and galvanizing plants. In the boiler it immediately attacks the metal, forming the sulphate of iron, which the heat decomposes, the hydrate of iron and free sulphuric acid. This acid, liberated, repeats its action upon the metal, and through an indefinite number of destructive cycles. The acid is nonvolatile, therefore the amount of the acid in the water in the boiler is constantly increased by the quantity introduced with the feed, so that the decomposition of the boiler metal is in direct ratio with the concentration which occurs in the boiler.

Carbonic acid is present in its free state in all natural waters. Its presence in the boiler promotes pitting and corrosion. It is also the acid which holds in solution the carbonates of lime magnesia.

Sodium sulphate, sodium carbonate, sodium chloride and sodium nitrate, are neutral, nonscaling and noncorrosive salts, and are not objectionable unless present in excessive quantities.

Steam generation is a continuous process, fresh feed water being supplied to the boiler as the water evaporated into steam leaves it; since none but volatile impurities pass out with the steam, this results in a continual concentration in the boiler of the impurities introduced with the feed water. The nonvolatile impurities collecting in the boiler, manifest themselves as suspended matter, scale, corrosion, or by an increased density of the boiler water.

Suspended matter may be carried in with the feed, or may be due to the accumulation of those substances that are forced out of solution as a result of either heat or concentration, or by the combined action of both.

Scale formation in the boiler is due to the action of heat, pressure, and concentration on the impurities in solution and suspension in the feed water.

Corrosion of the boiler is due to the introduction of gases and acids, or their formation from some of the impurities in solution in the feed water, by the reactions resulting from heat, pressure and concentration.

The increased density of the boiler water is due to the concentration of the sodium salts and of the scale-forming salts, to the limit of their solubilities.

That scale in the steam boiler is one of the great hindrances to economical and safe operation is beyond question. It is feared by all steam users, and their fear of the expense and danger from it is shown by the large number of manufacturers of boiler compounds, purifiers, cleaning machines, skimmers, filters, etc. Scale can nearly always be attributed to the lime and magnesia salts in solution in the water. The character of the scale depends upon the acids combined with the lime and magnesia; on the type of boiler in use; and on the rate, temperature, and pressure, at which the boiler is operated. For instance, the carbonates of lime and magnesia, when present alone, usually form a soft scale. The presence of calcium sulphate sometimes increases its hardness. A calcium-sulphate scale is generally quite hard.

Following are a few of the items which, from an economic standpoint, make it almost imperative to prevent scale formation, or at least to remove it periodically:

The reduced evaporation due to the insulating effect of the scale on the heating surfaces of the boiler.

The cost of labor required for cleaning the boiler and auxiliaries.

The cost of repairs to boilers, necessitated by their being subjected to overheating on account of the heating surfaces being scaled.

The loss of efficiency and earning power of improved furnaces and stokers installed to increase evaporation, which correspondingly increases the concentration of impurities, thus forming a greater deposit of scale, and hence a greater reduction in the efficiency and in the life of the boiler.

The cost of tube-cleaning machines, or of so-called "compounds" introduced into the boiler to prevent the adherence of the scale-forming matter to the shells and tubes.

The loss due to the investment in spare boilers to be put into commission when it is necessary to take boilers out of service for cleaning or repairing.

The waste of fuel due to heat lost in cooling a boiler for cleaning or repairing, and that required again to bring it into service.

The loss due to reduced efficiency of boiler auxiliaries, from lower temperatures of the feed water, especially in the feed-water heaters and economizers, thus materially increasing fuel consumption.

Corrosion

Corrosion is the most dangerous of the various troubles due to impure feed water, and the one in many cases the most difficult to overcome. It is usually due to the acids introduced into the boiler in the feed water, or those formed as a result of reaction between various substances in solution, caused by heat, pressure and concentration; in some cases it is due to the oxygen of dissolved air. The different acids cause different kinds of corrosion, and it occurs in different parts of the boiler, depending upon the nature of the acid.

The action of corrosive acids and salts on the boiler make operation dangerous and add to the expense, as follows:

The danger of rupture or explosion due to weakening of the parts.

The repairs made necessary by corrosion.

The necessity of spare boilers to replace those out of service for repairs.

The heat wasted in cooling boilers to make repairs and the fuel required to bring them into service again.

The expense for boiler compounds to prevent corrosion.

The author then goes on to consider the different methods for preventing and removing scale, as by hand scrapers, chisels, etc., mechanical cleaners, boiler compounds, feed-water heaters and purifiers, both live and exhaust steam, with and without the use of chemicals, and the surface blowoff; and he concludes with an argument in favor of purifying and softening the feed water before it is put into the boiler.

"Social Engineering," by Dr. W. H. Tolman, director of the Museum of Safety and Sanitation, is being translated into French under direction of Vuibert & Nony, publishers, of Paris.

The Standard Oil Company has completed the pumping stations and pipe lines necessary to pump crude oil from the Kansas and Oklahoma oil fields to the Atlantic seaboard, 1500 miles.

Connecting Up Transformers for Synchronizing and Phasing Lamps

By F. J. Foote

The transformers used with incandescent lamps for synchronizing or phasing alternators may be of any capacity down to about 100 watts, the small switchboard transformers being often used for this purpose. The high-tension winding of the transformers must, of course, be suitable to stand the operating voltage; the low-tension winding is preferably arranged to give 50 or 100 volts, so that not more than two lamps will be required in each set.

With transformers there are two methods of connection possible. The method indicated in Fig. 1 is shown on account of its similarity to the direct method described in the previous article.* The primary windings of the transformers are connected directly across the open switches. By properly checking out the connections in a way similar to that to be explained in connection with Fig. 2, one can get good results. The method represented in Fig. 2, however, is the one most frequently used because it is more convenient of application and involves less liability to make errors. The primary windings of the transformers are connected, not across the open switches, as in the first method, but across the "line" or the two leads of a phase. One transformer is connected to the leads above the switches and the others to the leads below the switches, on each phase. The two secondary windings of each pair of transformers are connected together through enough lamps to withstand the maximum voltage of the two secondary windings in series. With this arrangement the lamps will alternate in brightness and darkness just as in the direct method.

It will be seen from Fig. 2 that the primary windings of the transformers are always energized at normal voltage. The lamps will therefore be bright or dark according to the method of connecting the secondary windings. In other words, it is possible to have the lamps either bright or dark at the instant when the phases are in step. There is some difference of opinion as to which is the better of these two methods. I prefer to have the lamps dark when the phases are in step, largely for the reason that with the direct method only dark lamps can be used. In the following discussion it is assumed that the lamps are to be dark when the phases are in step.

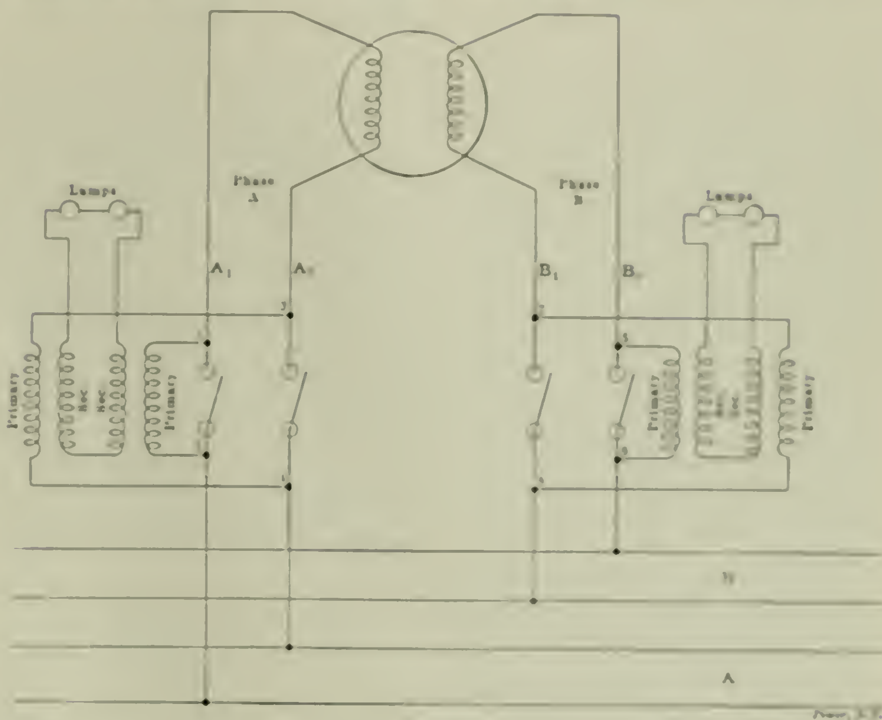

FIG. 1

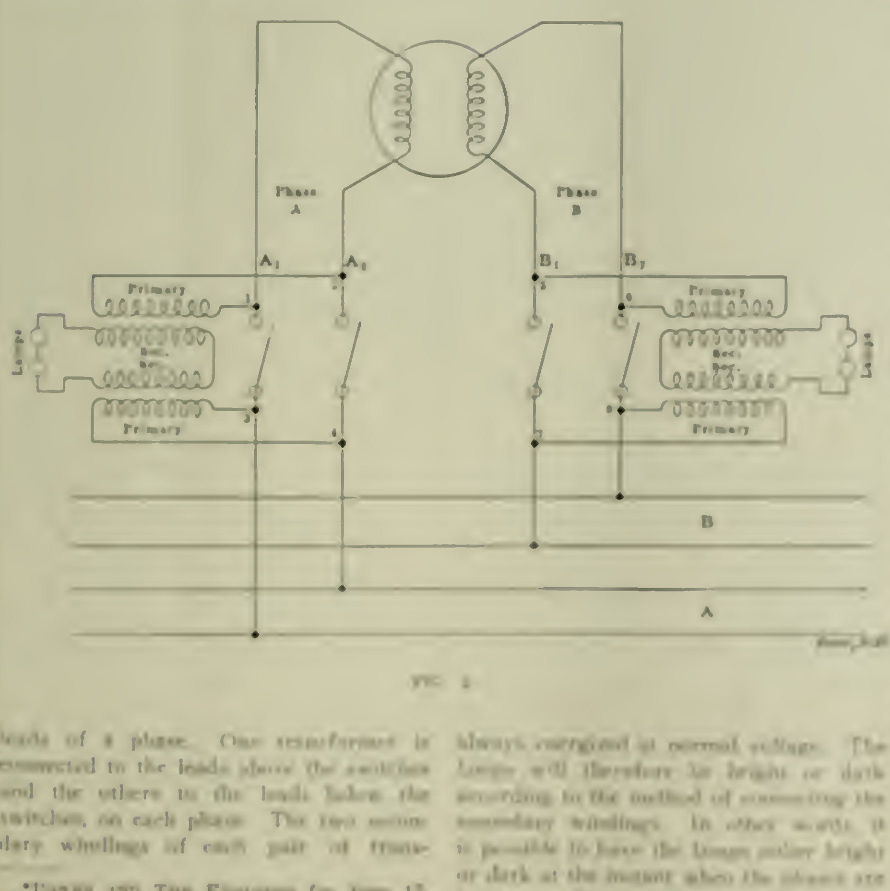

FIG. 2

The one vital point in this method, and the one on which its success or failure in large measure depends, is that of checking out or proving the connections, for one cannot depend on the leads from transformers always coming out of the case the same way. This matter is very simple. All that is required is to connect the primary windings of both transformers of a set in the same circuit and adjust the secondary connections of one of them. For instance, in Fig. 2 one could disconnect the lower transformer primary leads 3 and 4 and connect them to the points 1 and 2. Care should be taken to connect each lead to the other side of the same switch that it was originally connected to; that is, 3 to 1, and 4 to 2. Since both primaries are connected across the same source of current, the secondary relations are necessarily the same as the primary relations, and if the lamps do not show dark under this condition, it is only necessary to reverse the leads of one secondary winding; then the lamps must show dark. When the primary leads are put back in their original position, as in Fig. 2, the checking out is complete for phase A.

Phase B must, of course, be checked out in the same manner, after which the lamps will indicate exactly the same as though they were connected on the direct method.

*Power and The Engineer for June 15, page 1014.

Design and Operation of Cooling Towers*

Comparison of Relative Merits of Natural- and Forced-draft Types; Conditions Which Shauld Determine the Kind to be Selected

BY M. R. BUMP

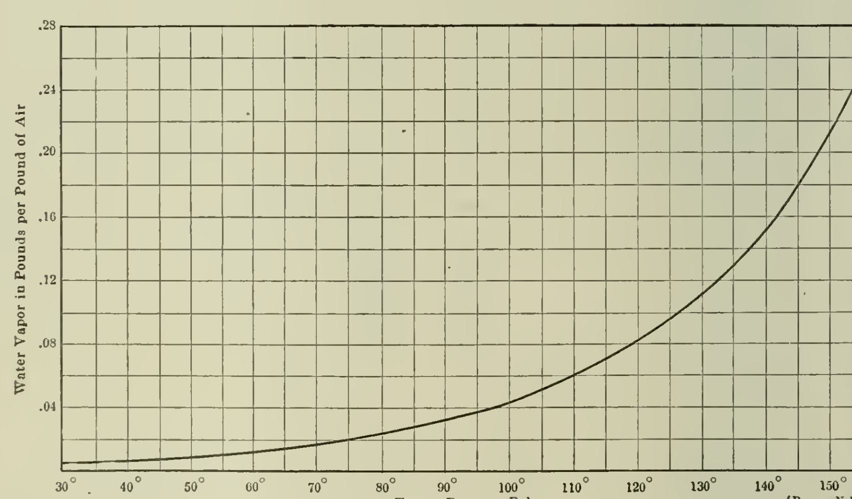
The design and operation of cooling towers is a matter so closely associated with the design and operation of condensers that the combination of condenser and tower must be considered as a single unit and the same general principles applied as noted above. In localities where a supply of condensing water is not obtainable, recourse must be had to the use of cooling towers. The general principles of the tower are in a measure a reverse proposition from those embodied in the condenser. The problem becomes one of dissipating to the atmosphere the greatest possible amount of heat from each pound of water with a minimum expense for fixed and operating charges.

Cooling towers are classified in two general classes, namely, forced-draft and natural-draft towers, the distinction being in the method of circulating the air in the towers. The comparison of the relative merits of the two types is one that involves the consideration of climatic conditions, of ground space, of the cost per unit of surface as compared with the cost of fans plus the operation of fans and of the adaptability of towers of varying capacities to the condenser.

The climatic conditions, namely, temperature and humidity, are of greatest importance in cooling-tower design, and on this account each installation must be treated as a separate problem, and there can be no standard sizes for towers of varying capacities that would be generally applicable to all locations. The greater portion of the heat extracted in a cooling tower goes to supply the latent heat of vaporization of enough water vapor to saturate the air leaving the tower. The balance goes directly to heat the air passing through the tower. During winter months the proportion of the heat that goes to heat the air is much greater than in the summer months and may exceed the amount of heat that is dissipated in supplying the latent heat of vaporization. Taking as an example an air temperature of 82 degrees Fahrenheit and supposing the air to be saturated (raining) at that temperature, and that the air is heated to 92 degrees Fahrenheit in the tower and leaves the tower saturated at that temperature, the heat extracted by each pound of air would be as follows:

To heat the air 10 degrees Fahrenheit would require 2.375 B.t.u. The saturated air at 92 degrees will contain 0.03289 pound of water vapor and at 82 degrees it contained 0.02361, the balance of 0.00928 pound having been accumulated in passing through the tower. The heat required to evaporate one pound of water from and at 90 degrees is 1051 B.t.u., and the heat extracted in evaporating 0.00928 pound of water would be approximately 9.75 B.t.u. Therefore, each pound of water leaving the tower at 92 degrees would carry away 2.375 + 9.75, or 12.125 B.t.u., and the work done by the evaporation would represent about 80 per cent. of the total. If the air entering the cooling tower was not saturated it would be able to pick up a still greater quantity of water and the proportion of heat extraction evaporating would be still greater. In this connection it is interesting to note that where the air entering the tower is comparatively dry it is possible to cool the water below the temperature of the air, and this effect has been noted in several tests on a natural-draft tower in Denver. The effect is, of course, produced by the heat extracted from the water to supply water vapor partly or completely to saturate the air, and this effect will continue even if the water is considerably colder than the air.

Attention should be directed to the accompanying saturation curve for air at 29.92 inches barometric pressure. The very rapid rise in the amount of water vapor required to saturate the air as the temperature increases indicates the greater opportunity for extraction of heat at the higher temperature and it becomes desirable to heat the air leaving the tower as high as possible. This in turn requires that the temperature of the water leaving the condenser and entering the tower be raised as nearly as possible to the temperature of the exhaust steam. For a given range in temperature in the tower it is readily seen that the warm air has a much greater effect, and the reduction of the temperature of the water to or below that of the entering air is more easily accomplished than when it is cold. One pound of saturated air heated from 90 degrees Fahrenheit and discharged as saturated air at 100 degrees Fahrenheit will extract approximately as much heat as one pound of air raised from 0 degree to 40 degrees Fahrenheit and saturated when leaving at that temperature.



AIR-SATURATION CURVE; BAROMETER, 29.92 INCHES

Localities possessing a dry climate are best suited for the use of cooling towers, and it is exceptional to find the temperature of the air very high before or during a rain storm. On the other hand, moist climates do not as a rule have as high temperatures during the summer months. For average conditions a tower can usually be figured safely upon a basis of maximum temperature of 90 degrees Fahrenheit during a rain storm when the air is saturated. On days when the temperature

*Read before the National Electric Light Association convention, Atlantic City, N. J., June 1, 2, 3 and 4, 1909.

is in excess of 90 degrees Fahrenheit the humidity will be considerably below saturation, as a rule, and the capacity of the tower will equal that for the conditions named. Basing estimates upon the air supply as stated, the problem becomes one of determining the amount of surface required.

The amount of heat to be extracted from the water can be accurately estimated by the steam consumption of the unit and the quality of the steam entering the condenser. The temperature and humidity records should then be considered as outlined above and the steam economy of the unit at various vacua compared to note the effects of periods of hot weather and the economical reduction of vacuum that can be allowed rather than to go to the increased expense for larger condensers and towers.

Allowing that the water leaves the condenser at a certain temperature and enters at a certain lower temperature, the quantity of water required is determined. In making these figures it will be seen that the widest possible range in temperature of the water should be secured. Then in cooling this amount of water in the cooling tower the amount of surface required must be calculated. This is one of the most indefinite points in cooling-tower design and is the most important one. The rate of transfer of heat from water to air, either direct or through a diaphragm, varies through rather wide limits. With increased circulation of the air the rate increases, but the exact ratio of increase is not definitely established. The effect upon the absorption of water to saturate the air is undoubtedly greatly increased by rapid circulation of the air. On the other hand, if the air is forced through the tower too rapidly it does not become fully saturated and therefore the quantity of air required is greatly increased. In the ordinary natural-draft tower the greatest care must be used to get full benefit of all the air passing through the tower, while in forced-draft towers there is always more or less water carried away mechanically and the water leaving the tower is seldom saturated, indicating that more air is being used than would be necessary in a properly designed tower.

The rate of transfer of heat from water to air through a metal diaphragm is about 2.5 B.t.u. per square foot per degree per hour. If the outer surface is kept wet the heat transfer is materially increased, and if, in addition, the air is circulated rapidly the rate of transfer can be increased to several times the figure named. In the cooling tower the heat is transferred directly from water to air and the amount of surface depends quite largely upon the rate of circulation of the air, and no definite figures were obtainable upon the transfer in forced-draft towers. By calculating this coefficient upon a natural-draft tower in Lincoln, Neb., a heat transfer of 6 to 8 B.t.u. per square foot per degree per hour was shown upon a series of tests. Using 7 B.t.u. as a basis it is seen that the surface required to produce very high vacua during hot weather would be enormous. Taking the temperature of steam at 28-inch vacuum at 102 degrees Fahrenheit and allowing 5 degrees differential between steam and discharge water, would make the temperature of the water entering the tower 97 degrees Fahrenheit. If the air were up to 90 degrees Fahrenheit in temperature, this would allow a maximum working range of only 7 degrees and the surface required would be 22 square feet per pound of steam condensed per hour. For a differential of 10 degrees the surface required would be 15 square feet, for 20 degrees 7.5 square feet, and for 30 degrees 5 square feet per pound of steam condensed per hour. In each of these cases the vacuum would be reduced and at the 30 degrees differential it would be 26 inches.

In the case of the forced-draft tower the size of fan and power required for its operation would decrease in about the same ratio as the decrease in surface noted above by allowing larger differential temperatures and obtaining correspondingly smaller vacua. In either case the fixed and operating charges on condenser and cooling tower must be balanced against the cost of extra fuel, and the like, required when the vacuum is reduced in order to determine the most economical installation.

Various materials have been used for wet surface in cooling towers. Rough boards have been successfully used, but they take up a great deal of room, and the cost per square foot of surface is high when compared with other materials. Wood blocks, tile, and the like, have been used largely in forced-draft towers, and the results are satisfactory except as to first cost. The use of curtains made of galvanized-wire screens has been tried, but the first cost is high and the screens are not entirely satisfactory in distributing the water. A number of tests have been made with burlap curtains, and the results thus far have been above expectations. The burlap is very cheap and is easily made into curtains. These curtains are comparatively light and easily suspended in the towers. The only difficulty has been to secure a long-fibered burlap so that a portion of the threads will not wash out and enter the piping system. Some of these curtains are now three years old, and the expense for renewal will be nominal. Several suggestions have been made as to tarring or painting the curtains as a preservative, but the cost and value of these treatments are doubtful.

In the design of forced-draft towers, the following conditions must be considered: (1) The tower should be laid out with great care to secure proper distribution of the air and water. (2) The fan capacity should be figured upon a basis of handling saturated air, and the path of the air should be such as to bring the water and air into intimate contact so that the air will leave the tower as nearly saturated as possible. (3) Care must be taken to prevent loss of water by being carried away mechanically with the air leaving the tower. (4) On account of the increased cost of pumping water to high heads, the tower should be as low as possible and the water pumped no higher than absolutely necessary. (5) In laying out the water-distributing system care must be used to reduce the friction head to a minimum.

In combustion work it has been found that in forcing or pulling air through a fuel bed the induced draft which pulls the air through is much preferable to forced draft for securing proper distribution of the air. The distribution of the air in the fuel bed is much more uniform, and especially in gas producers a more distinct advantage is gained in the suction-type producer. More fuel can be burned per square foot of grate surface and with less excessive clinker than with forced draft. The same general principles apply to air distribution in cooling towers, and it is the author's opinion that much more uniform and satisfactory results can be obtained by placing the fan at the top of the tower and drawing the air through the tower. On account of the moisture present it would be necessary to protect the fan blades from rust by galvanizing or frequent painting. The results from combustion work would indicate at least 20 per cent. improvement and would reduce the amount of air required and the power consumed by the fans materially.

In the design of natural-draft towers, the principles are very similar. These towers should be set in as open a location as possible so that full advantage can be taken of winds to aid the draft created in the towers. Where set in open spaces it is advisable to have the sides, or at least a portion of each side, equipped with removable doors so the air openings can be changed to suit the direction of the wind. In the tower the greatest freedom of air movement is necessary, and the design of the water-distributing system must be made with a view of leaving as much free air space as possible. The passage of the air through the tower will create a certain amount of draft caused by the heating of the air and the absorption of water vapor, which further reduces the density and increases the stack effect. The tower can be designed to create a draft sufficient for all the air required, but it is usually desirable to use the added advantage of the winds wherever possible in assisting the air circulation. In spacing the curtains in the tower it is necessary to place them close enough together to get the full benefit of all the air passing; but, as pointed out, the distributing troughs must be laid out to allow as free air travel as possible. If the amount of water flowing down the curtains is too great it will create a counter-effect to the draft and will retard circulation of air in the tower.

An important feature of the tower is to house the air openings properly, to prevent loss of water during high wind storms. If no loss of water occurs, the amount of condensation, if the jet condenser is used, will be more than sufficient to supply the water evaporated in the tower. If a surface condenser is used, the makeup water required in the tower should not exceed and will ordinarily be somewhat less than the amount of water supplied to the boilers. Where a jet condenser is used, the cold-water supply to the boilers can be passed into the tower pit and condenser inlet and the water for boiler supply drawn from the hot water leaving the condenser.

In the design of the water-distribution system, the friction head must be kept down as much as possible when proper distribution of the water is maintained. It is very essential that the water be distributed evenly over all of the curtains or wetted surface, and this as a rule necessitates some experimenting on the tower in order to reach all the curtain with an equal supply of water. An effective means of accomplishing the result is to distribute the water from two or more troughs. The water discharged from the pipe at two or more points in each trough will maintain practically uniform level in the troughs. The discharge from the main troughs should be through vertical slotted openings in the sides, so that the quantity discharged to each curtain will vary as the head of water in the troughs without creating any friction head. The individual troughs supplying each curtain should be made as narrow as possible in order to leave ample space between troughs for air openings. These troughs should discharge through slotted openings, similar to the main troughs, against a metal strip or vane which acts as the hanger for the curtains and on which the water is uniformly distributed across the full width of the curtain.

Cooling ponds with jets scattered through the pond and discharging into the air above the pond are used to some extent. The amount of power required for pumping the water is large, and the first cost, unless the pond is already in existence, is prohibitive. On very still days the capacity is limited, as wind is depended upon for air circulation. On days when the wind is brisk the loss of water carried off mechanically is excessive and the amount of make-up water is consequently increased.

Some very interesting experiments have been made on a combination of condenser and cooling tower in which the steam discharged from the unit enters coils of pipe or chambers over which water is sprayed and air rapidly circulated. This plan has shown some promising results. The amount of water required in the condenser is practically the same as the amount condensed. This plan could possibly be made feasible for small units, but for large units it could not be applied. Fair vacua were obtained on certain tests of this outfit at the Virginia Agricultural college.

The extension of this plan along the lines of the radiator of automobiles leads to a very interesting problem, which merits some study for applications to small units.

The majority of the larger installations in this country are forced-draft towers, while European practice seems to be toward using natural-draft towers wherever ground space permits. With plenty of ground space available the natural-draft tower should receive most careful consideration, and the application of a natural-draft tower to a condenser that will discharge the water practically at the temperature of the steam makes a very desirable combination for the average installation.

Piping Oil from the Pacific to the Atlantic

On December 15, 1906, the waters of the Pacific ocean, for the first time in history, mingled with the waters of the Atlantic ocean, across the Isthmus of Panama. It was not, however, through the great canal, but through the oil pipe line of the Union Oil Company, of California, which was being tested with sea water, under a pressure of 800 pounds, before being put into service. The installation of this line opened the Eastern market for the first time to California oil and gave it opportunity to compete with the product of the great oil combination.

The laying of the line and the construction of the pumping stations were in charge of R. W. Fenn, one of the company's engineers. Six months' time was given the company under its concession from the Government. On April 16, the pipe laying was begun, and the line was completed October 16, six months to a day. Jamaican laborers were employed, in gangs of 70 each, divided into sections. First came the "brushers," cutting all the grass and brush, followed by the "stringers," who laid the pipe in line, end to end.

The next division removed the thread protectors and painted the threads with a preparation of oil and graphite. The pipe-laying gang proper consisted of the men who handled the lifting jacks, jack boards and chain tongs for holding the finished line in place, and 20 men on the pipe tongs, 5 men on each of four pairs of extra-heavy long-handled lay tongs. Another section lifted the next joint with pickups, and the pipe steerer lined it up so the thread would enter properly, while the joint was twirled by the friction of a length of rope passed around it several times and drawn back and forth until the pipe would enter no farther in the collar without the aid of the tongs.

The foreman then sat astride the collar and beat time with his hammer, while the tongsmen "broke out"—two tongs up and two down, with the precision of a military drill.

It is hard to realize the difficulties which presented themselves during the work, which was begun during the rainy season. The Panama Railroad was double-tracking its line and canal construction was going on everywhere. Steam shovels were at work, tracks were being shifted and plans were being changed all the time. There is no wagon road across the isthmus and it was necessary to dodge the heavy dirt-train traffic continually.—*Bulletin American Republics.*

Old and New Water Power Companies

Clemens Herschel, writing of the old water-power companies which sold mill sites and furnished water power at an annual rental, says:

"At the present day, companies of precisely the nature described are no longer being organized. Indeed, the time has come when, in certain cases, it would be materially profitable to convert such companies, and they should be converted, into the modern form of power company which distributes power on wires instead of distributing water through canals, as was the old-time method. The large areas of land hitherto occupied by the canals could then be sold or used for other purposes, the proceeds of such sales possibly paying for the whole improvement, while much power now wasted by hydraulic losses in long canals and at many power plants would be recovered and all the power to be distributed and used would be generated at and distributed from one central power station."

Aluminium paint is made by blowing air or gas through molten aluminium while it is setting and at the same time stirring violently. This forms a spongy or granulated metal that is easily pulverized. The powdered metal is sized and polished.

In 1907, the United States produced 166,000,000 barrels of oil, and in 1908, according to unofficial estimates, the total was in excess of that amount. The United States produces 63.12 per cent. of the entire oil production of the world.

Economy of Four Valve Engines

By Thomas Hall*

The Dean and Wood report, as presented at the Detroit Meeting, in June, 1908, of the American Society of Mechanical Engineers, has so often been misquoted, misrepresented and misused, sometimes for the purpose of injuring prospective business of builders of four-valve engines, that it seems eminently proper for some comment to be made by builders of this type of engine. There is hardly a comment or statement in the Dean and Wood report that has not been twisted and distorted almost beyond recognition. The argument has even been advanced that builders of four-valve engines must realize that the four-valve proposition is a failure, because they had not in any way defended themselves in print since the issue of this paper.

In answer to such comments, I have to say that in so far as builders of four-valve engines with the Corliss-type cylinder are concerned, no defense was called for. The tests were not made on engines of this construction and the adverse comments were made only with reference to the types of engine tested. We indorse many of the statements made by Dean and Wood and shall endeavor in a brief manner to discuss the comments made by them in so far as they pertain to four-valve construction, presenting them in the light in which we understand them.

The first comment which has been widely quoted reads: "There are several features in these results, as follows: The most important is that the four-valve engines, which were built to be more economical than single-valve engines, have utterly failed in their object."

This comment has been quoted in abstract as applying to all types of four-valve engine, without quoting other sections of the paper forming a part of this comment. Dean and Wood made this statement as applying only to the engines tested, and not to four-valve construction in general.

In further comment on the two four-valve engines tested we quote the paper: "These results show that efforts to realize economy by duplication or multiplication of parts, even if ports are shortened and clearances reduced, accomplish nothing. The duplication of valves used in both four-valve engines simply increases the opportunity for leakage."

This comment, fully discussed, would form a very long article itself. We can only, therefore, refer to it briefly. It is an oft-proved fact that increased wall area does increase cylinder condensation and consequently steam consumption. It has also frequently been proved that increased clearance does increase steam consumption, unless compression is carried well up to the admission pressure. There is very little loss, however, if compression is carried well up to the admission line. Any loss that does occur is largely due to condensation caused by the increased wall area incidental to increased clearance. These principles, we believe, are now well recognized by most steam engineers.

As a check on increased wall-area effect, the writer once used thin sheet steel to make a clock-spring shaped coil, having an area nearly twice that of the wall area of one end of the cylinder, including the piston face and port walls. The cylinder head was moved back to obtain unchanged clearance volume. The engine selected was of the single-acting type, which made it necessary only to make the changes for one end. With this added wall area, the steam consumption was increased nearly 25 per cent.

In economy tests of single-valve engines we have many times reduced the steam consumption nearly a pound where compression was low, by adding exhaust lap and thus carrying the compression higher on the card. Neither of these, however, is anywhere nearly as important a factor as leakage. The Dean and Wood comment makes this fact plain. With some designs, if not in first-class condition, the leakage goes so far toward offsetting better steam distribution and decreased clearance that little gain is effected.

The next comment made by Dean and Wood is as follows: "After considering these tests we do not hesitate to advise builders to abandon four-valve for high-speed engines, unless they are prepared to build a really high-class engine, having four Corliss or gridiron valves made and fitted in the best manner." This sentence has been twisted and made to read that Dean and Wood advise abandoning the building of four-valve engines of every type except drop-cutoff Corliss, which is not at all the real meaning of the Dean and Wood comment. Such engines as the Harrisburg four-valve, the Ball four-valve and the Ridgway four-valve, for example, are of the general design and construction referred to by Dean and Wood as the only types having economy possibilities. Very naturally we agree with Dean and Wood to a large extent in this belief, or we would not be building an engine of this construction. This general type is illustrated by the Ridgway four-valve engine.

Continuing the Dean and Wood comment, it reads: "Even then it would be necessary for them to prove that such steam engines of whatever type should have valves that are not only tight originally, but that should become so by wear, if they are not so originally. The wearing process should be a tightening process."

In this connection we believe that practically all Corliss-type valves tend to tighten, except those which span too wide an arc in covering the ports, as, for example, if ports are placed on opposite sides of the valve, as the valve wears smaller in diameter it cannot wear tight, but will do the reverse. The same thing is true of a valve which spans too large an arc only to a lesser extent. Many Corliss engines, but by no means all, are successful in this respect. The Corliss engine reached good economy because of its excellent steam distribution due to its four valves and drop cutoff, and because of the valves tending to wear tight rather than leaky. The Corliss valve does not have a heavy overtravel; it rests during the heavy pressure period of expansion and moves when the pressures on it are light; consequently, its wear is not as serious as it would otherwise be. In many Corliss engines the valve does not span a wide arc and, therefore, it keeps tight more easily. There are, on the other hand, some Corliss engines that do not by any means wear tight. The pressure on the steam valves is the difference between that in the steam chest and that in the cylinder. It is readily seen, therefore, why there should not be heavy movement of the valve during expansion; this means the overtravel should not be more than that required to make it steam-tight. "The strains, the consequent wear and the resultant length of life of the valves and the valve gearing are very nearly proportional to the overtravel." Some makes of four-valve engine have as much as two inches overtravel, while half an inch is ample for steam-tightness. To get a really good valve motion—one which will cut off the unnecessary overtravel and give sufficient port opening—is the most difficult problem of the four-valve builder. Once this is accomplished the motion is very similar, indeed, to that of the Corliss engine, and is adapted to the higher speeds so desirable for direct-connected service.

While the Dean and Wood report calls attention to the necessity of the valve to tend toward tightening, it is well also to bear in mind that the valves and their seats should be of hard close-grained iron and should be well fitted in such a manner that they will start off to glaze at once without having first to make a proper seat. There is seldom any trouble with the exhaust valves, where the Corliss wristplate movement is used to reduce excessive overtravel. The difference in pressure on the two sides of the exhaust valves is almost as great and in some makes greater during their period of movement than that of the steam valves; as a rule, however, exhaust valves give less trouble than steam valves. There are some makes of four-valve engine which give entirely too much overtravel to the exhaust valves as well as the steam valves. The nearer the travel of both steam and exhaust valves approaches that

*Superintendent, Ridgway Dynamo and Engine Company.

of the Corliss engine and yet eliminates the drop cutoff, the less will be the valve and gearing strains and wear of these parts. There are several four-valve engines on the market in which these strains are very apparent when the engines are running. Leakage by the steam valves and piston is more commonly a source of serious loss of economy than that of the exhaust valves. Leakage is very nearly proportional to the length of the edge times the number of edges past which it can take place. If, however, the valve spans too wide an arc, wear makes leakage even more serious. A four-valve engine is purchased in preference to a single-valve engine solely because of better economy. To insure this a purchaser should examine leakage possibilities and the nearness of the valve movement to that of a Corliss engine. Bear in mind that the drop cutoff gives a very different movement to that of a plain fixed wristplate motion.

Possibly the only expression of doubt regarding the Corliss-type four-valve cylinder contained in the Dean and Wood report is the clause: "Even then it would be necessary for them to prove their case." In this connection we have to say that the mere fact of building a Corliss-type cylinder does not by any means insure *maintained economy*, and while we believe this type of cylinder is the proper channel through which to seek economy, we also believe, with Dean and Wood, that the valves must be properly designed and fitted.

In dealing with the foregoing comment by Dean and Wood, we associate with it a part of their next and last reference to the four-valve class of engine, reading as follows: "From the results we are justified in thinking that most high-speed engines rapidly deteriorate in economy. On the contrary slower-running Corliss or gridiron-valve engines improve in economy for some time and then maintain the economy for many years. It is difficult to see that the speed is the cause of this, and it must depend upon the nature of the valves." While we agree with this statement in the main, we believe that many Corliss engines do not maintain their economy, due to bad valve design and construction. We refer to designs in which the valve spans and is depended upon to maintain tightness over too wide an arc of its seat. Also to rough machining and ports and steam chests with sand scale sticking to their walls, a condition not at all uncommon with some makes of Corliss engine. We firmly believe that four-valve engine builders have given greater attention to these details. We do not believe roughly fitted valves with ports improperly cleaned can ever fit themselves and glaze to a condition possible with a properly fitted valve. This, of course, applies equally to four-valve and Corliss engines. We also believe the steam-valve seats should always be fitted with cages of a closer- and harder-grained iron than that used in the cylinder. Some four-valve engines do rapidly deteriorate in economy and naturally so, because of too great overtravel, resultant heavy strains and wear, and some because of necessary seal over too wide an arc of the valve seat. The higher speed may contribute slightly to greater wear, but the nature of the valve and its motion are the real factors determining deterioration or maintaining economy. The valves of Corliss engines do not as a rule span a wide arc and do not have heavy overtravels and, consequently, do not, in the better makes, where properly fitted, deteriorate rapidly. If the four-valve engine is properly designed and built it will, due to its higher speed, exceed the Corliss engine in economy. Cylinder condensation is considerably reduced by the higher speed.

Economies have been obtained with the simple noncondensing four-valve engine that, as far as the writer is aware, have never been reached under the same steam conditions by any other type of engine. For example, a test conducted by Professor Spangler, of the University of Pennsylvania, on a 16x16 Harrisburg four-valve engine, running noncondensing at a speed of 210 revolutions, gave an economy of 22¾ pounds at full load and slightly better at ¾ load, with 125 pounds gage pressure.

A test of a 19x19 of the same make, made by Professor Diederichs, of Cornell, gave 22.77 pounds at full load and slightly better at ¾ load. The steam pressure was about 125 pounds and the speed 205 revolutions, running noncondensing.

We know very little of results obtained from Ball engines, but understand that they have obtained better than 23 pounds noncondensing, with 150 pounds steam pressure. For a tandem noncondensing, 150 pounds steam, they have reached 18½ pounds.

A test of a 19x18 Ridgway four-valve engine, at 200 revolutions and 100 pounds steam pressure, gave results as follows:

Load.				
¼	½	¾	Full	1¼
30.7	24.4	23.2	23.8	25.4

Tests made by this company of this engine gave for its best result at 130 pounds pressure, 21.6 pounds; at 115 pounds pressure, 22.6 pounds; at 85 pounds pressure, 24.3 pounds.

Three later engines of the same size tested by this company gave results at 100 pounds steam pressure, 200 revolutions, as follows:

	Load.		
	½	¾	Full
Engine No. 2306	25.25	22.8	22.7
Engine No. 2307	24.9	23.46	22.65
Engine No. 2308	24.59	22.3	21.9

Engine No. 2308 was tested at 130 pounds steam pressure and gave 20.17 pounds per indicated horsepower per hour. Engines 2306, 2307 and 2308 were not in any way especially fitted up to secure economy but simply built according to our standard practice. The results given herewith on these three engines are those of the first and only tests made on them. The uniformity of the tests from all three engines we believe to be unusual.

The results of tests cited as sample cases, of Harrisburg, Ball and Ridgway, we believe were obtained by men whose integrity, as far as I know, is unquestioned. If better results have been obtained from any other type of engine under like conditions with equal evidence of truth, we will be glad to know of them. There are many four-valve engines of good design which have been in service from six to eight years, with valves in fine condition and practically tight.

To repeat, we believe maintained economy in this type of engine is dependent upon reduction of unnecessary overtravel, properly fitted valves, valves which do not span a wide arc, close approach of the movement of the valves to that of a Corliss engine and good materials.

The foregoing article was referred to F. W. Dean for criticism. His reply follows:

By F. W. Dean

Referring to the foregoing, I wish to state, in order that the matter may be clearly understood, that the paper on the subject of the tests was written by me and then shown to Mr. Wood for criticism. Mr. Wood approved of the paper in a general way, except that he considered that my conclusions were rather broader than the results of the tests warranted. Perhaps he is right in this, but I decided after considering the matter that I would let the paper stand as written.

It often happens in matters of this kind that conclusions are of doubtful meaning, but my general opinion of the matter of the four-valve engines tested was that they were of the kind that are not likely to give economical results; but it is also my opinion that four-valve engines can be designed that will give economical results and which will continue to be economical for very many years. The understanding of my view as stated in the foregoing article is correct. In one place I recommended the abandonment of four-valve engines unless engines having four Corliss valves or four gridiron valves should be built. It now appears that there are three makes of engine of this class which seem to fulfil every requirement for permanent economy.

In one of my comments I stated that it would be necessary for the makers of high-class four-valve engines to prove their case. The reason for this statement was that there were very few tests made up to the time of writing the paper and I was not in possession of data which showed what such engines could do. The results of tests quoted in the foregoing article, however, show without any doubt that engines of this class can give unusual economy for simple noncondensing engines. My opinion is that if people really desire economy with simple noncondensing engines it would be desirable to buy engines of this class. Wherever the exhaust steam can be used this is of little or no importance.

A Reciprocating Engine Enthusiast

By F. L. Johnson

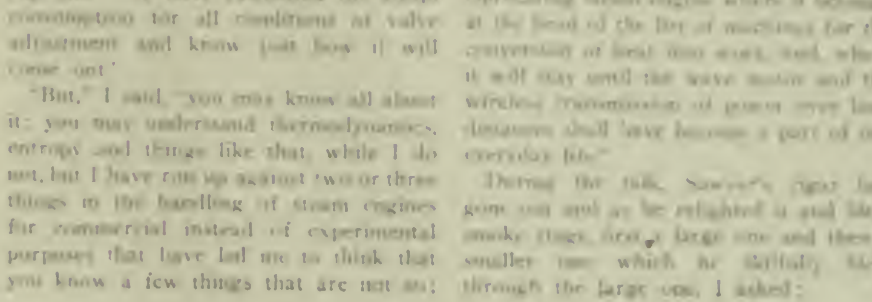
The engineer who is always down on his luck had just left me, after making a "touch" that showed that for once at least luck was with him "momentarially," as the overhead guarantees say. I sat thinking about him and his kind and wondering how an inspector could be influenced or convinced that a man who took such poor care of himself could be trusted with the care of boilers and engines. His address card (minus the address), covered with thumb marks and the emblems of a half dozen engineers and fraternal societies, coupled with the talismanic letters, "M. E.," would lead one to think that such a man, if really in good standing in so many organizations, and if even tolerably clean, would always have work, and never be found jobless and moneyless on Manhattan island. His was perhaps a common if [illegible] predicament. His wages had been reduced by his employer, who was losing money. Without stopping to consider that while looking for a new situation a poorly filled pay envelop is almost infinitely better than no envelop, he left, and with his last dollar bought a ticket for the city and helped to swell the ranks of the great army of unemployed engineers.

As he went out Sawyer came in and seated himself, and looking quizzically in my direction, said:

"I passed your friend in the hall, but I saw him first and gave him no opportunity to notice me. I have known him by sight a great many years as a man of wide experience in losing situations. Somehow he always seemed to strike a perishable job, or if not naturally so, he soon made it one. I never really understood until today how such helpless and incapable men got along in the world, but I see it plainly enough now. There are a whole lot of easy ones like you, who have been moderately successful, and who more or less patiently attend to periodical holdups and thus help to keep them going.

"But I wanted to see you about something else. Some time ago you published some indicator diagrams that I gave you along with some remarks about the necessity for compression and effect on the coal pile. Since that time I have had talks with three professors of mechanical engineering in different parts of the country, who have complete mechanical laboratories under their supervision, and I have asked all of them to try an engine with a fixed load, such as could be furnished by the use of a water rheostat, with different conditions of steam distribution (I called it steam distribution instead of valve setting, because I was talking to professors instead of to engineers), and determine if more or less indicated horsepower would be needed with one condition than with another. Well, each and every one was bored and practically said 'There is no need of doing this. We have calculated the steam consumption for all conditions of valve adjustment and know just how it will come out.'

"'But,' I said, 'you may know all about it; you may understand thermodynamics, entropy and things like that, while I do not, but I have run up against two or three things in the handling of steam engines for commercial instead of experimental purposes that have led me to think that you know a few things that are not so; and I want you to show me. If I have been wrong all these years, I want to know and admit it to all of my friends and take the "joshing" that is due me. I do not care to be the last person in the world to discover that I have been mistaken all the years of my engineering life.'



WHICH DIAGRAM WILL DELIVER THE GREATER AMOUNT OF POWER AT THE RIM OF THE FLYWHEEL?

"I also suggested that this be chosen as a subject for a thesis by some graduating student, but all to no purpose. I got one or two reluctant promises from some of them that an experimental run would be made. Months have passed and I have heard nothing, and I am beginning to think that not one of the professors of mechanical engineering in the country dares to conduct an exhaustive test and publish the results.

"What I am after is this: Here are two diagrams, of equal area and consequently representing equal indicated horsepower, from the same engine. Applying Thompson's rule for finding the steam accounted for by the indicator, I find a slight difference in the amount used per horsepower per hour. But what I want determined by competent, unquestionable expert authority is, which diagram will deliver the greater amount of power at the rim of the flywheel?

"So far as I can discover there has been nothing at all except arguments unsubstantiated by facts, published on this subject and now at a time when the field of the reciprocating engine is being invaded by the gas engine from one side and the turbine from the other, the few who are certain that the engine has not been allowed to do its best want to have some questions settled. With the question of the best steam distribution settled, and after this about a quarter of the extensive experimental work that has been given to the development of the turbine and the gas engine will place the reciprocating steam engine where it belongs, at the head of the list of machines for the conversion of heat into work, and where it will stay until the wave motor and the wireless transmission of power over long distances shall have become a part of our everyday life."

During the talk, Sawyer's cigar had gone out and as he relighted it and blew smoke rings, first a large one and then a smaller one which he skilfully blew through the large one, I asked:

"Why are you so sanguine about the possibilities of the steam engine?"

"Well," he replied, "for a long time designers have been ready to guarantee an indicated horsepower-hour for ten pounds of steam. If they are willing to guarantee this they can deliver a brake horsepower-hour for the same amount, but no man will go to the limit of his ability when making a guarantee. He wants a margin and never promises to give all that he knows he can give. With a horsepower-hour delivered at the rim of the flywheel for ten pounds of steam let into the cylinder, a kilowatt-hour can be delivered at the switchboard at a total cost that the turbine cannot touch."

I was about to tell Sawyer that he appeared to be the most enthusiastic reciprocating-engine advocate that I had met, when a clumsy, worried person, for short, carrying some of the goods on a [illegible] charged right into the office furniture, and in the knocked-off gear that followed my friend remembered another engagement and wended his way to the elevator softly whistling, "Gee! I wish I had a girl!"

Low-Pressure Steam Turbines*

The Rateau-Smoot Compared with the Parsons and Curtis Types
Extreme Accuracy Not Necessary to Reliability and Efficiency

BY C. H. SMOOT

It has now been thoroughly established that the most efficient possible steam engine is a compound unit consisting of a reciprocating engine, acting between boiler pressure and approximately atmospheric pressure, exhausting to a low-pressure turbine, which in turn discharges to the condenser.

Were it not for the fact that high-pressure turbines in large sizes are vastly cheaper than reciprocating engines, it would be a safe prediction that all future plants would include turbines and engines.

It is still a moot question, however, whether the greater cost of combined engine and turbine plant over that for turbine plant alone is authorized by the increased economy.

In any event, however, existing plants equipped with reciprocating engines will show improved economy by running them noncondensing and installing low-pressure turbines.

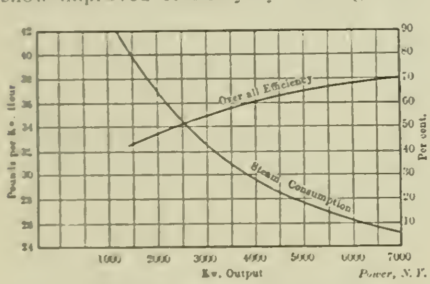


FIG. 1. EFFICIENCY CURVES OF 7000-KILOWATT LOW-PRESSURE TURBO-GENERATOR

It was not until the low-pressure turbine had been commercially developed that engineers fully realized the significance of the fact that the available energy per pound of steam between 150 pounds boiler pressure and 28 inches of vacuum was cut practically in halves by the line of atmospheric pressure.

This fact appears almost like a discovery, because reciprocating engines have heretofore been wholly incapable of utilizing efficiently the energy below the atmospheric line. To obtain the expansion in an engine which can be readily reached in the turbine would require an enormous cylinder, whose friction would consume a large portion of the available energy. The turbine, however, can utilize as effectively the energy between 26 and 28 inches of vacuum as it can utilize the energy between atmospheric pressure and 5 pounds below.

Fig. 1 gives the manufacturers' guaranteed steam consumption curves for a 7000-kilowatt low-pressure Rateau-Smoot turbine at 28.5 inches vacuum with an admission pressure of 16 pounds absolute. At 7000 kilowatts the machine is guaranteed to deliver one kilowatt-hour at the switchboard for 25.7 pounds of steam.

An investigation of the steam consumptions obtained when such a turbine is used to compound high-pressure noncondensing engines will prove of interest. The accompanying table shows the steam consumption, efficiencies, etc., for each of these two units. The figures taken for the steam consumption in both cases are rated very conservatively for machines of large power, the turbine being of 7000 kilowatts capacity and the engines of over 2000 kilowatts each, several of which could be used in conjunction with a single turbine.

	Pounds Steam Pressure Absolute.		Theoretical Steam per Kw.-Hour.	Steam per Kw.-Hour at Switchboa'd.	Combined Efficiency of Engine and Dynamo.	Steam per Indicated H.P.-Hour.
	Admission.	Exhaust.				
Engine	214.7	16	18 lb.	27.7 lb.	65 per cent.	23.4 lb.
Turbine	16	0.75	17.8 lb.	26.6 lb.	67 per cent.	....

Boiler pressure, 200 pounds, no superheat. Vacuum, 28.5 inches on 30-inch barometer.

Steam per kilowatt from combined plant =

$$\frac{1}{\frac{1}{27.7} + \frac{1}{26.6}} = 13\ 6$$

pounds of steam per kilowatt-hour.

The combined mechanical efficiency of heat transformation into electricity represented by these two units working in conjunction is approximately 66 per cent., after allowing for all losses in turbine, engine and dynamo.

This combination of turbine and engine represents the very highest efficiency possible to obtain in any kind of steam engine, since it places to best advantage the reciprocating engine and the turbine, neither one of which can, unaided, accomplish the same result. The figures entering into these calculations are taken conservatively, and it is believed that the rating given to the reciprocating engine of 23.4 pounds per indicated horsepower-hour compound noncondensing is a figure readily obtainable.

Fig. 2 is a logarithmic plot of the available energy in steam for given admission and exhaust pressures. A straight line passing from the pressure at the throttle to the pressure of the exhaust intercepts the central scale at the corresponding quantity of steam per unit of power available in the steam. This figure, divided by the efficiency of the engine, gives the quantity of steam per unit of power developed. The formula from which this plot was made was originally developed by Professor Rateau from the entropy diagram and published in many of his papers on the subject of steam turbines.

The question of the most suitable intermediate pressure for engine exhaust and turbine admission is not so important as it might seem from a cursory consideration. The pressure giving the maximum efficiency for the whole plant is obviously the pressure that allows approximately equal efficiencies of heat transformation into power for engine and for turbine.

In the case of highly inefficient engines, however, such a condition can never be reached, and the intermediate pressure giving a maximum output from the whole plant should be taken as high as the condition under which the engine is working will permit. This latter condition is generally the case in engines working in steel mills doing highly intermittent service, for here, at the very best condition, the efficiency of the engine is always lower than that of the turbine.

The type of engine used in central stations, however, when exhausting in the neighborhood of atmospheric pressure, will show an efficiency practically equal to a low-pressure turbine, consequently very little difference in the plant efficiency will be made if the intermediate pressure is taken anywhere from 3 or 4 pounds below atmosphere to 15 or 20 pounds above. The reason for this wide range in pressure is to be found in the fact that the efficiency curve for both

*Read before the National Electric Light Association convention, Atlantic City, N. J., June 1, 2, 3 and 4, 1909.

engine and turbine has a very flat top within this range, showing but slight rise or fall between either extreme.

Condensing Apparatus

Since low-pressure turbines work efficiently on high vacua, it is well worth while to investigate thoroughly the vacuum of maximum economy, putting on one side the cost of obtaining the vacuum and on the other the economy resulting in the turbine.

With barometric condensers, no real

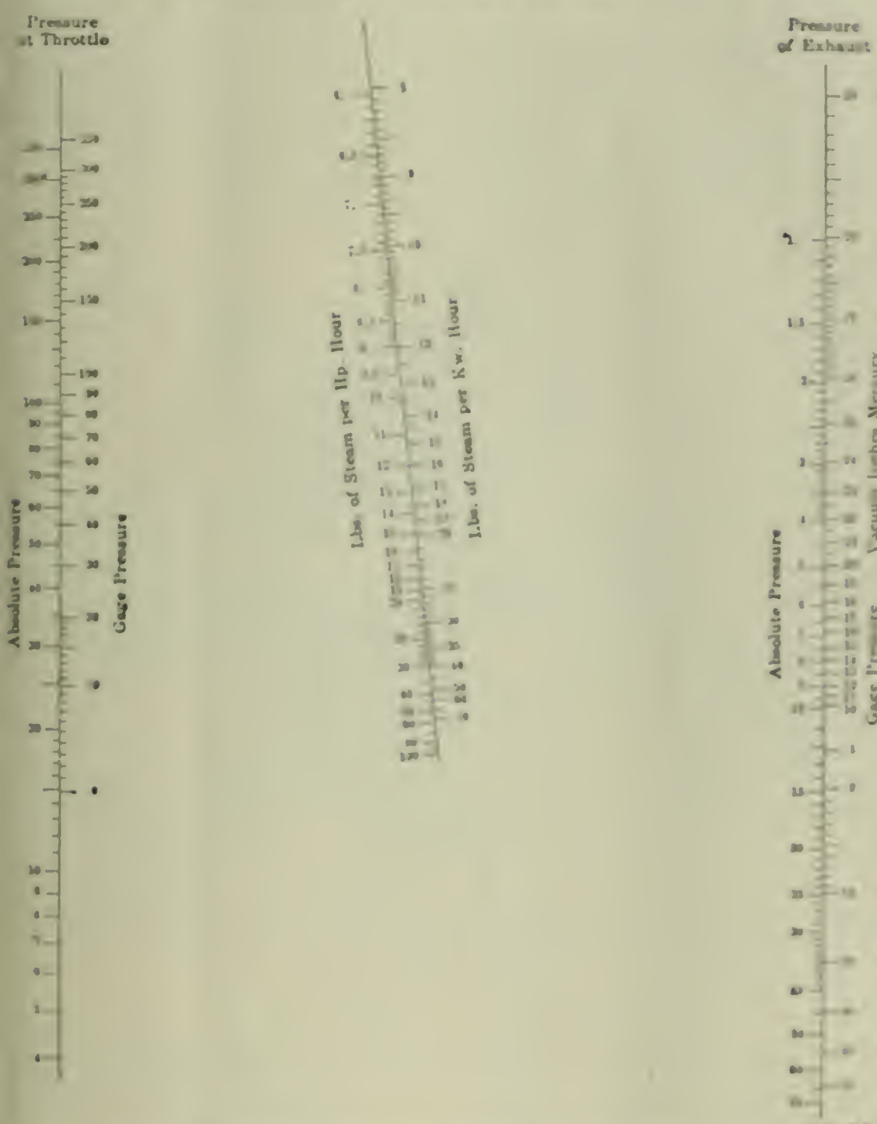

FIG. 2. THEORETICAL STEAM CONSUMPTION OF PERFECT ENGINE

difficulty is encountered in obtaining a vacuum of 28½ inches with water under 70 degrees Fahrenheit, and similar results can be obtained with a surface condenser, provided a large water supply is available which does not require a high lift to reach the condensing vessel.

To obtain a high vacuum with either type of condenser, dry-air pumps are essential.

When working on vacua over 28 inches, because of the low temperature of the steam, barometric condensers require much less water than surface condensers, since, in a well-designed barometric condenser, the water discharged may be within one or two degrees of the temperature of the incoming steam, thus utilizing practically all of its heat storage capacity. A surface condenser, on the other hand, when reduced to practical dimensions, requires a much larger difference in temperature between the discharged water and the entering steam, and consequently more water to carry away the heat.

The limitations of the condensers, which, from a practical point of view, limit the obtainable vacuum, are—in the barometric case, the air pump capacity, and in the surface condenser, the quantity of water.

Under fairly favorable conditions, the power expended to maintain a vacuum as high as 28½ inches on a low-pressure turbine, does not exceed 5 per cent. of the turbine output.

Types of Turbine

The two types of turbine in existence are known as action and reaction machines. To the action type belong the Curtis, De Laval and Rateau machines. The reaction type is represented by the Parsons turbine. In an action-type machine the pressure drop occurs principally in the stationary nozzles, while in the reaction machine a uniform pressure drop occurs in each row of stationary and rotary buckets; consequently, in the reaction type of machine steam leaks around both stationary and rotary blades, thus necessitating that the running clearance between stationary and rotary elements be reduced to the minimum possible value, from which reduction in clearance arises the greatest source of trouble in turbines of this sort, i.e., stripping blades from their stationary and rotary elements.

Stripping of the blades may sometimes be the result of improper fastening of the buckets to the rotor drum. Obviously, the larger the number of rotary buckets, the greater becomes the danger of stripping; first, because each additional blade is an additional possible cause of trouble; and second, because the larger the number of blades, the more restricted the turbine designer is in his method of attachment, owing to the space available and to the permissible cost of construction.

The successful operation of this type of turbine has always depended on most accurate workmanship, together with extreme care in assembling, and thoroughly reliable means to prevent foreign matter being carried by the steam into the turbine.

The close clearances necessary in these machines to show good steam economies is frequently sacrificed in order to obtain greater reliability of operation.

Particular care is also required in starting the larger machines of this type, as they must be brought to a uniform temperature, corresponding nearly to the temperature at which the machine is to work before starting, this being necessary in order to allow the various parts to reach their working temperatures and their corresponding heat expansions.

The importance of this feature is readily seen from the fact that the expansion of the rotor when heated from the temperature of the atmosphere up to that of the working steam often exceeds the clearance between rotor and stator. The process of warming up such a machine is a slow one, because, as steam is first admitted, the upper portions of casing and rotor are heated first, causing them to expand; the lower portions, not expanding as much, give a slight curve to both casing and rotor. This dispersion for the casing portion of the turbine to rise is further augmented by the resistance of the lower portion of the turbine casing to slide lengthwise of the subbase as it is expanded by increasing temperature.

The significance of these features would not appear if it were not for the close-running clearances. An action type of machine, on the contrary, having large running clearances, can with safety be brought up to speed and full load, when cold, in two or three minutes.

In the action type of machine the moving element has no appreciable pressure drop from entering to leaving side of its buckets, and therefore no disposition for steam to leak around the buckets in preference to passing through them; consequently, a large clearance is permissible round the rotary buckets. Furthermore, the rotary buckets are carried by wheels mounted on a shaft and between contiguous wheel elements the stationary diaphragm containing the expanding nozzles can be carried down to the shaft, and between it and the shaft is a running clearance of very much less diameter than that necessitated by the reaction type of machine.

Turbines, in common with all engines, are subject to deterioration with service. The actions tending to lower their steam economy are:

First—A gradual increase in the quantity of steam leaking through clearance spaces, which bypass the active portion of the turbine; and

Second—The wearing of the buckets and guide vanes, distorting them from their proper shape, thus lowering their mechanical efficiency.

The losses coming under the first case are of very little significance in the action turbine, because in such a machine the diameter of the clearance space is small, usually that of the turbine shaft; but in the reaction type of machine the diameter of the clearance space is large and equal to that at the buckets, giving a leakage area much larger than that of the action machine. The clearance is increased with use of the machine, by the wear from steam passing at high velocity, together with the entrained water and particles of dirt.

On both action and reaction machines the buckets are subject to wear, the extent of which depends upon the relative velocity of steam passing over the bucket, the maximum value of which varies inversely as the square root of the number of pressure stages. In the reaction type of machine the wearing of buckets is largely a question of design, and is more or less unaffected by the number of stages. In general it seems probable that the reaction type of machine is subject to a much more rapid loss of efficiency than an action machine, when both causes are taken together.

Reliability of Operation

A turbine is subject to few, but very serious, accidents, which may be classified as follows:

First—Contact between stationary and rotary elements.

Second—Stripping of the blades.

Third—An accident arising through an interruption or failure in action of the auxiliaries employed to maintain the turbine in operation.

The rotary element can come in contact with the stationary element only when the clearance space is small, and when such is the case the intervening space can be bridged by an unequal heat expansion, through foreign matter becoming wedged in the opening, or through a slight loosening of any one of the numerous rotary buckets. If contact is once established, the damage is liable to be severe. It has frequently been stated that the clearance is automatically maintained by the wear which it produces. This may have happened in some instances, but usually the cuttings are welded to the rotary element and pile up, increasing the violence of contact until the heat generated results in serious damage. The damage produced in this manner, through contact of the rotary element, is above all else the most frequent trouble encountered in turbine operation, and every effort should be made so to design and manufacture turbines that this source of annoyance is either entirely eliminated or the probability of this kind of trouble reduced to a minimum.

It appears safe to state that a clearance between stator and rotor less than three-thirty-seconds of an inch is absolutely unsafe, and that a clearance of one-eighth of an inch to five-thirty-seconds of an inch is vastly preferable, so long as the resulting steam leakage is not serious. In the larger action type of machines, clearances of this magnitude produce losses of less than one per cent.

The buckets may be stripped by contact with the stationary element. An action turbine has a very large clearance around its buckets (one-quarter of an inch or more) and therefore is practically free from damage of this character. In this type of turbine the minimum clearance occurs between the pressure diaphragm and shaft. When contact occurs between shaft and diaphragm, the resulting damage is generally a warped shaft, caused by a spot on the shaft becoming overheated and, through its expansion, permanently warping the shaft out of line.

An interesting phenomenon is illustrated when shafts come in contact with diaphragms. No matter how perfectly the rotary elements may be balanced, it is impossible to have an exact coincidence between the geometric center of the shaft and the mass axis of the rotary element. When the machine is running at full speed it rotates as nearly about its mass axis as possible, throwing the shaft slightly eccentric, and when contact is established it occurs first at that portion of the shaft surface farthest from its axis of rotation; consequently, there is always one spot in the shaft which touches the stationary element first and localizes the heating to a small section of the shaft periphery. The heating of the shaft at this spot expands it, thus lengthening one side of the shaft more than the other, causing it to warp slightly out of true, pushing the spot which has been heated by contact still farther away from the axis of rotation and increasing the violence of contact. This can be largely—or entirely—overcome by presenting to the shaft but a very small metallic surface, or by facing the diaphragms with carbon blocks, which, through their nature, are incapable of presenting sufficient resistance to cause a violent heating.

The preservation of a proper clearance between rotor and stator, as between one type of machine and another, is a question of its design and construction. The machine that is so constructed that, when nearly assembled, the running clearance may be inspected, has a great advantage over the machine which must be put together piece by piece.

The vertical machine is at a disadvantage in this respect on account of the necessity of assembling it piece by piece, threading over the shaft successively diaphragms and wheels, thus placing on the erector of the machine a great responsibility and difficulty in maintaining the clearance; for after a wheel and diaphragm have been placed, it is difficult to inspect the clearance. A horizontal machine, on the other hand, eliminates this difficulty almost entirely, for in such machines it is possible to split the machine through its horizontal center and assemble in position each half, then inspect the clearance in both halves.

The turbine auxiliaries are the pumps for lubrication and for supplying the fluid pressure to step bearings. Frequently, also, the governor mechanism includes an auxiliary as a connecting link between the flyball governor and the control valves. Any one of these may cause trouble to the turbine, since its operation is dependent upon them, and their failure results in the failure of the whole turbine.

All of these auxiliaries appear unnecessary, and it would seem that they were introduced as a means of patching up features which might better have been omitted.

Bearings have been lubricated by oil rings for many years, and the bearing of a turbine may be lubricated by an oil ring with the same ease as the bearing of a 1-horsepower motor.

The auxiliaries to maintain in action a step bearing have been made more reliable by the installation of two pumps and an hydraulic accumulator, so that any two of these elements may fail, leaving one in operation. This seems a somewhat elaborate method of increasing the reliability of an essentially simple machine, and perhaps the easiest way to obtain the desired results would consist in omitting entirely the step bearing by placing the turbine in a horizontal position.

A forced-feed bearing lubrication is thought necessary in the reaction type of turbine, because in such machines, having as necessity a close running clearance, he bearings must also be given a close running clearance, which is too small to permit oil to enter the rubbing surfaces unless its entrance is forced. In a vertical-type machine, oil ring bearings are of course an impossibility.

As an example of what can be done in simplifying turbines, Fig. 3 illustrates a Rateau-Smoot turbine. In this machine the bearings are babbitt-lined, self-aligning, water-cooled and lubricated with oil rings. The complete journal bushing can be removed without disturbing any other portion of the turbine except the bearing which is to be opened. Between the shaft and diaphragms the least clearance is three thirty-seconds of an inch, and between buckets and casing the minimum clearance is one-quarter of an inch. The wheels are of the type illustrated in Fig. 10. The buckets are illustrated in Fig. [illegible] and are held astride the wheel periphery by transverse rivets, thus eliminating all metal at the wheel periphery not absolutely required for the bucket attachment.

The governor of this machine is mounted directly on the turbine shaft, and the motion from the flyballs is transmitted by a solid steel link to the steam admission valve, which is of the well-known double poppet balanced type, and controls the machine by throttling the steam, thus varying gradually the amount of steam admitted to the turbine.

The writer thinks that this is a better method of governing a turbine than by means of a series of nozzles which are operated either wide open or closed, for it frequently happens that the load which the turbine is driving is represented by a certain number of nozzles wide open, plus an additional amount less than one complete nozzle opening; consequently it is impossible to maintain the turbine at a constant speed, for a slight increase of speed is necessary to open wide the additional nozzle, and a slight decrease necessary to cause its shutting, thus compelling the turbine to run between these two limits, i.e., the speed sufficient to open the valve and a speed sufficient to close it. This is particularly annoying when turbines are operating in parallel with other turbines having a similar control, or with reciprocating engines, for it is possible that the disposition for slight speed oscillation may fall in step with those of other turbines or engines, and cause fairly pronounced oscillations in the entire system. Instances of this kind have been noticed. With a straight throttling governor, on the other hand, the variation in the amounts of steam admitted to the turbine is absolutely gradual, and a perfect balance can be maintained between the load and the quantity of steam applied to the turbine.

Governing mechanisms in which the flyballs do not control directly the admission valve, but do so through the agency of an intermediate motor or relay mechanical device whose source of energy is independent of the flyballs, are always equipped with a speed-limit device, and advisedly so, because of the intermediate motor, which is a break in the connecting link between flyballs and control valves. The presence of this intermediate motor is required by the large amount of energy needed to operate unbalanced valves, on the one hand, and the small amount of energy available in the flyball governor on the other hand.

A more practical method is to put the control valves approximately in balance and to connect them by solid links to the governor flyballs, which may be given sufficient energy to operate the valves within the speed regulation desired.

Comparison of Curtis and Rateau Turbines

The types of action turbine which have been most fully developed and which represent the most promising features, both in economy and reliability of operation, are the types known as "Curtis" and "Rateau." Both of these types lend themselves to the construction of units in sizes up to the largest single power-producing unit yet conceived.

Aside from very important considerations of general arrangement, the essential difference between the Curtis and Rateau machines lies in the following:

In the Rateau machine steam is expanded successively in a series of nozzles playing on moving buckets which absorb entirely the tangential component of the exit velocity from the nozzles. After leaving the row of moving buckets, the steam, which has been reduced to only sufficient velocity for its flow through the turbine, enters another row of nozzles through which there is a pressure drop creating a second velocity, which is in turn absorbed by a second row of moving buckets, and so on to the exhaust end of the turbine.

In the Curtis machine the pressure drop, which in the Rateau type occurs through two nozzles, is lumped into one nozzle, which often is of the converging-diverging type, in order that the exit velocity may exceed the critical velocity for steam.

The steam from this nozzle is then received by a row of moving buckets, the speed of which, however, is insufficient to absorb completely the tangential component of the original velocity, and therefore the velocity of the steam leaving the first row of buckets represents a considerable amount of energy which is utilized in a second row of buckets by passing it through stationary guide vanes so arranged as to reverse its tangential component, directing the steam onto the second row of buckets.

At present a turbine [illegible] of large [illegible] would have [illegible] [illegible] eight successive steam nozzles and [illegible] rows of moving buckets. The corresponding Curtis machine would probably have four [illegible] steps [illegible] and [illegible] on two rows of moving buckets, making a total of eight rows of moving buckets. Under these conditions, with an admission pressure equal to [illegible] and an exhaust [illegible] of [illegible] inches [illegible], the steam velocity leaving the Rateau nozzles would be approximately [illegible] feet per

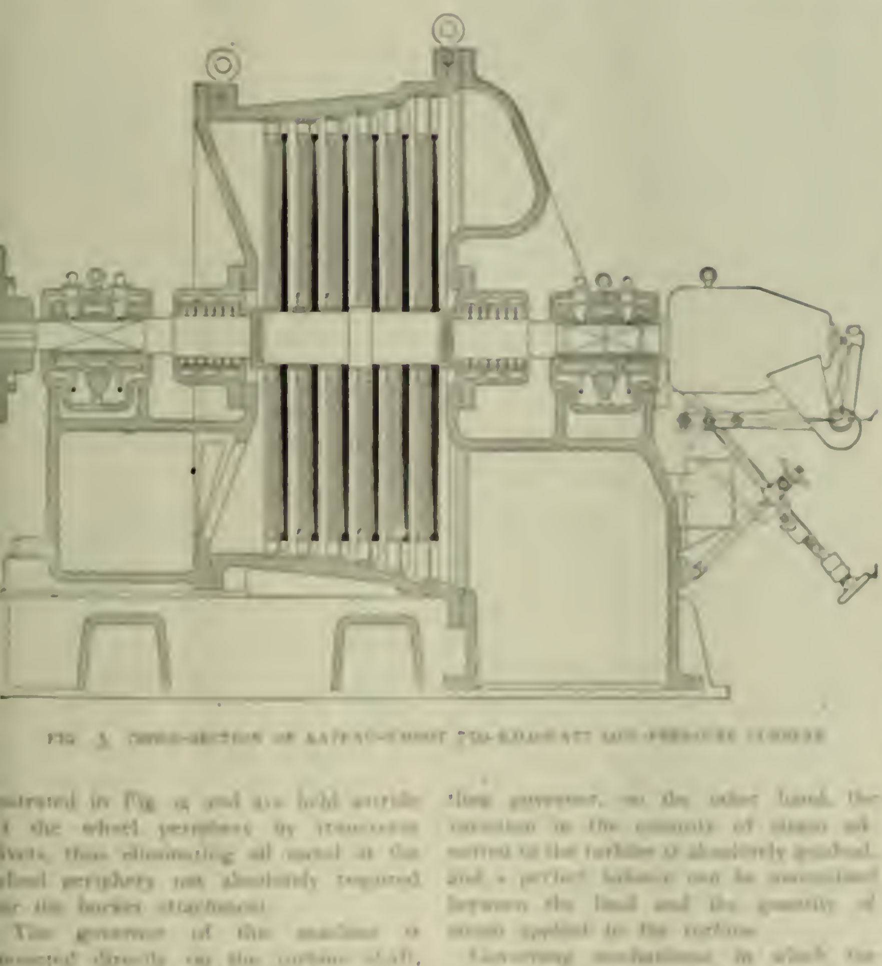

FIG. 3. CROSS-SECTION OF RATEAU-SMOOT 750-KILOWATT LOW-PRESSURE TURBINE

second, and the velocity leaving the Curtis nozzles would be approximately 456 meters, at which condition it enters the first row of buckets. In the Rateau machine this velocity is reduced to just enough for the steam to flow into the next succeeding nozzles, while in the Curtis machine such a reduction is impossible and the large exit velocity from the first row of buckets passes through guide

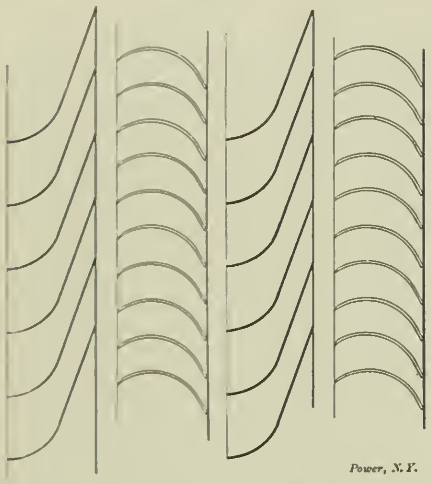

FIG. 4 RATEAU BUCKETS AND NOZZLES

blades, which, without a change of pressure, reverse the steam flow and permit the velocity remaining to be absorbed in a second row of buckets.

It is of interest to note that experiments have thoroughly established the fact that the loss of energy due to friction and eddy currents in a well-designed steam nozzle, in which velocity is created by a reduction of pressure, does not ex-

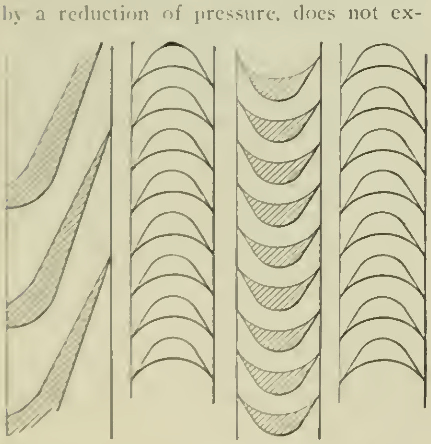

FIG. 5 CURTIS BUCKETS AND NOZZLES

ceed 5 per cent.; and in nozzles of large sectional area comes down to 2 per cent., while the energy loss when steam at high velocity is caused to move in a curved channel—as in the rotary buckets and stationary guide blades of the Curtis machine, which are equivalent to buckets—runs all the way from 15 to 30 per cent.; dependent upon the design, construction, size, etc., of the buckets.

For equivalent pressure drops, the Rateau type of machine has two nozzles, in which the loss is small, and two rows of moving buckets, in which the loss is large. The equivalent Curtis element representing an equal pressure drop has one nozzle, in which the loss is small, followed by two rows of moving buckets and one row of stationary guides, three in all, for which the loss is high. Figs. 4 and 5 show, respectively, the corresponding elements of Rateau and Curtis turbines.

Professor Rateau, in a paper read at the St. Louis Exposition, showed that the maximum possible obtainable efficiency with each type of turbine differed some 20 per cent. with the bucket construction then in use, and that the difference could not be overcome by any feature of bucket construction or design, since whatever is obtainable in one type of machine in the way of reducing losses in buckets is also possible in the other type of machine, the Curtis type having, however, always the additional loss represented by the stationary guide blades constructed like buckets and having losses equivalent to those occurring in a bucket, while in the Rateau type of machine the corresponding element is an expanding nozzle in which the losses are very small. In addition to this, the losses of energy due to shock are greater in the first row of buckets on the Curtis machine, because the entering steam has some 40 per cent. greater velocity than in the Rateau type. These differences cannot be overcome.

Turbine Buckets

Fig. 6 represents a row of buckets, the center portion of which has been increased to give between adjacent buckets approximately a uniform width of steam channel. The angles of entrance for steam at full load and light load are shown by arrows in the cut. Fig. 7 shows the type of bucket employed in the Rateau-Smoot turbine, with the angles of steam entrance for full and light load also indicated.

These figures show that it is a mistake to increase the thickness of a bucket toward the center, as at light loads the entering steam abruptly strikes the rear of the buckets. The loss resulting is doubled. First, there occurs the loss due to the steam shock itself; and, second, the loss due to the fact that the reaction from this shock is tending to drive the turbine backward and not forward.

The writer is quite unable to see any advantage in a bucket which is thicker in the middle, having a crescent section. As a matter of resisting the steam wear, it should be noted that the edges of all buckets, whether of crescent section or otherwise, are the portions principally subject to the steam erosion and are of necessity made thin in order to reduce the steam friction of the jet entering the bucket wheel. When these thin edges are worn the bucket has lost its proper section and becomes highly inefficient, for the crescent section equally as well as for a section of uniform thickness. In addition to this time, which is negative in its character, a crescent-section bucket presents the disadvantage already noted of increased losses on the light loads; but still more serious from the designer's point of view, it greatly increases the weight of metal in the bucket.

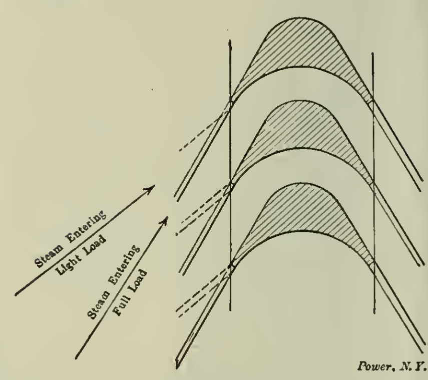

FIG. 6. STEAM FLOW AT FULL LOAD AND STEAM AT LIGHT LOAD IN CRESCENT-SHAPED BUCKETS AND IN BUCKETS OF UNIFORM THICKNESS

At ordinary bucket speeds for the multi-stage type of turbine, the centrifugal force per pound of bucket weight amounts to from 1000 to 2000 pounds, and therefore each additional pound of material over that absolutely necessary adds to the wheel an enormous disruptive effort.

The function of the wheel is primarily to hold the buckets, and if the weight of

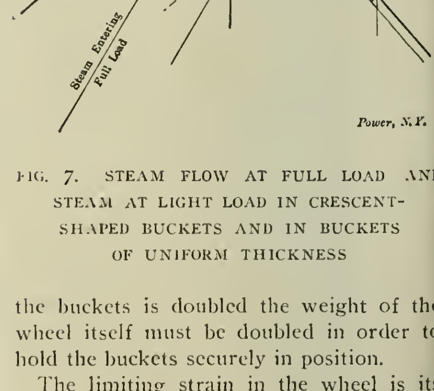

FIG. 7. STEAM FLOW AT FULL LOAD AND STEAM AT LIGHT LOAD IN CRESCENT-SHAPED BUCKETS AND IN BUCKETS OF UNIFORM THICKNESS

the buckets is doubled the weight of the wheel itself must be doubled in order to hold the buckets securely in position.

The limiting strain in the wheel is its elastic limit and not the ultimate strength of the material employed, for if once the elastic limit of a wheel has been exceeded, it is stretched out of its original shape and the running balance destroyed, causing the turbine to become inoperative through the violence of vibration ensuing.

With equal weight, the strongest wheel is the one which has the lightest periphery, for it is the weight of the periphery which produces the strains.

Buckets which are held in position by means of a dovetailed fit are objectionable because of the large amount of weight entailed by the dovetail construction. On the other hand, the bucket which is held astride of the wheel and riveted through by rivets parallel to the shaft has maximum lightness for the strength requisite to hold the buckets in place.

Fig. 8 shows a typical dovetailed method of mounting buckets on their wheel, and Fig. 9 shows the type of mounting adopted in the Rateau-Smoot turbine.

FIG. 8. BUCKETS DOVETAILED

FIG. 9. BUCKETS HELD ASTRIDE

It should be noted that much less metal is required at the wheel rim in the Rateau-Smoot turbine than is required by the dovetail construction. This metal is entirely unable to hold itself against the centrifugal force produced by its rotation and therefore must be carried by metal provided at the center of the disk, a heavy section being a source of weakness rather than one of strength.

The cross-section of the Rateau-Smoot bucket and wheel is taken from a 300-kilowatt, 1500-revolutions per minute low-pressure turbine which can be driven at 3000 revolutions per minute without producing a strain in buckets or wheels exceeding the elastic limit of ordinary flanged steel plate.

Bucket Wheels

Since the original single-wheel turbine, running at enormous speeds, invented by De Laval, various analyses have been made of the strains and strengths of disks turning at high speeds. All of these analyses unfortunately contain as prime assumption a practical fallacy. These wheels have been designed for uniform strains in both tangential and radial directions, and the material of the wheel has been treated as if its elastic limit coincided with its ultimate strength, the point of danger being considered as the elastic limit. The result produces a wheel section whose fallacy will be obvious when it is borne in mind that all metal placed within the radius lettered *R*, Fig. 10, is capable of holding itself and also an additional load, while all metal external to the radius lettered *R* is incapable of holding itself against centrifugal force, consequently it is simply necessary to add sufficient metal within this radius to hold together the entire wheel. When a wheel has been designed for uniform radial and tangential stresses, the section is that shown by Fig. 11, in which it will be noted more metal is added outside of the critical radius than for the wheel illustrated in Fig. 10. The assumption of equal radial and tangential stresses as the basis for wheel design leads to an irrational conclusion, either radial or tangential stress is sufficient to hold the wheel together, as all material suitable for the construction of a turbine wheel possesses in a high degree the property of stretching beyond the elastic limit, and when tangential stresses exceed the elastic limit and radial stresses fall under the elastic limit an infinitesimal stretch in a tangential direction will allow a sufficient elongation radially for the radial stresses to carry their proper share of the load.

While it is true that a wheel is unsatisfactory if both tangential and radial stresses exceed the elastic limit, it should also be borne in mind that either one can hold in position the wheel, regardless of what happens to the other.

For example, in the wheel illustrated by Fig. 10, the maximum stress has been taken at 8000 pounds per square inch, the material being ordinary flange steel. At the position lettered *A*, the tangential stresses may considerably exceed the elastic limit. The radial stresses, however, are much under the elastic limit, and when under test prior to assembling on the shaft the wheel has been brought to double its normal speed, a minute tangential stretch of the wheel allows the radial stresses to reach a sufficient value to hold the outer periphery to the interior central portion, the permanent stretching occurring tangentially but not radially, thus allowing the radial stresses to assume a value sufficient to hold the wheel together.

Turbine Shafts

Starting from a bucket of known weight, a wheel can be calculated strong enough to hold the buckets in place. The heavier the bucket, in equal proportion the heavier the wheel, consequently heavy buckets produce heavy wheels. Heavy wheels reduce the critical speed of the shaft, unless the shaft is also made heavier to offset the effect of the increased weight placed upon it. It is objectionable to use a large shaft, for two reasons. First, because it increases the peripheral speed of rubbing surfaces in the bearings, making them more difficult to keep cool; and, second, because it increases the diameter of the clearance space between shaft and pressure diaphragms, adding to the steam leakage.

Various attempts have been made to operate turbines in which the normal running speed was greater than the critical speed. (The critical speed of a shaft is the speed corresponding to the number of vibrations which the shaft, together with its carried weight, will make, and when given in revolutions per minute is the oscillations per minute which the shaft can sustain when once started oscillating.)

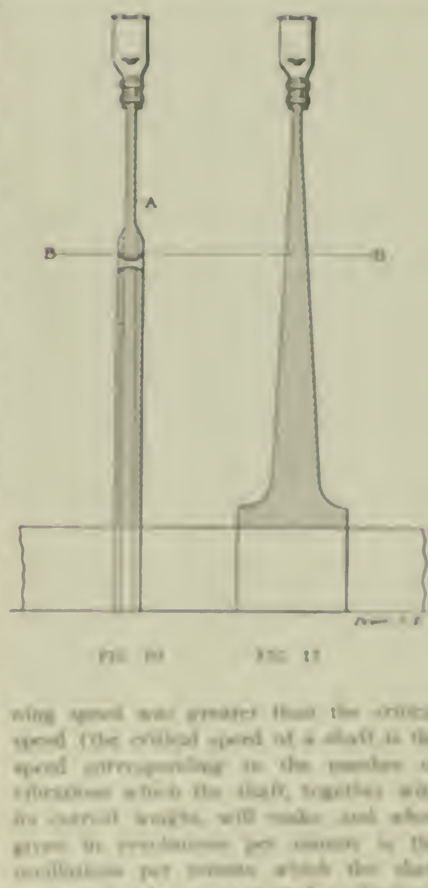

FIG. 10 FIG. 11

The calculation of critical speeds can be carried out by the process of graphical integration and highly accurate results obtained, no matter how complex the distribution of load upon the shaft may be or how widely varying may be the shaft diameter.

The execution of such a calculation, however, is a cumbersome matter, and when the critical speeds of a series of different shafts have been determined in this manner, the corresponding constants go in the following formula for critical speeds:

Critical speed (r.p.m.) = [illegible]

$$g \times 10^6 \times \frac{D^2}{L\sqrt{L \times W}}$$

are determined for all shafts whose essential characteristics are similar to those whose complete analysis has been carried through.

When sufficient experience has been gathered to determine for a given shaft the value of this constant, the critical speed of the shaft may be taken from a logarithmic chart, as shown in Fig. 12, which gives the critical speeds for the value of the constant g equal to 1.05, the value most frequently encountered in turbines of the multicellular type. For turbines whose shaft construction entails a different value of g, the corresponding critical speed may be directly deduced from that given by the logarithmic chart.

Vibrations

A turbine may vibrate objectionably or destructively, depending upon the amplitude of the vibrations. The causes of the vibrations may be found either in a shaft whose critical speed is under the running speed, or in wheels which have strains both radial and tangential near the elastic limit, thus causing a slow and continued deformation of the wheel and consequent shifting of its mass axis. From the dynamo end, vibrations can also be set up if the windings are insecurely held in position and gradually shift their position.

A properly designed turbine and dynamo, when once placed in balance so that the unit runs quietly, should never show a tendency to greater vibration; and, when such is the case, the design is at fault, for the weights carried on the shaft must shift in order to throw the machine out of balance.

Incidentally, this would seem to condemn a turbine and dynamo running on three bearings, for in such a machine any slight disposition toward vibration in turbine or dynamo will be transmitted through the solid shaft and set up vibrations in the other unit, thus causing the turbine to vibrate and its shaft to tremble when the turbine itself is not at fault, but the dynamo is out of balance. I consider the three-bearing machine questionable for this specific reason, in addition to the well known difficulty of maintaining in perfect alinement three bearings. Another serious objection to a three-bearing machine is that the shaft may pound on the central bearing, for the unit endeavors to run as a two-bearing machine running free of the central bearing and oscillating by the clearance given that bearing, thus placing on the central bearing the duty of restricting oscillations and limiting their amplitude by absorbing the blow struck by the shaft at each oscillation.

In vertical machines this sometimes results in very serious damage to the fastenings of the central bearing, for under these conditions it is subjected to enormous lateral strains, capable in some instances of shearing loose the attachment of the central bearing to the supporting framework. I consider it vastly better, although somewhat more expensive, to allow a bearing at each end of turbine and dynamo shaft and to insulate against transmitted vibrations from one to the other by using two separate shafts, placing between the two central bearings a nonrigid coupling which will allow one shaft to bend without transmitting a bending movement to the other shaft.

Oil Ring Bearings

The writer had the opportunity of investigating the action of oil in bearings running at high speed, and ran a 5x13-inch bearing at full speed (1500 revolutions per minute), with normal load with the top cap removed.

The bearing in which the experiment was made was provided with the usual oil grooves and lubricated by rings having a positive pumping action, supplying oil from the oil reservoir to the journal. At half speed and above, oil, instead of being carried into the journal through the oil grooves, squirted upward from the grooves against the direction of rotation, each groove throwing a stream of oil 0.25 inch in diameter several feet into the air, showing that the grooves simply provided vents for the back flow of the oil, which would otherwise have been carried into the journal, through its adhesion to the shaft, and indicating the truth of a theory which we have all held, but with considerable doubt, that a high-speed journal floated on an oil film.

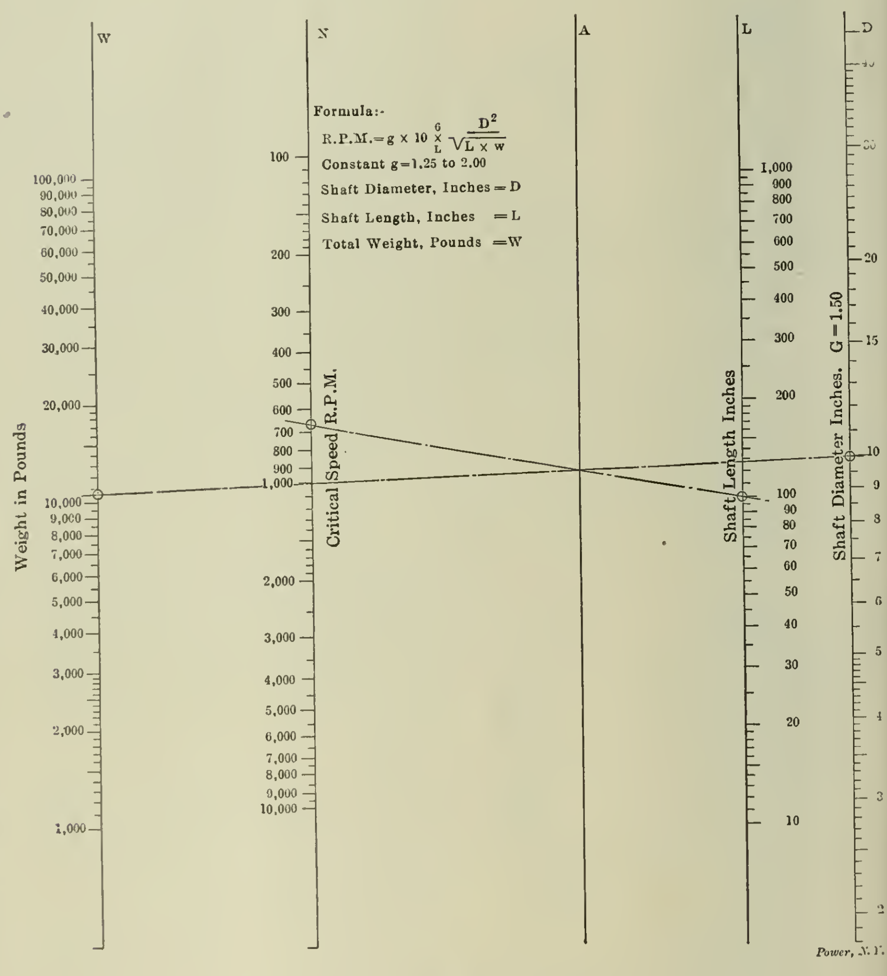

FIG. 12. CRITICAL SPEED OF SHAFTS

Summary

In this paper I have endeavored to show that steam turbines are in no way dependent on accurate workmanship for their reliability, and that simplicity and reliability will always go together in their construction.

I have also wished to express the idea that high efficiencies can be obtained without endangering the reliability of the turbine.

Furthermore, I strongly suggest that owners of noncondensing plants consider the opportunity of utilizing the exhaust of their reciprocating engines in low-pressure steam turbines, and thereby adopt a method of rejuvenating their plants by one of the most efficient methods of developing power from steam.

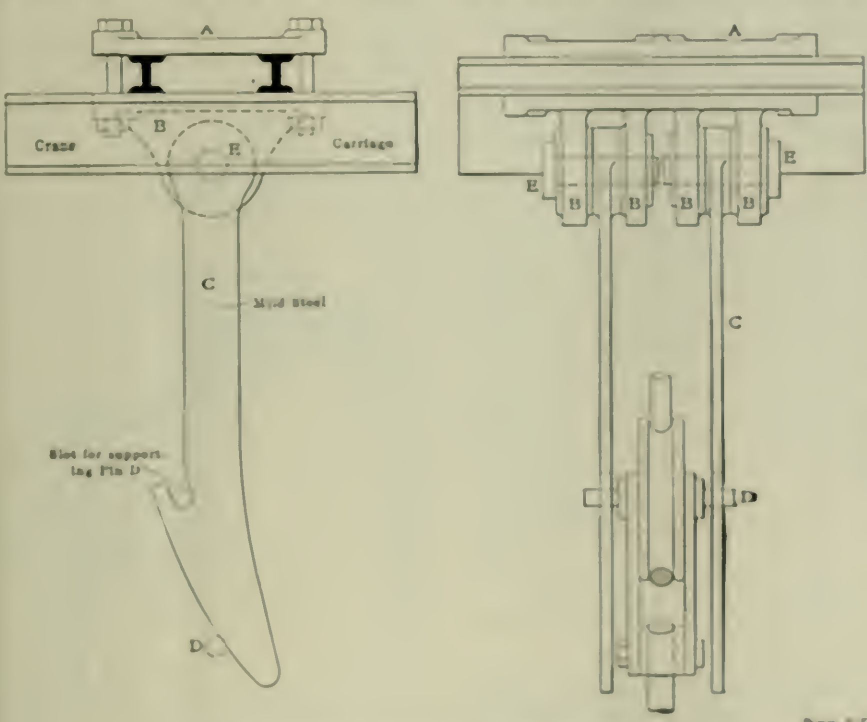
Traveling Crane Trouble Remedied

At one place where I was employed, a rope traveling crane was constructed. When this crane was put into operation it was found that when traveling longitudinally the load suspended from the crane hook swung violently, thus increasing the tension in the rope and the bending in the crane girders, making these stresses more than due to the load itself. To obviate this the following addition was made:

Two short H-beams were laid across the crane-carriage girders as shown herewith. On these beams a cast-iron plate *A* was placed with ears for six bolts, these bolts holding a corresponding plate, made from the same pattern with the two additional ears *B* hard against the under side of the beams. From these ears were hung the links for supporting the load when the crane was traveling, as may be seen at *C*. These links were free to rotate about the pin *E*, so that when the crane was about to travel longitudinally the load was raised, the pin *D* pushing the links *C* aside until the pin *D* was sufficiently high so it could be lowered into the slot provided in the link for it. As the load then rested on these links, the tension was thus taken from the rope. When lowering the load, it was first raised a little, the links *C* were then swung to one side, thus permitting the pin *D* to be lowered clear of the slot.

JOHN DOE.

Glasgow, Scotland.



REMEDYING A TRAVELING-CRANE TROUBLE

Allowance for the Difference in Water Level When Testing Boilers

The A. S. M. E. standard method of testing boilers directs that the allowance for any difference in the water level between that at the beginning and at the ending of the test should be computed, and the amount properly credited. The method of making the computation, however, is not explained.

As there is very little published relating to this phase of boiler testing, the writer believes the following formula will be found useful to those who have not developed a convenient method of doing the work. This formula applies to the case where the water is lower at the end than at the beginning of the test, or

$$A = \frac{C \times W\,(H - h)}{H - K},$$

where

- A = Amount of water, in pounds, to be added to the weight already furnished to the boiler,
- C = Space in cubic feet that must be filled in order to bring the water level to where it was at the beginning of the test,
- W = Weight of a cubic foot of water at the temperature due to the steam pressure,
- H = B.t.u. in the steam at the given pressure,
- h = B.t.u. in the water in the boiler,
- K = B.t.u. in the feed water.

The boiler should be measured, and the volume of the deficit in cubic feet calculated. The weight per cubic foot of the water at the temperature corresponding to the boiler pressure can be found in steam tables of almost any engineers' handbook. The other data required are furnished by the boiler-test log or taken from steam tables.

The following example is given to illustrate the use of the formula:

The log of a test shows boiler pressure, gage, 110 pounds; water supplied to the boilers by the pump, 96,800 pounds; temperature of the feed water, 174 degrees Fahrenheit; deficit at end of test, 25 cubic feet.

According to the formula the feed-water allowance is

$$25 \times 55.75 \left(\frac{1188.8 - 314}{1188.8 - 143}\right) = 1124$$

pounds. The temperature of the steam at 110 [illegible] gage, was taken at 344 degrees Fahrenheit, and the weight of a cubic foot of water at this temperature, according to a table in Kent's, is about 55.75 pounds. The total heat of steam of 344 degrees Fahrenheit, gage, is 1188.8 and the feed water at 174 degrees Fahrenheit contains 143 B.t.u. Therefore, the total amount of water that must be allowed for in the test of the boilers is

$$[illegible] + 1124 = [illegible]$$

pounds.

Scranton, Penn.

Use and Misuse of Graphite

Graphite properly used is the engineer's friend, and there are numerous uses to which it can be put with very satisfactory results. It is good to mix with oil and use on the bolts and nuts of cylinder heads, steam-chest covers, pipe flanges, etc., because it makes the nuts work easy

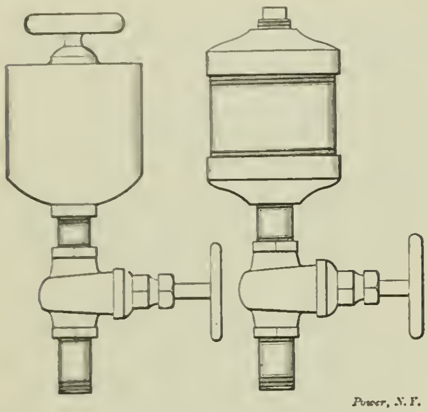

FIG. 1 FIG. 2

when one wishes to break a joint. If the nut and bolt of the rear handhole plate of a horizontal tubular boiler are well coated with graphite, and the bolt, nut and crab covered with a few handfuls of asbestos mortar, they will stand a fierce heat for months, and a wrench is all that will be needed to remove the plate.

Never plaster graphite and oil all over a gasket and then cuss because the packing slides out of the joint when the bolts are set up. Graphite one side of the gasket only. Put the gasket on the plate and graphite the exposed side. The gasket will then come off with the plate and leave the other surface clean and smooth. For this purpose the graphite should be mixed to a thick paste with cylinder oil.

Rod and valve packing for steam should be given a liberal coat of graphite when putting in place. The packing commonly used in the water end of a pump is made of several layers of heavy cotton cloth cemented together with a rubber compound, and it is nothing uncommon for the rings of packing to stick together so firmly, especially in hot water, that the expanding device is unable to set them out as they wear. A little graphite between the rings will prevent their sticking and the packing will run much longer without attention.

As a lubricant for steam cylinders and internal combustion engine cylinders, graphite is undoubtedly valuable, but the difficulties of feeding it discourage many from trying it. To get graphite into a cylinder all that is needed is a small cup with a straight, free outlet.

Fig. 1 shows how a cylinder-oil cup may be made over to feed graphite. Use a gate valve or plug cock, and attach the cup to the steam chest, or as near to it as possible. Fig. 2 shows how a cup may be made of pipe fittings, and, if carefully made of brass, it does not look bad.

Having attached the cup, put in about a teaspoonful of oil and graphite, mixed to the consistency of paint, close the cup and open the valve wide. In my plant I have a 7½x6-inch duplex boiler-feed pump which has had no lubrication except graphite for the past three months, and I have never seen a smoother or quieter working pump, although it is taking the returns direct from a heating system. This pump has been working constantly day and night and every day in the week on about three teaspoonfuls of graphite per twenty-four hours. In the three months we have used in the pump less than two pounds of graphite and hardly a gallon of cylinder oil. It was formerly nothing uncommon to feed a quart of cylinder oil to such a pump every twenty-four hours. This would be 7½ gallons per month, which at 50 cents per gallon, is $3.75 per month, or $11.25 for three months, a matter of $10.35 saved on lubrication in that time. If this amount can be saved on one small pump, what about a plant where there are a number of pumps of various sizes? This same scheme can be used on engines, also, although I should not advise discontinuing the cylinder oil altogether. Aside from economy, this should interest engineers who are using condensed exhaust for feeding boilers.

One reason why some make a failure of graphite as a lubricant is because they use too much, both in cylinders and elsewhere. During my early experience with it the outboard bearing on a 16½x48-inch Corliss engine heated up one day, and as oil failed to produce the desired result, I gave it a bountiful supply of dry flake graphite, and the heating rapidly decreased. I then flushed the bearing with oil and soon had it in normal condition.

H. L. STRONG.

Portland, Me.

Substitute for Sheet Packing

It sometimes happens that the engineer runs out of sheet packing. I find that paper will do the work, sometimes better than rubber; in fact, I prefer oil paper to rubber for water. Oil paper and thin, tough paper are the best, and roofing paper is fine. For small work, and in oil lines, it is better than rubber, as it will not soften and fill up the pipes; it will also stand a high temperature.

In one plant there was a great deal of work to get things going and as we could not readily get any sheet packing, we packed everything with paper and roofing paper from the manhole to the suction pipe of the big pump, using tar paper in the steam lines and manhole.

A recent letter from the engineer says that the most of it is still there and shows no signs of leaking. The worst thing about paper is that if it starts to blow it will mean a new gasket, but it will not blow out entirely.

ALDEN SEARS.

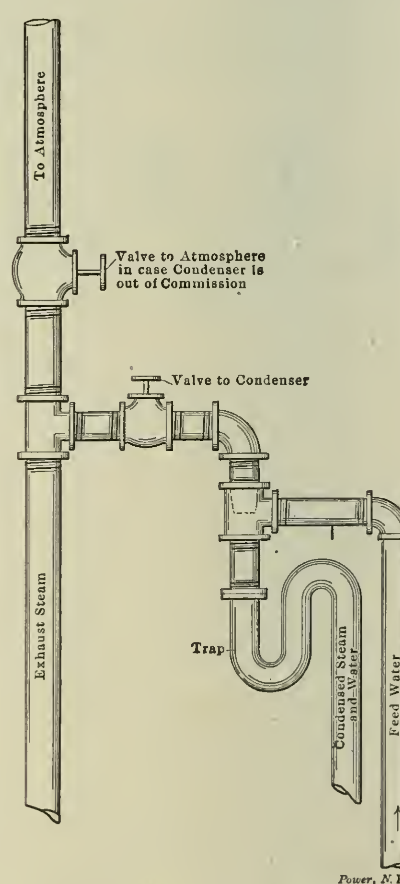
Electron, Wash.

Homemade Condenser

The accompanying illustration is of a homemade condenser made of pipe and fittings; the construction is very simple.

The exhaust steam from the engine, pump or heating system, etc., passes through a tapered nipple which is screwed past the center of the tee. The cooling water enters the side outlet of the tee and condenses the steam, causing a vacuum on the exhaust-steam line.

The trap connected to the bottom of the condenser creates a vacuum on the ex-



HOMEMADE CONDENSER

haust-steam line and water-feed line and also siphons the air out of the tee. It also prevents any water from getting into the exhaust-steam line.

In case the condenser should get out of commission the valve to the condenser can be shut off and the bypass valve opened to the atmosphere.

E. H. MARZOLF.

Bellaire, Ohio.

Handy Homemade Tools

Fig. 1 shows a packing hook used in stuffing boxes where the packing can neither be pulled out nor blown out by steam. The tool is a combination of a hook B and worm A. The latter is first screwed into the packing, then, holding the inner rod B by the faucet handle D in such position that the pendant hook faces the opening in the casing, the two handles being properly marked, the plug C is screwed down into the outside handle, thus forcing the hook to undermine the old packing. With the aid of a common worm hook, driven in a short distance from the tool, and on which most of the pull must be applied, satisfactory headway can be made. The opening in the casing

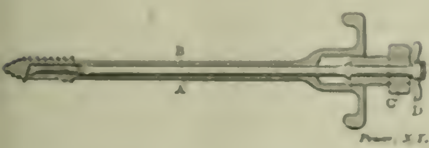


FIG. 1

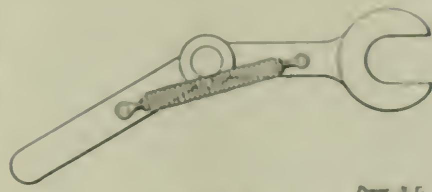

FIG. 3

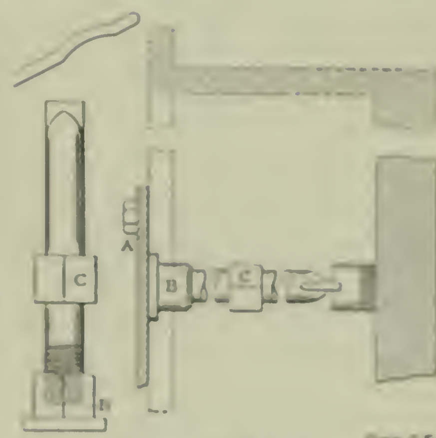

FIG. 5

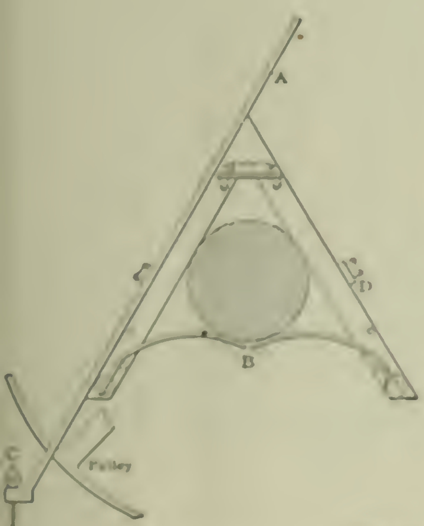

FIG. 2

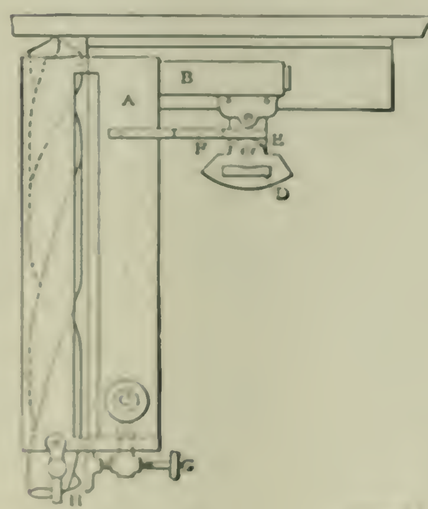

FIG. 4

FIG. 6

should be of such size that the hook will not entirely pass out through it but will become wedged against its containing walls, thus relieving the small junction pin of all pressure when the pull is applied.

The device shown in Fig. 2 is used for leveling shafting by the sighting method, and is worthless unless accurately made. At A is a straightedge, long enough to clear all pulleys and hangers; BB are flat springs to steady the tool after leveling it on the shaft; C is the sight and D is a counterweight, balancing the straightedge.

The sight is movable, perpendicularly, and on the largest-sized shafts should be placed as shown. To accommodate small-sized shafts, simply raise the sight a distance equal to the difference in the diameters. When it is possible to see through all the sights at one time, on a continuous line of shafting, it will be a pretty good job.

In Fig. 3 is shown a wrench, mainly used in connection with a socket wrench for tightening follower bolts. By making the tension of the springs adjustable, and using shims, this wrench will be found very handy for various other purposes, such as for equalizing the tension on the two springs of a governor.

Fig. 4 shows a tool for squaring a drill or tap, when using a ratchet wrench. At A is a piece of steel straightedge, hinged at B to a common try square, and adjusted by means of thumb screw C, so that it hangs exactly parallel to the blade of the square, and slotted almost its entire length to facilitate sighting the drill. When the edges of the drill are seen to be parallel to both square and straightedge then the hole will be bored at right angles to the face. The tool is particularly handy when a narrow surface is to be drilled, as then an ordinary square can be used to square the drill in one direction only. A small level is shown at D. This is used when the surface is uneven, in which case shims are placed under the stock of the square. It is also used where several holes are to be drilled at the same angle in the direction of the length of the work, as it is adjustable, swinging on the pivot E. When two or more holes are to be drilled at a certain angle in the other direction, the narrow width of the work, the swinging straightedge is used, which is tilted to the proper angle by means of the adjusting screw C, the flat spring F serving to keep the screw in contact with the blade. The two small thumb screws G and H are used to square the shank of taps. The tool is meant for ordinary work and is not supposed to be used where micrometrically correct drilling is required.

Fig. 5 shows a tool to back out the glands of condenser tubes. The method used at a large electric-light station is to back out as many as possible by the hand-tool method; then the plate A, of any desired width, is fastened across the face of the condenser, using the cover bolts to secure it. Placing the thin end of the tool in the slot of the gland, the jacket box B is backed up firmly solid against the plate A. The pitch of thread on the box should correspond with that on the tube gland. A monkey wrench applied at C will soon make that gland start. The plate A should be wide enough to cover at least five or six rows of tubes. The number of glands saved will soon pay for the time and trouble of making the device.

Fig. 6 shows a pair of fiber tongs, used to replace glass-inclosed, spool-holding fuses on very high-voltage oil switches. The shallow bag is used to catch the broken glass, and the tongs to close the spring end clamps.

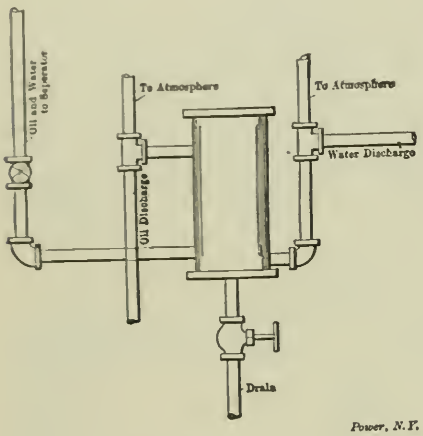
Framingham, Mass.

Homemade Oil Separator

The accompanying illustration is of a homemade oil separator, constructed of pipes and pipe fittings.

The condensed water and oil are fed through the bottom of the separator. The oil discharge is taken from the top and the water discharge from the bottom.



HOMEMADE OIL SEPARATOR

Both the oil and water discharge outlets have nipples to the atmosphere to prevent siphoning.

E. MARZOLF.

Bellaire, Ohio.

Sarcastic Advice

If the water in the boiler becomes so low that the plates are heated red hot, build a hot fire and turn on the cold-water pump. This will contract the overheated metal and all your troubles will be over in a few moments.

If the governor sticks, causing the engine to run away, don't get excited and close the throttle. Engines so affected invariably stop of their own accord in a few minutes.

If the safety valve leaks, hang a little more weight on the lever. An old 8-inch gate valve will be about the right weight.

Do not monkey with the blowoff. Let it fill up with scale. Then it will not leak.

If the boilers are so full of water that heavy slugs are coming over into the engine cylinder, you can judge of the quantity by holding the ear near the cylinder head. Water will clean the cylinder out.

A bag in a boiler does not hurt anything. It will soon fill up with scale.

A babbitt lined wrench should never be used on those polished nuts of the engine. It might slip off and skin your fingers. Use a pipe wrench or a hammer and cold chisel.

Do not clean the soot off the tubes oftener than once a week. It is hard on the tubes, cleaning them so often.

Engineering papers are like scientific books, all theory and of no practical benefit to anyone. A dime novel is much more interesting and costs less; besides, "book men" have not got a very high standing in the engineering profession.

I do not know anything about an indicator and do not want to know anything about it, for it is an abominable nuisance and should never be permitted in an engine room.

JAMES JORDEN.

Barberton, O.

More Frequent Internal Inspection

Milton Heglin, on page 939 of the May 25 number, misses the true purpose of my letter of March 9. I did not make a sweeping condemnation of boiler inspectors. He knows full well that most of them are conscientious men of high purpose. But he also knows that men have their limitations, that no one is infallible and that some are not unwilling to make an "absent-treatment inspection for revenue only," to borrow a phrase the editorial on "Boiler Inspections and Explosions" in the May 25 number. What I aimed at was simply to impress upon engineers and boiler owners the importance of *more frequent* internal inspections of boilers. I cited a few concrete cases to show that in many cases such inspections proved profitable. For it must be obvious that very few people would go to the trouble of making an internal inspection of a boiler right on the heels of an inspection by an insurance inspector unless there was some chance of being rewarded for their work. In other words, the boiler owner and engineer must see good reason for the undertaking. Mere checking up of the inspector's work is not a sufficient reason.

The writer has no grudge against boiler inspectors. Whether he is or is not selling boiler-cleaning devices does not alter the truth of his premises. They are generally accepted where people have gone to the pains of investigating. In some cases, investigations even become unnecessary—the facts force themselves upon us. Proof of this is seen in the editorial mentioned. The writer contends that the day of the auditor has not passed. Over and over again we are brought face to face with the fact that checking up (in whatever field it may be) means economy and safety. And no boiler inspector should be chagrined because his inspection report is not taken as the final word in the matter.

Mr. Heglin himself unwittingly gives one good reason why we should take some inspectors' reports with a grain of salt. "Another phase of this question," he states, "is that a great many owners, managers and superintendents become very indignant when told the boilers need better cleaning, maintaining that they have a good engineer, who knows his business, and that the boilers have never given them trouble from being dirty; and there it ends."

Suppose your inspector, instead of ordering the insurance canceled until the boilers were cleaned and kept in a less dangerous condition, preferred to be considered a "good fellow." Does it take long to guess what he might do? Is it not true that there are more men who want to be "good fellows" than who want to be somebody else? Is it not conceivable, then, that where there is no imminent danger, where conditions are safe enough, your good-natured inspector will jolly along the engineer and superintendent by saying something about the remarkable cleanness of their boilers? A boiler can be terribly inefficient because of scale and still be safe. The inspector is not a consulting engineer employed to point out possible economies in operation or to recommend appliances. If his suggestions are obnoxious, why should he volunteer them and become a boor? And he is right.

Now, don't misunderstand the writer's position. If possible, give us a more efficient inspection service. But efficient or otherwise, I hold that for economy's sake alone it will pay the owner and the engineer to make frequent internal inspections of their boilers.

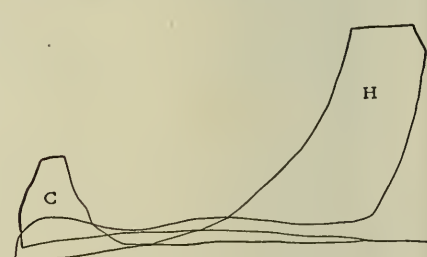
H. E. GANSWORTH.

Buffalo, N. Y.

What Was the Trouble?

The accompanying indicator diagrams were taken from the high-pressure cylinder of a Westinghouse horizontal cross-compound Corliss engine.

Before the defect shown on the card occurred, the dashpots closed the steam valves properly. After the trouble started, the crank-end dashpot refused to close



WHAT CAUSED THE TROUBLE?

its steam valve when the trip released the hook, the valve being closed positively by the movement of the valve gear.

No trouble was experienced at the head end in getting the dashpot to close its valve, and as soon as the defect was remedied, the crank-end dashpot worked as before, very satisfactorily.

It might be remarked that the crank-end steam valve was in proper working order in regard to workmanship and valve-gear arrangement, and that the trouble was not due to the dashpot, and no attendant had disturbed the valve gear. What caused the trouble and the appearance of the card?

J. W. Stoliker.

Shelton, Conn.

Steam Engine Testing

In testing steam engines to ascertain their performance, or to discover any cause of loss of power or illegitimate steam consumption, it is often thought necessary to know the quality of the steam in the cylinder at each point in the stroke.

Referring to the indicator diagram in Fig. 1, it is necessary only to draw the saturation curve for a quantity of steam equal to that taken into the cylinder at each stroke, plus that in the clearance. Then the quality of the steam at any point in the expansion is equal to the ratio of the volume of the steam in the cylinder at this point, to the volume shown by the saturation curve for the same pressure. These two volumes are represented by the lines AB and AC. Therefore, $X = AB \div AC$.

In some cases of "jacketed" cylinders with high ratios of expansion, especially in the cases of multiple expansion, the expansion curve crosses the saturation curve. This shows that there is superheated steam in the cylinder. Beyond this point the ordinary method of determining the quality will not apply.

Some years ago Power published a formula for determining the quality of superheated steam in a cylinder. The formula there given was not homogeneous, contained R, the latent heat of vaporization, and gave X the quality, which in the case of superheated steam means nothing.

My formula is practically homogeneous, does not contain R and gives the degree of superheat direct.

Referring to Fig. 2, P, V and T of the formula are the pressure, volume and absolute temperature at any point on the saturation curve; p, v and t are the pressure, volume and absolute temperature at any point on the expansion curve.

It is desired to find the degree of superheat at the point B. Select the point C on the saturation curve so that $P = p$. Now considering dry and superheated steam as a perfect gas, which it very closely approximates, volume V may be divided into T equal parts $= V \div T$, each part representing the increase in volume that will be caused by the increase of one degree of temperature. Now to increase the volume from V to v, it will be necessary to raise the temperature as many degrees as $V \div T$ is contained in $v - V$, or

$$\frac{v - V}{\frac{V}{T}}.$$

But the number of degrees of temperature necessary to raise steam from its volume at saturation to any larger volume is its superheat at that point. Therefore the degree of superheat at that point is

$$D = \frac{(v - V)\,T}{V},$$

or

$$D = \frac{(AB - AC)\,T}{AC}$$

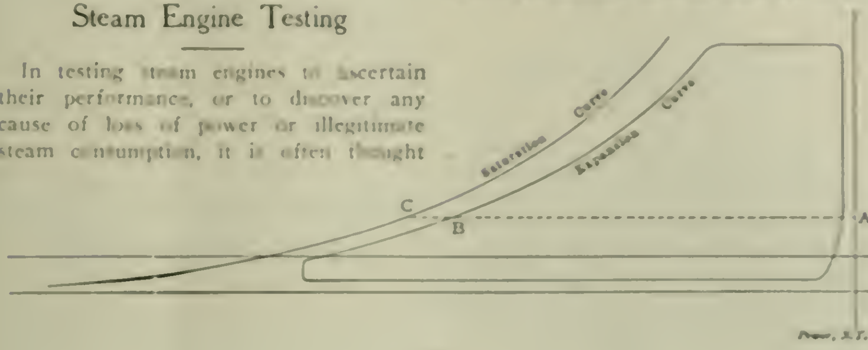


FIG. 1

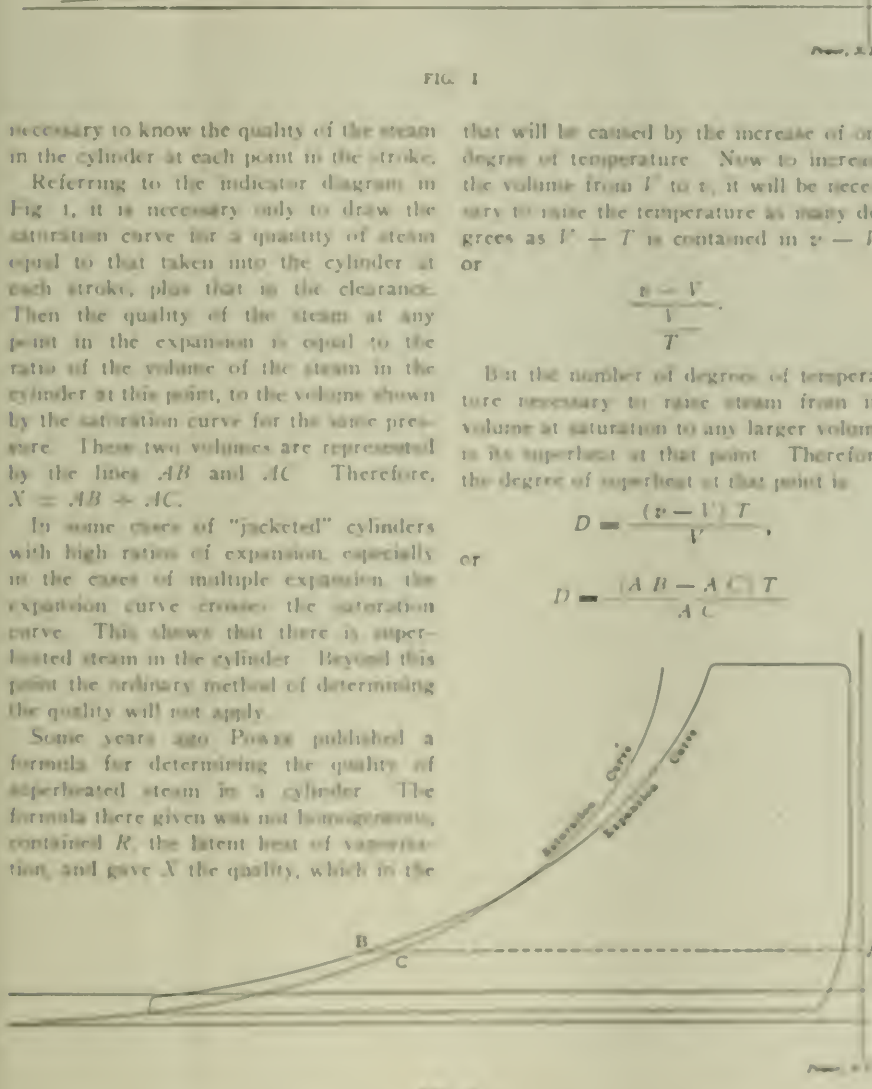

FIG. 2

on Fig. 2, which may be figured out in actual quantities from any indicator diagram where the expansion curve crosses the saturation curve by simply scaling the lines AB and AC in inches or any other unit, and from a steam table, taking the T that corresponds to the pressure at the point C.

J. H. Wiswar, Jr.

New York City.

Expert Advice

In the April 13 number, H. E. Samuels has an article on the actual cost of power. It is quite true that an engineer can figure his power cost, including charges, depreciation, taxes, etc., but does he? A very large proportion of the engineers cannot do this because they are not given the opportunity. The cause for this is, first, many of the engineers will not take the trouble, even if the information is given them, to enable them to make these figures; and, second, the plant owner is unwilling to give the engineer the information necessary for him to make a careful estimate.

As a rule in the moderate-sized plants the engineer is not only the engineer in the steam plant, but he also has to care for a very large part of the machinery throughout the plant, and has little time to look into the finer points of his plant and to discover where the leaks happen and take means to prevent them. The matter as it stands today is such that the average plant can be very materially assisted by the employment of an expert to go over it carefully in connection with the engineer if he can succeed in inducing the engineer to coöperate with him, determine where the plant is at fault and remedy these places. As far as this is concerned, it has one great objection, mainly because of the jealousy or ill feeling caused by jealousy, or any other feeling of the engineer, who apparently feels that he should be left alone to work his own will on the plant, and that the calling in of any outside assistance is a grave reflection on his ability.

This may or may not be true. An engineer, if he is a true engineer, is always glad to learn; and if his plant is not working to its best advantage, he should be exceedingly glad to have an opportunity to learn how it may be made to do so and take advantage of this opportunity so that the same troubles will not happen again. It is no reflection upon the ability of any engineer to have an expert called in to advise him, because the expert has had experience in a number of plants of widely varying characters. The engineer has probably been confined to one, two or three plants of very nearly the same general type. His duties, besides operating the engine and boilers, have been so numerous that he has not the opportunity to make studies into the various features of his plant, and has not had the time to study out how this plant study can be made, without serious loss of time. The expert can and will put him in a position to make these studies systematically and easily without loss of time or interference with his regular duties.

There is another point which Mr. Samuels does not seem to realize. There always seems to be a feeling between the engineer and the employer, such that it is very hard for the engineer to get the employer to believe things may be done to improve the plant, to advantage; whereas if the engineer is backed up in his opinions by an expert, the work can be done and is done. There is quite as much trouble in the engine and boiler room due to the dictation of an employer with reference to the kind of coal, oil, etc., as there is from lack of attention of the engineer to his duties; also because the employer expects the engineer not only to be the engineer of his plant, meaning by plant the steam end, but also to look out for every bit of shafting and machinery there is in the plant. This is not the province of the steam engineer. His duties should be to keep his steam plant running continuously and at the same time as economically as possible, and the employer should take careful notice of the recommendations of his engineer.

I am not recommending the employment of a supervising expert continually on the staff of the manufacturing company, as has been suggested by a number of people in your paper. I believe that if an expert is employed who is competent, he can give the engineer the points necessary to enable him to carry on his work successfully; and the expert will not be required to visit the plant at stated intervals. It is wise, however, when any trouble occurs or the power cost seems excessive, to call in an expert to see if he can discover the difficulty, as his wide experience will enable him to find troubles which the continuous service of the engineer and his long service in the same plant make him believe that it is inherent in the plant to have certain defects or certain losses, which cannot be reduced. The expert, however, not having this experience, examines carefully the records and notes those which seem to be excessive, and looks for the cause. Having found it, he suggests and tries a remedy.

The main trouble, therefore, seems to be too many duties for the engineer imposed by the employer; a belief of the employer that the engineer should do well with little or no encouragement; a resulting lack of interest in the plant by the engineer; and a gradual deterioration, which needs remedying and which can be done most cheaply and quickly by the employment of an expert. There is no question in my mind that the engineers can and should wake up to their opportunities; and that the employment of an expert, which is now of very great advantage to most manufacturing companies, could be made less necessary. To my mind it can never be entirely obviated, because the engineers do not wake up, the engineers do not have an opportunity to study and visit other plants, keep in touch with the advancing scientific knowledge, and are, therefore, at a disadvantage as compared to the expert whose opportunities are so much greater. If the engineer of most plants would be willing to put aside his petty jealousies against the expert and work with him, it would be much to his advantage. This fact is very well expressed in the April 13 number, under the heading of "Drops of Ink to Make You Think."

HENRY D. JACKSON.

Boston, Mass.

Expanding Boiler Tubes

When leaking tubes of horizontal return-tubular boilers are located in or near the center and are thickly covered with a hard scale, which prevents them from coming out of their own tube holes, even when hammered and a chain tackle is used to pull them out. The majority of engineers cut off the bead, if there is any, and rip the tube with the bur inside and close the ends in as usual. This is all right, but after the tube is started out and is only 8 or 10 inches outside the hole, and cannot be driven out any more from the other end, they try a chain tackle, and hammer the tube for hours with very little result and with a strain on the tackle nearly pulling the boiler from its settings.

I have seen nine such tubes which could not be taken out of their own holes. The proper thing to do would be to cut out all the tubes and jump them through the manhole or handholes if there are any, but in many cases they do not want to take out all the tubes and only want to remove the leaking ones. The only remedy for such tubes is to cut them off when they are stuck out of the hole 8 or 10 inches and rip and close the end of the remaining part of tube in the boiler as before and push the tube back into the boiler out of the way for the present until you get a roller tube expander, and roll the tube hole (that is, in the tube head) larger, which is only upsetting the plate and can be done very easily if you have an expander 1/4 inch larger than needed to roll the tubes, but if you have not an extra expander the same expander will do if you use a strip of sheet steel about 1/4 inch thick, 3/4 inch wide and 5 or 6 inches long if they are 3/4-inch tube holes, having made the tube holes larger, the tubes can be pulled out easily; and when putting in new tubes it will be necessary to use a ferrule of either copper or sheet-iron strips, about 1/16 inch thick, 3/4 inch wide and long enough to fill the holes when the new tubes are in place. The tubes can be put in without ferrules if the ends are heated and opened out with a wooden plug or drift driven in several inches, thus making bell-mouth tubes of them.

STEPHEN C. CAFIERO.

Brooklyn, N .Y.

Equivalent Straight Pipe for Globe Valves, Bends and Elbows

The accompanying data sheet gives the lengths of straight pipe which are equivalent in resistance to globe valves, bends and elbows. The table is calculated from the following:

d = Diameter of pipe in inches,

A = Length, in inches, of pipe equivalent to globe valve,

A' = Length, in feet, of pipe equivalent to globe valve,

B = Length, in inches, of pipe equivalent to bends and elbows,

B' = Length, in feet, of pipe equivalent to bends and elbows,

$$A = \frac{114\,d}{1 + \frac{3.6}{d}}.$$

$$B = \tfrac{2}{3} A = \frac{76\,d}{1 + \frac{3.6}{d}}.$$

$$A' = \frac{9.5\,d}{1 + \frac{3.6}{d}}.$$

$$B' = \frac{A}{18} = \frac{6.33\,d}{1 + \frac{3.6}{d}}.$$

The formulas for A and B are taken from the catalog of the Ingersoll-Sergeant Drill Company.

The Rathbun Engine Test

In the issue of April 6 occurs an article entitled, "Test of a Vertical Engine," giving the economies of a 12x13, 100-horsepower, Rathbun, single-acting, vertical engine. Owing to the extremely low economies shown, I have taken the

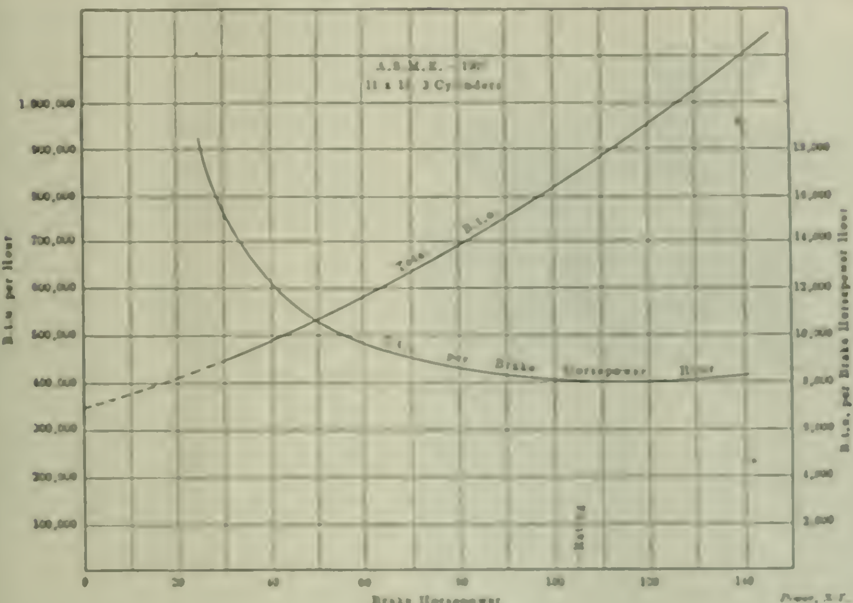

FIG. 1

trouble to analyze the results therein presented, and believe it will be of interest to other readers to do likewise. Allow me to say at the start that I should have no desire to question the accuracy of these results if they did not, by reason of the extraordinary economies claimed, reflect on the entire gas-engine industry outside the Rathbun engine. If the Rathbun company will publish all the facts, so that the public will be able to judge what economies this engine is really capable of, then may one feel justified in taking at face value these extraordinary statements.

To come down to figures, I submit reproductions, drawn exactly to scale, from two published tests from Rathbun engines of about the same size. Fig. 1 is reproduced from a chart accompanying a test record from a three-cylinder 11x13 natural-gas engine which was presented by Mr. Rathbun before the American Society of Mechanical Engineers in 1907. Fig. 2 is the chart from the two-cylinder 12x13 natural-gas engine described in POWER AND THE ENGINEER, April 6. I have added to these charts certain other curves necessary for a rational comparison of results, namely, the line of total B.t.u. consumed per hour at various loads extended back to the origin. As the total consumption line in Fig. 2 was not plotted to complete scale, but only to about 18 horsepower, it is somewhat misleading to one not familiar with the meaning of such curves. To Fig. 2 I have also transferred the total heat line from Fig. 1,

and we have the curious condition that while the two-cylinder engine required at no load, only about 25 per cent. of full load gas, the three-cylinder engine required nearly double this amount. Moreover, the shape of the total heat consumption lines is quite different in the two cases. The intersection of a tangent from the origin shows that while the three-cylinder first engine gave its best economy at about 130 brake horsepower, the second engine gave its best economy at slightly under 100 horsepower, which, considering the respective ratings, represents a singular difference in the performance of the two engines.

FIG. 2

In Mr. Rathbun's A. S. M. E. discussion he says:

"The inference seems to be obvious. Design an engine that will give a brake horsepower of 8000 B.t.u.; proportion the clearance so that the maximum indicated thermal efficiency is obtained at 20 per cent. below the maximum horsepower. This will give an engine an overload capacity of 25 per cent. with practically uniform efficiency. This proposition undoubtedly offers difficulties, particularly on some designs, etc."

I do not believe that Mr. Rathbun is serious when he proposes 25 per cent. overload capacity. In any event, the performance of his 12"x13-inch engine shows that he has not done what he proposed.

Coming down still further to details, I do not find in any of these results the necessary indications of accuracy to permit the results to carry conviction. In my own engineering work I have never considered a curve in any sense authoritative from a quantitative standpoint unless the points from which it is plotted are somewhat available. It is extremely easy to extrapolate or interpolate from irregular results without full warrant. These economies, if accurate, represent the highest thermal efficiencies in small engines that have ever been claimed in gas-engine practice. It is due to the public that the Rathbun company enlighten them more in detail as regards the actual figures—how they were obtained, what corrections were made, etc.

It is usual practice to reduce gas consumption to standard gas of 60 degrees 30 inches. Yet, the article of April 6 says: "The gas averaged about 1,000 B.t.u. per cubic foot at the temperature at which it passed the meter, so that the thermal efficiency of output was practically ... per cent." In the first place, this is not a sufficiently tangible expression of economy to be of any value. In the second place, this per cent., on a thermal basis, is equivalent to not quite 8500 B.t.u. per brake horsepower-hour.

The speed regulation was given as 4.5 per cent. It is not customary to speak of speed regulation except between no load and full load. The speed curve, however, shows a rapid drop between 35 and 70 horsepower. If this speed curve were carried back to zero load, the speed drop would be excessive and entirely beyond the limits of good generator practice.

The article speaks of the advantage of automatic adjustment of ignition, which is advanced on light loads. If the results were so extraordinary, why does the light load heat consumption shown in Fig. 1 appear nearly twice that of Fig. 2? As I understand it, this feature was to be of assistance on light loads, especially in point of economy.

In view of the foregoing, I believe it is incumbent upon the Rathbun company to explain its position on this question of economy in full detail.

KENNETH C. MCALPIN.

Chicago, Ill.

[In justice to Mr. Rathbun we explain that the temperature at which the gas passed the meter, about 50 degrees Fahrenheit, was inadvertently cut out of the article by the member of the staff who handled it. The efficiency figure was inserted by the same editor, and as the exact figure would be 29.22 per cent., on the basis of the data furnished, "practically 30 per cent." is not far out—EDITORS.]

Repairing a Broken Cylinder

The liability of wrecking steam cylinders of engines driving air compressors or blowing engines equipped with mechanically operated inlet and discharge air valves, and connected to a common receiver with other compressors, by allowing them to turn in a reverse direction when the throttle valve on the steam cylinder is closed, is well illustrated by accompanying photograph.

The engine in question is one of six Norberg Corliss cross-compound condensing blowing engines, compressing air to 50 ounces per square inch, and all discharging into a common receiver.

There are gate valves to cut out each engine (300 feet distant) attached to the main drum where individual blast pipes enter the drum. When necessary to stop the engine in case of accident or minor repairs, the custom is generally to stop and hold the engine from turning in a reverse direction by unlatching the high-pressure wristplate, raising the steam valve, and then admit steam to one end of the cylinder, move the piston to one end and leave steam on with the throttle open. The engine cannot move when left in this condition. This is done only when small repairs are needed, such as loose nuts or bolts or in keying up. At all other times the valve is closed on the blast line and the throttle is not closed until the air pressure is all off the engine.

The primary cause of this broken cylinder was that the engineer in charge,

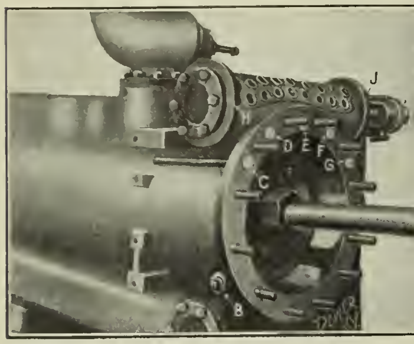

FIG. 1

in stopping to tighten a loose truss rod on the main eccentric rod, closed the thottle and did not unlatch the wristplate.

While making this repair the engine started to run backward driven by the air pressure in air cylinders, and before the engineer could reach the throttle, open it and latch the wristplate into the gear, the cylinder cracked across the top of the back steam-valve chamber as indicated by the line drawn across the top of the patch and the dotted line down through the side of the valve-chamber bonnets.

The brass box on the crosshead pin was crushed back out of shape and the key sheared in the crank ⅛ inch. No

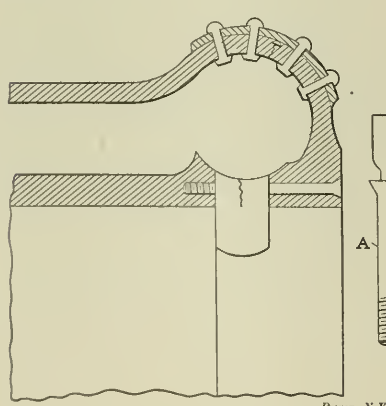

FIG. 2

damage was done to the piston, piston-rod or cylinder head.

If the cylinder relief valves had been attached to this engine the probabilities are that no damage would have been done, as they would have opened and relieved the pressure.

The point *B*, Fig. 1, shows where we have since drilled and attached eleven 2-inch spring relief valves.

As the engine was needed to blow a furnace with, repairs were effected by fitting a patch of 5/16-inch steel over the crack in which we had previously cut a dovetailed groove and filled it with "Smooth-On."

Patch and cylinder were drilled for a double row of ¾-in rivets, figured to give a joint efficiency of 70 per cent.

The cracks extending down through the bonnet flanges into the cylinder were dovetailed out and an annealed copper wire calked in. Two 1-inch bands of swedish iron were shrunk around the bonnet flanges as shown at *H* and *J*.

The broken portion was further strengthened by drilling through the flange of the cylinder back through the steam port under the valve and putting in bolts *C*, *D* and *E*. These holes were drilled 13/16 inch through to the steam port and then drilled 1⅛ inches into the metal beyond the port. The ⅞-inch hole only was tapped out, and a bolt put in, as shown in Fig. 2. The portion of the bolt marked *A* was used to screw into place and then twisted off, and afterward filed down smooth. Bolts marked *C*, *D*, *E*, *F* and *G* were put through the flange as shown on side of the cylinder, and fastened with a nut.

As the crank was found to be tight, the cylinder head was put on and the engine slowly heated up to allow the cement to dry. Pressure was gradually put on and small leaks around the patch were calked. The jacket was put back on the cylinder and except for the rings *H* and *J* on the bonnet flanges projecting a trifle above the jacket the engine is to all appearances as good as ever. It has been running constantly for two months, and has neither leaked nor shown any signs of distress.

A new cylinder put in position ready to run would cost $600. The repairs cost less than $100, including material and labor.

G. L. FALES.

Copperhill, Tenn.

Braces Were Sprung

While visiting an electric-lighting plant, I happened to look in through the bottom manhole of a 72x16-inch return-tubular boiler that was being washed out, and I noticed that some of the tubes in the bottom row were sprung sidewise, in some cases almost touching one another; also, the two through braces were sprung up about 4 inches. The superintendent said the boiler had been that way for six months and he thought it all right.

If those through braces were straightened out, would the tubes spring more or would the through braces stretch again?

Saskatoon, Can.

The National Electric Light Convention

Low Pressure Steam Turbines, Gas Engines and Producers and Grounding of Secondary Circuits Prominent Topics at Recent Meeting

The thirty-second annual convention of [the] National Electric Light Association, [he]ld at Atlantic City in the week ended [J]une 5, was not the usual, to-be-expected, [su]ccess; it was an astonishing eclipse of [al]l previous conventions of this organiza[tio]n. In point of numerical attendance, [qu]ality of program and real interest mani[fe]sted by the delegates, it was a record [bre]aker.

The meetings were held on the new [M]illion Dollar" pier, where the exhibi[ti]on hall was also located, and the open[in]g of the convention was preceded by a [re]ception and ball in the exhibition hall [on] the evening of May 31. The center [of] this hall is provided with a splendid [po]lished floor for dancing, and one-half [of] the floor was kept clear for that pur[po]se. The music for dancing was sup[pl]ied by a small string band, and the [ce]lebrated Filipino orchestra, located in [a] gallery at one end of the huge hall, [re]ndered high-class music between the [da]nce numbers.

On Tuesday morning, June 1, the con[ve]ntion was formally opened by President [W.] C. L. Eglin, and welcomed by Mayor [Stoy], of Atlantic City. The president [th]en delivered his annual address, in the [co]urse of which he indicated the ad[va]ntages derivable from the policy of es[ta]blishing State sections of the associa[tio]n wherever it is feasible to maintain [the]m.

The sessions of the convention were [di]vided into four classes: General, cover[in]g committee reports and papers not [st]rictly belonging to one of the other [th]ree divisions; Technical, dealing with [en]gineering papers and discussions; Com[m]ercial, devoted to business methods; and [Ac]counting, the scope of which is indi[ca]ted by its title. The sessions of the [lat]ter divisions were held separately, and [o]n account of the large amount of work [to be] done, parallel sessions were held in [di]fferent parts of the pier on the third [d]ay of the convention. The first day was [de]voted to committee reports and papers [i]n the General division, which do not [co]me properly within the field of this [jo]urnal.

Developments in Storage Batteries

The first paper of interest to Power [re]aders was one by Joseph Appleton, en[ti]tled, "Advanced Information Regarding [D]evelopments in Storage Batteries," in [w]hich the author presented a compari[so]n of a modern high-duty "Exide" cell [an]d the standard Manchester cell, such as the Edison stations have used for several years, and pointed out improvements which have been made in recent years in end-cell switches and automatic boosters. The comparison of battery cells may be tabulated as follows:

FIG. 1. 175 [illegible] GAS PRODUCER [illegible]

	Manchester.	Exide.
Number of plates	[illegible]	[illegible]
Weight of cell, pounds	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]

The two cells are of the same size, but the Exide plates are the thinner, permitting the use of 11 plates in a tank which holds only 49 Manchester plates. As an example of the latest development in the application of a storage battery to smooth out a power-plant load curve, the author cited the installation in the huge steel plant at Gary, Ind., where two series of 125 cells each are connected in parallel.

The complete battery is capable of discharging [illegible] amperes, [illegible] [illegible]. The battery is used to smooth out the fluctuations in both the [illegible] and direct-current loads, the former being [illegible] to the battery by [illegible] rotary converters.

Recent Developments in Electric Apparatus

A paper with the above title, read by E. W. Allen, was rather disappointing. The author contented himself by outlining the general features of a 14,000-kilowatt Curtis turbine-generator unit of 6600 volts and 60 cycles, a small belt-driven direct-current dynamo, a 1000-kilowatt split-pole rotary converter, a 2000-kilowatt frequency-changer, and a 3000-kilowatt transformer. All of the information presented in the paper, and much more, can be found in the literature of the various manufacturers.

Gas Engines and Producers

The report of the Committee on Gas Engines was the first paper presented in the Technical division of the convention. In the absence of J. B. Klumpp, the chairman of the committee, the report was presented in abstract by Irving E. Moultrop, of the committee. The report consisted chiefly of elementals with which all interested readers of Power have had ample opportunity to become familiar. "Producers using anthracite coal have been in use continuously for 10 or more years, giving absolute satisfaction." Several types (of bituminous producers) have been on the market in recent years and have been operating with more or less success. Some gasify the entire product of the coal [including ash?] while other types necessitate the use of auxiliary tar-extracting plant to obtain gas suitable for engines. "The quality of producer gas varies with the grades of fuel and the method of operating the producer, but the fixed carbon of all fuels is the basis of producer action and the yield of gas."

By far the greater part of the report consisted of rudimentary statements such as the foregoing and elementary descriptions of the principal types of apparatus and methods. This statement is made not in a carping spirit but as an explanation of the relatively small amount of space which we devote to the report. The elementary information referred to is of value to those who are entirely unfamiliar with the subject, as most central station managers probably are.

The committee described briefly the general features of the gas-power plants of the American Locomotive Company, Richmond, Va.; American Steel and Wire Company, at Worcester, Mass.; Boston Elevated Railway Company, Boston, Mass. (two stations); Charlotte Consolidated Construction Company, Charlotte, N. C.; Georgia Railway and Electric Company, Atlanta, Ga.; Merrimac Chemical Company, North Woburn, Mass.; Milwaukee Northern Railway Company, Port Washington, Wis.; The Norton Company, Worcester, Mass.; Swift & Co., New York City; The Phoenix Tube Works, Brooklyn, N. Y., and the Watson-Stillman Company, Aldene, N. J. The printed report also contained illustrations of a number of representative gas-power plants, most of which have been fully described in this journal, and illustrated descriptions of the Loomis-Pettibone, R. D. Wood, Westinghouse and Pintsch producers. Of these, the new double-zone bituminous producer of the Westinghouse Machine Company is the only one that has not been described at length by the engineering periodicals. Fig. 1 is an exterior view of this producer, Fig. 2 a sectional elevation and Fig. 3 a chart of average test results. From Fig. 2 it will be evident that the cleaning equipment is considerably smaller than that commonly required with other types of producer. The gas, which is taken off at the middle of the generator, passes to a small wet scrubber and thence to a horizontal holder from which it is drawn by the rotary exhauster. The vaporizer surrounds the central portion of the fuel bed, where the two zones merge; consequently it abstracts heat from the gases delivered by both zones. The upper zone is practically a simple down-draft bituminous producer in which most of the green fuel is coked; the lower zone is an up-draft coke producer, supplied with coke from the upper zone. The supply of air and steam to each combustion zone is adjustable independently, of course, so that the proper balance between the two zones may be preserved.

In the discussion following the presentation of the report, M. R. Bump called attention to the producer plant of the Western Chemical Company at Denver,

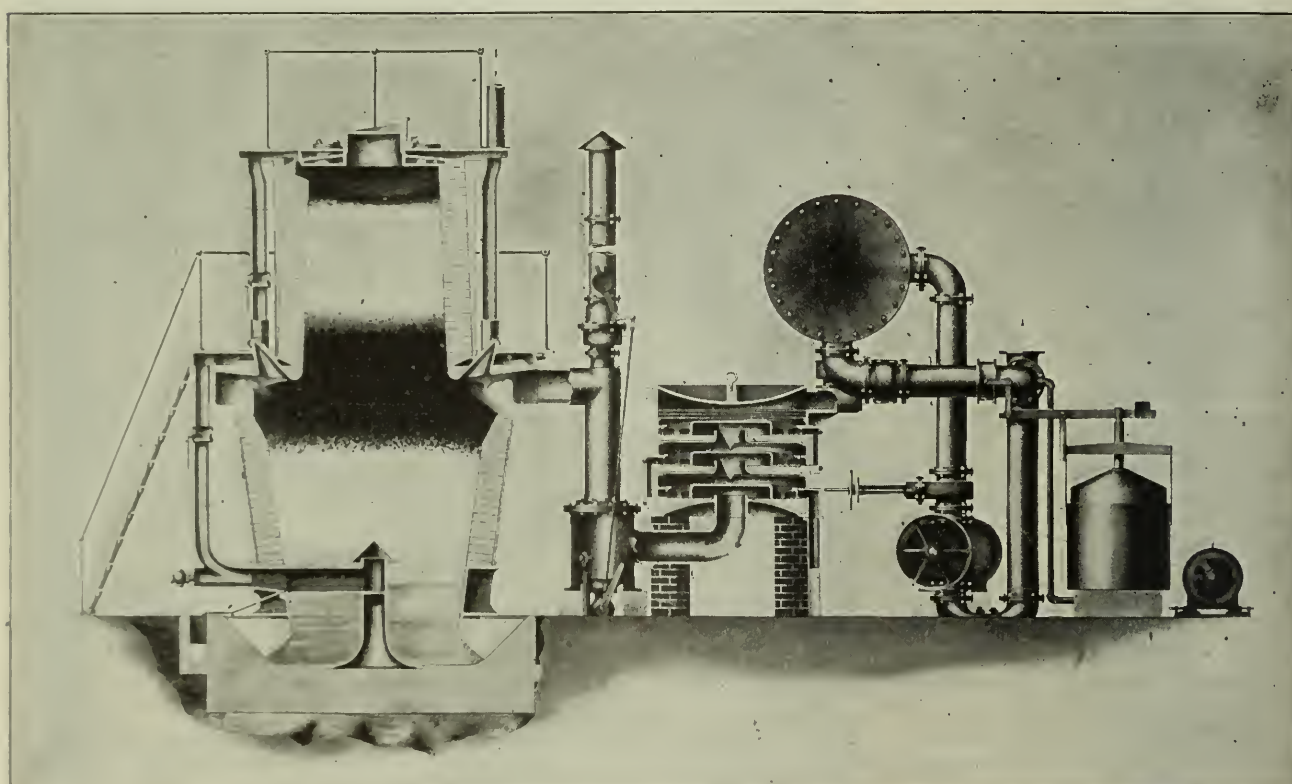

FIG. 2. SECTIONAL VIEW OF 175-HORSEPOWER WESTINGHOUSE BITUMINOUS GAS PRODUCER RECENTLY TESTED AT EAST PITTSBURG

where lignite is gasified, the gas used in engines and the carbon dioxide in the exhaust gases is utilized for charging soda-water fountains.

George R. Stetson gave some results of a year's experience with a pressure producer and engine equipment operated in conjunction with a steam plant at New Bedford, Mass. He said that his experience indicated that the producer is the principal source of whatever troubles occur in a gas-power plant. The steam engines take very readily to the handling of gas engines but boiler firemen do not so readily learn to handle producers intelligently. He also found it difficult to keep producer men because of the unavoidable escape of carbon monoxide gas, his being a pressure plant.

water-proofed. Exploring tubes connected through flexible rubber hose to a 24-inch U-tube of glass were inserted throughout the different parts of the condenser and air pump, in order to make a thorough survey of the interior of the condenser under operating conditions. With a vacuum of 28½ inches and the injection water at 50 degrees Fahrenheit, the amount of air drawn up through the discharge column and from the upper spray plate of the condenser was enormous. The drop of vacuum between the turbine base and the air pump was easily located, but later, by slight modifications in design, was considerably reduced. All indications seemed to show that the more readily the air was permitted to reach the air-suction connection the less was the drop in

ably cheaper to clean one 6000-kilowatt condenser than to clean eight boilers representing the same amount of station output.

In reply to a question by Mr. Chesney, the author stated that in Denver it occurred many times when the air was very dry that the water when leaving the water tower would go below the temperature of the atmosphere, due to the low humidity of the air. Some records, he said, showed that the water leaving the water tower was 6 degrees to 10 degrees below the temperature of the atmosphere. As to the difficulty of keeping the water free from air, he said that by constructing a sunken sink beneath the cooling tower, he had been able to secure water as free from air as the average water supplied

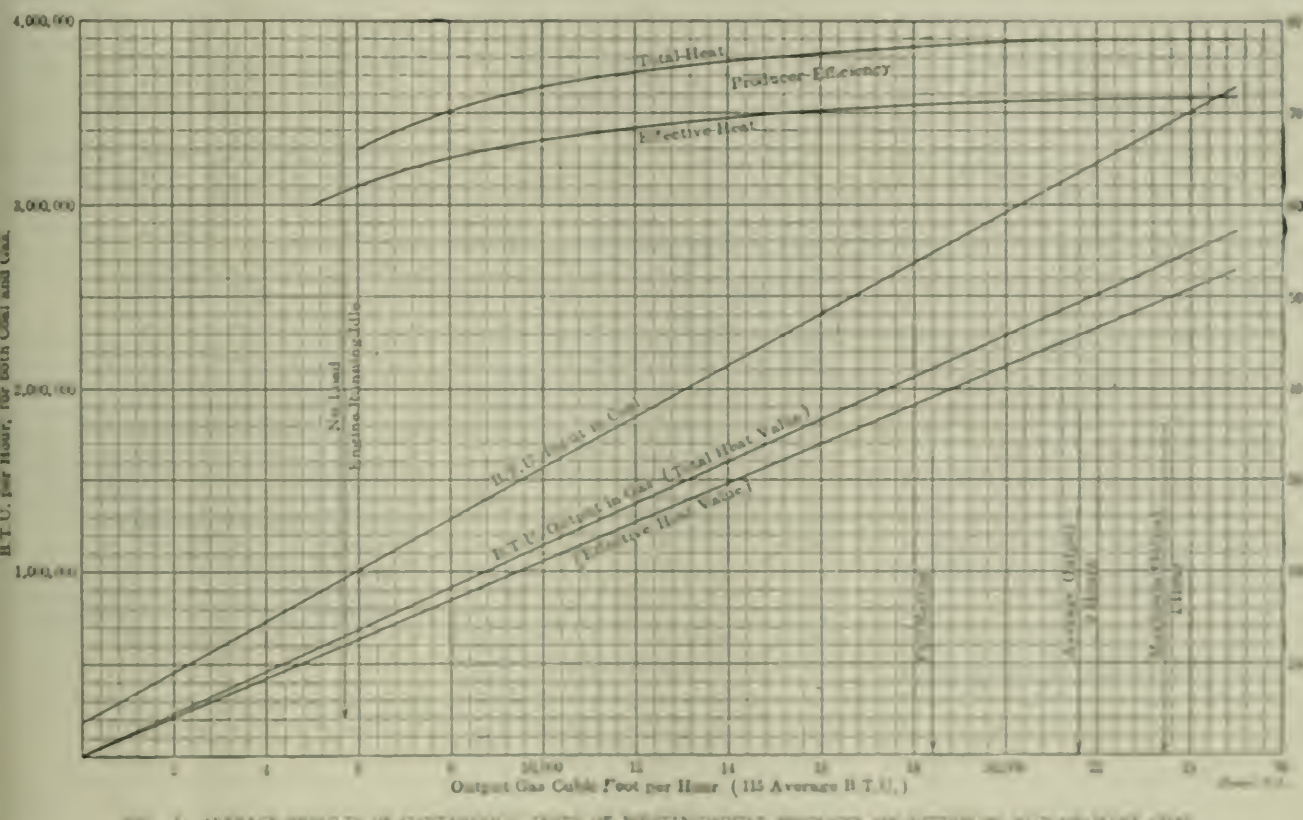

FIG. 3. AVERAGE RESULTS OF CONTINUOUS TESTS OF WESTINGHOUSE PRODUCER ON PITTSBURG RUN-OF-MINE COAL

Condensers and Cooling Towers

The next paper was one by M. R. Bump, devoted to the design and operation of condensers and cooling towers. The section of the paper relating to condensers was printed in the June 15 number of Power; that referring to cooling towers will be found elsewhere in this issue.

Discussing Mr. Bump's paper, A. R. Chesney described some interesting experience made with barometric column condensers used with 3000-kilowatt Curtis turbines. Six-inch bull's-eyes of heavy glass were installed at frequent intervals along the length of the discharge column of the condenser and the condensing chamber and the whole interior lighted by means of incandescent lamps, properly

vacuum. While this trouble with air does not exist in the case of a surface condenser, the many advantages in the barometric column type, such as freedom from repairs, low first cost, and readiness for duty at all times, make it well worthy of careful consideration. With this type of condenser a vacuum of 28 inches or over can be reached with an injection temperature in the summer of 85 degrees Fahrenheit, while in the winter months the vacuum is considerably higher. The quality of the feed water must also be carefully considered in choosing the type of condenser, as with very poor water the surface condenser, with a certain amount of make-up water added from the city mains, will keep the boilers in first-class operating condition. It is consider-

from any stream that is used for condensing purposes.

Reactance Coils in Generating Systems

P. Junkersfeld, of the Chicago Edison Company, presented a brief but meaty paper pointing out the advisability of using reactance coils in the main leads of large alternating-current generators and between different sections of the busbars in order to prevent damage to the machines when a short-circuit occurs on the external circuit. Where large powers and high voltages are dealt with, the automatic circuit-breakers used with machines and circuits of lower voltage or smaller power are not effective. This is particularly true with respect to bushing-delivery generators, because of their high speed and relatively low frequency. With such generators the instantaneous current produced by a short-circuit may be as high as 50 times the normal full load current. An automatic circuit-breaker, even if it could open the circuit absolutely, could not operate quickly enough to protect the generator from the enormous momentary shock inflicted by such an increase in current; hence the advisability of using reactance coils in the circuits. Ordinarily, these do not cause a serious drop in volatge, but a practically instantaneous

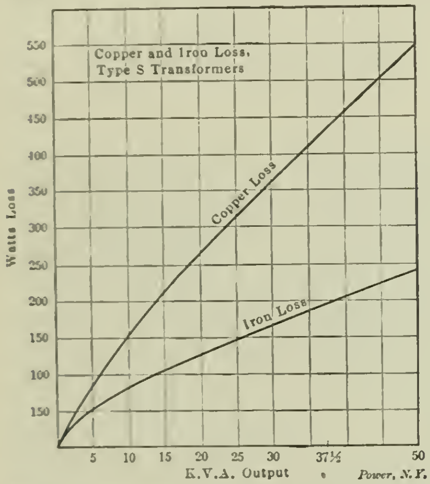

FIG. 4. IRON AND COPPER LOSSES OF TRANSFORMERS OF RECENT DESIGN

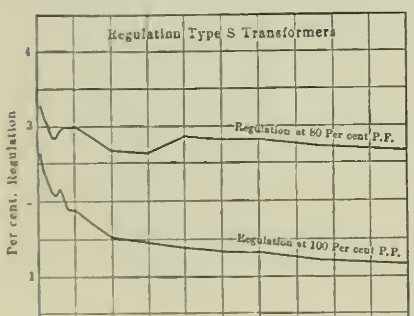

FIG. 5. SHOWING REGULATION OF TRANSFORMERS OF RECENT DESIGN

rise of current, due to a short-circuit which would ordinarily increase the current fifty-fold, will greatly increase the reactance of the coil and thereby choke itself down to a much less destructive overload.

In the discussion of Mr. Junkersfeld's paper, A. S. Loizeaux presented a contribution on the design of reactance coils for the protection of turbine-driven generators. Dr Charles P Steinmetz pointed out that reactance coils inserted in the neutral connections of three-phase generators will protect the machines only from internal short-circuits; in order to protect them from short-circuits on the lines, the reactance coils must be inserted in the main leads of the generators.

He commended Mr. Junkersfeld's suggestion to use coils between sections of the station busbars but said it was unnecessary to have them normally cut out by switches arranged to open automatically at overloads.

Improvements in Transformers

The history of transformer development was briefly traced in a very comprehensive paper by E. G. Reed, and the latest forms of construction were described in detail. The author presented several charts showing the characteristics of modern transformers, among which were Figs. 4, 5, 6, 7 and 8; these, with their captions, are self-explanatory. The improvements due to the use of silicon steel in transformer cores were referred to briefly, and the author pointed out that while the use of this alloyed steel gave

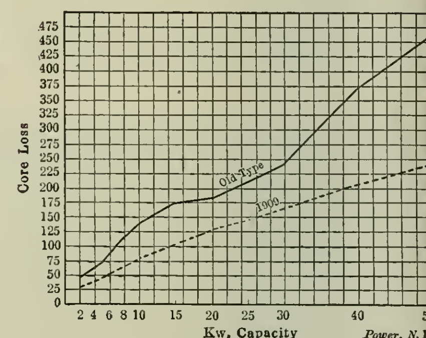

FIG. 10. COMPARISON OF CORE LOSSES IN TRANSFORMERS

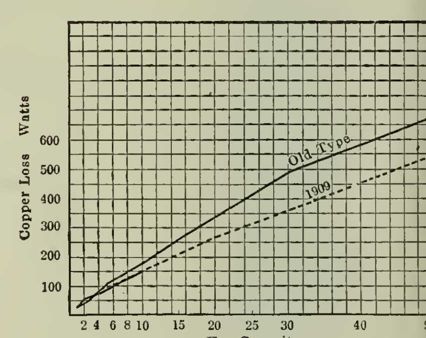

FIG. 11. COMPARISON OF COPPER LOSSES IN TRANSFORMERS

lower core losses for given conditions and therefore permitted the use of smaller cores for given outputs at given efficiencies, the cost of the transformer was not reduced because the new silicon steel is more expensive than the steels formerly used.

This latter point was also brought out in a paper by W. A. Layman entitled "The Practical Aspects of Recent Improvements in Transformers." Mr. Layman's paper was rather more analytical than Mr. Reed's, and brought out more clearly the improvement in transformers which has been effected within the past five years or so. Figs. 9, 10 and 11 present graphically the chief comparisons of the old and new types, the improvements being due entirely to the use of steel containing a high percentage of silicon—about forty times as much as the old steel. Mr. Layman also presented the following comparison of all-day efficiencies:

Size of Transformer		1 Kw.	10 Kw.	50 Kw.
All-day losses in kilowatt-hours	1906	903	4,187	14,415
	1909	610	2,646	8,760
Saving in kw.-hrs. per day		293	1,541	5,655

The foregoing comparison was based on 24 hours of core loss and 5 hours of copper loss per day.

In order to facilitate the parallel operation of transformers, Mr. Layman suggested, manufacturers might advantageously include in their published tables of data the impedance of each size and type of transformer regularly built. With these data before him the user could predetermine accurately the division of load that he would obtain by paralleling transformers of different sizes or makes. The author also suggested that buyers of transformers should require the seller to specify the magnetizing current (primary current when the secondary circuit is open) and the impedance of each transformer. [The former is the determining factor in all-day efficiency, under given load conditions, and the significance of the latter was just explained.]

In discussing Mr. Layman's paper, W. S. Moody said that the effect of silicon upon the permeability [magnetic quality] of the steel varies; at low magnetic densities the magnetic quality is improved and contrariwise at high densities (100,000 lines per square inch and over).

Low Pressure Steam Turbines

In a paper of the above title, C. H. Smoot presented an interesting analysis of the physical features of the various steam turbines as well as a discussion of their application to the use of low-pressure steam from high-pressure engines. This paper is printed practically in full on another page of this number.

The discussion of the paper was disappointingly meagre and spiritless.

Some Unique Power-house Features

In a paper of the above title, G. L. Knight described some forty unusual features found in various prominent central stations. Among these were the following:

The Boston Edison Company has increased its furnace economy considerably by lengthening the arches over its Roney stokers by about 3 feet 10 inches. The arch brick now becomes practically incandescent. The company has also added small individual accumulators to control the oil pressure at the turbine step bearings. The large accumulators originally installed maintain the pressure on the oil pipe main and each of the small accumulators controls the steam supply to the step-bearing pump of its particular turbine unit.

The New York and Brooklyn Edison Companies have increased the output of their boilers very much by the use of large grates. The boilers are hand-fired with anthracite coal, and the grates are 12 feet deep by 12 feet 7 inches wide, sloping toward the bridge wall with 16 inches difference in elevation between the front and back of the grate. The fire door is set at an elevation of 2 feet 10 inches above the firing aisle. Over the furnace are built three reverberatory arches with steel, I-beam skew-backs built into the steel columns of the boiler setting, these arches being placed at sufficient distances apart to afford ample area for the passage of the gases. The arches become practically incandescent and have greatly improved the furnace economy. The side walls of the boiler are arched between front and bridge wall, so that in case of repairs the brickwork below the arch may be removed without disturbing the rest of the setting.

In the power house of the Hudson and Manhattan Railroad Company, at Jersey City, two 5000-kilowatt Curtis turbines are equipped with three condensers, one on the outside of each turbine and one between the turbines. The exhaust from each turbine to the condenser on each side of it is led through three circular cast iron pipes, each equipped with a gate valve. The three gate valves are connected by gearing to a small engine for closing or opening the gates quickly and simultaneously. Each condenser is equipped with the usual auxiliaries, and the arrangement permits taking out a condenser for tube or other repairs without shutting down a turbine.

A pneumatic system for handling ashes in the power plant of Swift & Co. at Chicago comprises a closed chute into which the ash hoppers discharge and which leads to a general tank or hopper at such a hight as to allow the ashes to be discharged from its bottom into the usual ash pocket. The tank or hopper is kept under vacuum by an exhauster connected to the top of the hopper. Two gates are placed across the mouth of the tank at the bottom, the gates being operated alternately so that when the top gate is opened a quantity of ashes fills the space between the gates; the top gate is then closed and the lower one opened, the ashes falling to the pocket without breaking the vacuum in the tank. When the gates of the individual ash hoppers are opened the rush of air to the tank carries with it the ashes and water discharged from the ash hoppers, which are carried to the tank at great speed.

A dry-tube condenser of 18,000 square feet of surface is said to give the same results at the No. 2 Waterside station of the New York Edison Company that are obtained from condensers of the ordinary types having 25,000 to 30,000 square feet. The dry-tube condenser is similar to the usual type of surface condenser excepting that the shell is rectangular in cross-section and deflecting plates are provided for the purpose of carrying the exhaust condensate to the sides of the condenser instead of letting it drip over the tubes. The incoming exhaust steam therefore comes directly in contact with the cool tubes instead of meeting a film of water over each tube. The advantages claimed for this condenser are lower first cost, fewer tubes, better vacuum and hotter water of condensation.

Motor-generators versus Rotary Converters

This perennial topic was the text of a paper by F. M. Farmer, of the Electrical Testing Laboratories. Mr. Farmer presented a general exposition of the operating principles of converters and motor generators with the various standard methods of regulation and presented the results of some efficiency tests made on representative machines in regular operation. The results were most favorable to the ordinary rotary converter with synchronous booster regulation; the induction regulator converter came next in the scale of efficiency, the split-pole rotary converter third, the induction motor-generator fourth and the synchronous motor-generator last.

It would have been very interesting in connection with the efficiency tests to determine the distribution of the losses among the various parts of each equipment. The available time was too short to admit of this being done, but estimates from manufacturers' specifications give the following:

In converter equipments the loss in step-down transformers is about 15 per cent. of the total losses, induction regulator or synchronous booster, about 40 to 50 per cent., converter, about 30 to 40 per cent., low-tension cable, about 5 per cent. In motor generators the losses are probably about equally divided between motor and generator.

The following operating notes were obtained from the engineers in charge of the particular machines on which the tests were made, and from the operators. They are therefore opinions based on experience.

The synchronous converters on the Brooklyn Edison system are all started from the direct-current side, and, since storage battery current is always available in the substation, no other starting provision is made. The Boston Edison Company follows the practice of starting its motor-generators from the direct-current side, although provision is made for starting both the induction and synchronous machines from the alternating-current side.

The time required to start and get into service was reported the same for all equipments, except one, as three to five minutes. The exception is the split-pole converter, which requires one to two minutes more because every change made in the field, to adjust the alternating e.m.f. while synchronizing, affects the speed also. In case of emergency, other things being equal, preference would be given to the induction motor-generator over the synchronous motor generator and the synchronous booster converter over the other two types of converter. It may be noted that, of the various starting synchronous apparatus, the direct-current method is used by both of these companies, as it means the least disturbance to line. Where direct current is not available, an alternating-current starting motor on the shaft (extended) would probably give the best results.

In motor-generators the voltage and power factor are quite independent, but in synchronous converters a change in voltage at a given load produces more or less change in the power factor, hence more or less manipulation is required every time the voltage is changed. One of the author's charts shows the extent of this change in power factor with change in voltage, load and main field current remaining constant. The induction regulator converter and the synchronous booster converter lowered the power factor markedly at light loads with increase in voltage, but at 75 per cent. load and over the change was not appreciable. Of the three types of converter the power factor of the split-pole is least affected at any load. This is probably due to the fact that in this machine there are compensating windings on the main magnet poles in series with the auxiliary pole so connected that the main pole flux is decreased or increased when the auxiliary pole is increased or decreased respectively, causing the total flux to be automatically kept practically constant.

Converters with induction regulators and synchronous boosters have a practically constant power factor at all loads with constant direct voltage. The split-pole converter shows a slight falling off in power factor with increase in load.

The author's conclusion was that the answer to the problem "motor generators versus synchronous converters" for lighting and power work depends to a great extent on the circumstances in each individual case. In general, the data given in the paper indicate that the use of motor generators would not be justified except possibly on 60 cycles or where the alternating-current supply fluctuates badly. The principal advantage of the motor-generator is its flexibility and the entire independence of the direct-current system from the alternating system. If the high-tension alternating-current supply is reasonably free from fluctuations, these features are of small value and are more than counterbalanced by lower efficiency and increased first cost. Comparisons of the various types of synchronous converter are at the present time in favor of the synchronous booster converter, but the split-pole machine is so recent a development that improvements in design, which will undoubtedly be made, may improve the efficiency curve and the operation of the machine to such an extent that this conclusion may be modified or even reversed.

In the brief discussion of Mr. Farmer's paper, W. L. Waters manifested considerable satisfaction at the relatively unfavorable showing made by the split-pole converter. He didn't say he was glad of it, but he might as well have done so.

Grounding Secondary Circuits

The committee on the Grounding of Secondaries in its report expressed the unanimous opinion based on three years' continuous study of the subject and extensive correspondence and conferences with prominent engineers all over the country, that secondary circuits up to 150 volts should be grounded and the grounding of circuits of more than 150 volts prohibited. There have been very few, if any, fatalities from 150 volts but many cases at 200 volts and thereabout.

The only feasible method of protecting persons from circuits of 200 volts and over seems to be to install the apparatus in such a manner as to make it difficult for the user to stand on the earth or to be otherwise connected with the ground while touching lamps or motors. This would mean installing lights so that they would be out of easy reach, controlling them with wall switches, and keeping them away from gas and water pipes, telephones, etc. It would also require motor equipments so placed that the attendant must stand on dry boards or rubber mats, and not be within reach of metal framework of buildings, metal floors, grounded pipe rails, etc. The best ground, all admit, is a connection with an underground metallic water-pipe system. In many cities this exists, but its use is not always permitted. In nine cities with which we are familiar its use is prohibited. The committee suggested that the members of the association do a little missionary work in convincing water-works engineers and managers that when secondary alternating-current wires are connected to water pipes no current flows unless a transformer breaks down or a cross occurs; that should such an accident occur it would in nearly all cases cause a fuse to blow and immediately cut off the current; and that, in the event of a current flowing, it would be an alternating current, which, it is generally believed, produces no electrolysis. Where underground mains are not available other methods must be resorted to. The old method of a copper plate buried in coke, prescribed by the Underwriters, is not always reliable and in some cases has been found to be worse than useless. Iron pipes an inch or more in diameter, driven eight or ten feet into the ground, have in some cases been found to be very satisfactory, while in other cases valueless.

A recent suggestion has been made to saturate the ground around the pipe, at frequent intervals of time, with salt water. Tests thus far made show that this is an excellent method and that after a few applications of the salt water the ground becomes permanently moist and a good conductor. The committee suggested the placing around the pipes, and rather near the surface, of a quantity of rock salt, which will, because of its hygroscopic nature, draw the water and thus produce a ground of low resistance and one that would also remain permanent; the committee preferred, however, to have tests made of this in various parts of the country before giving it full indorsement. The report cautions users of this method to take great care in making the connection between wire and pipe, as the presence of salt will tend to increase corrosion. The pipe itself will doubtless corrode, but a plain iron pipe will last perhaps ten years, while one of galvanized iron will be good for several years longer. Brass pipe would last almost indefinitely and would not add materially to the total cost.

Dr. Steinmetz, P. Junkersfeld, Philip Torchis and other well-known central-station men agreed that all circuits up to 150 volts should be grounded, but objected to the prohibition of grounding circuits of higher voltages. On motion of Dudley Farrand this recommendation in the report was referred back to the committee for further consideration and report.

New Officers

The election of officers for the ensuing year resulted as follows: President, Frank W. Frueauff; first vice-president, W. W. Freeman; second vice-president, John F. Gilchrist; secretary, Frank M. Tait; executive committee, Frank W. Frueauff, W. W. Freeman, Dudley Farrand, A. J. Decamp, George H. Harris, R. M. Searle, Alexander Dow, Charles L. Edgar, Arthur Williams, C. A. Stone.

Studying High Voltages

With the purpose of studying enormously high voltages a short experimental transmission line has been built in Sweden which is adapted to operate at 500,000 volts. A special form of transformer is used to furnish this high electromotive force. Circulating oil is used for insulation between the high- and low-tension windings. The line is supported on the suspended type of insulators 11 feet apart. Tests of the surface discharge showed that a wire of 10 square millimeters (0.0155 square inch) cross-section would discharge at 35,000 volts, of 20 square millimeters at 50,000 volts, of 100 square millimeters at 200,000 volts, and of 250 square millimeters at 390,000 volts. As the tension was raised to 480,000 volts, the noise grew very loud and sparks leaped from the insulators. At night the glow of the discharge could be seen 2½ miles away.—*The Engineer* (London).

ormulas for Computing the Results of Gas Analysis

By Frank B. Shields

For calculating the pounds of air per pound of coal, having analyzed the chimney gas and knowing the percentage of carbon in the coal:

Pounds of air per pound of coal

$$= \frac{\text{wt. O in chimney gas} - \%\ \text{O in air (by wt.)}}{\text{wt. C in gas} - \%\ \text{C in coal}}$$

$$= \left(\frac{\%\ C\ \text{in coal}}{0.231}\right)$$

$$\frac{\text{wt. O in 100 liters of gas} \times \text{wt. per L.}}{\left[\begin{array}{l}(\text{vol. } CO_2 \text{ in 100 L. gas} \times \text{wt. per L.} \times \frac{12}{44}) + \\ (\text{vol. CO in 100 L. gas} \times \text{wt. per L.} \times \frac{12}{28})\end{array}\right]}$$

$$= \left(\frac{\%\ C\ \text{in coal}}{0.231}\right)$$

$$\frac{(\%\ CO_2 + \%\ O + \tfrac{1}{2}\ \%\ CO)\ 1.429}{\%\ CO_2 \times 1.965 \times \frac{12}{44}) + (\%\ CO \times 1.251 \times \frac{12}{28})}$$

$$= 0.1153\ (\%\ C\ \text{in coal})$$

$$\left(\frac{\%\ CO_2 + \%\ O + \tfrac{1}{2}\ \%\ CO}{\%\ CO_2 + \%\ CO}\right). \qquad (1)$$

This formula (1) gives exactly the same value that would be obtained by going through the longer calculation in which each of the components—carbon dioxide, carbon monoxide, oxygen and nitrogen—is considered separately. It may be further simplified if one takes into consideration the fact that, in nearly all cases, the quantity (% CO_2 + % O + ½ % CO) is equal to twenty. We should expect this to be almost constant, for it represents the oxygen of the air after it has passed through the furnace and combined with some carbon, and since the oxygen content of the air does not change appreciably, the only variations in the foregoing quantity must be due to a loss of oxygen by its combination with the hydrogen and sulphur contained in the coal. Neither of these losses would be taken into account in the course of an ordinary analysis with the Orsat apparatus. The results of a very large number of determinations show that if the quantity (% CO_2 + % O + ½ % CO) is taken equal to twenty, scarcely ever is an error as large as 2 per cent. incurred. Making this substitution in formula (1) gives the simpler formula:

Pounds of air per pound of coal =

$$2.31 \times \frac{\%\ C\ \text{in coal}}{\%\ CO_2 + \%\ CO} \qquad (2)$$

In most series of analyses, the percentage of carbon in the coal will be a constant; and if there is substituted this value of the per cent. of carbon as found by chemical analysis—suppose, for example, we use 83 per cent., which is fairly representative—we have the approximate formula:

Pounds of air per pound of coal =

$$\frac{191}{\%\ CO_2 + \%\ CO} \qquad (3)$$

For calculating the percentage of heat lost in the chimney gas, being given an analysis of the gas, its rise in temperature, the percentage of carbon in the coal and its heat value:

$$\textit{Per cent. of heat lost} = \frac{\text{heat lost in gases}}{\text{heat value of coal}} =$$

$$\frac{\text{heat in gases from 1 kilogram of C} \times \%\ C\ \text{in coal}}{\text{heat value of 1 kilogram of coal}} \qquad (4)$$

The heat in the gases from 1 kilogram of carbon is equal to the sum of the volumes of each gas multiplied by the weight per liter, by the specific heat, and by the rise in temperature. The volume of each gas is obtained by first finding how much carbon dioxide and carbon monoxide are necessary to contain one kilogram of carbon and then from the relative proportion, as found in the gas analysis, the corresponding volume of the other gases can be calculated. Matters are very much simplified (with but slight sacrifice of accuracy) by considering the gas as a mixture of two components—the carbon dioxide and the remaining gases. From the following table it is evident that the constant, *specific heat × weight per liter*, is about the same for all of the gases to be considered, except the carbon dioxide:

Gas	Specific Heat Multiplied by Weight per Liter
CO_2	0.463
CO	0.308
O	0.311
N	0.307

If 0.307 is taken as the value for all the other gases, an error of less than one-half of 1 per cent. will be incurred. With this explanation, let us take up the calculation. All values are based on atmospheric pressure and 0° Centigrade.

1 kilogram of carbon

$$= \frac{44}{12}\ \text{kilograms of } CO_2$$

$$= \frac{44\ 000}{12 \times 1.965}\ \text{liters of } CO_2$$

$$= 1866\ \text{liters};$$

and since any carbon monoxide would represent the same amount of carbon as an equal volume of carbon dioxide, then

$$1866\ \text{liters} = \text{vol. } (CO_2 + CO)\ \text{from 1 kilogram of C}$$

Let

x = % CO_2 in chimney gas (by analysis);

y = % CO in chimney gas (by analysis).

Then

$$\left(\frac{x}{x+y}\right) 1866 = \text{liters } CO_2 \text{ in gas from 1 kilogram of C}$$

and

$$\left(\frac{100-x}{x+y}\right) 1866 = \text{liters of all other gases}$$

Heat lost in gases =

$$[0.463\ (\text{vol. } CO_2) + 0.307\ (\text{vol. other gases})]\ R.\ \text{in}\ T \qquad (5)$$

Substituting equation (5) in (4):

$$\textit{Per cent. heat lost} = \frac{(\%\ C\ \text{in coal})\ R.\ \text{in}\ T}{\text{heat value of coal}}$$

$$\left[\frac{x}{x+y}\ (1866)\ 0.463 + \frac{100-x}{x+y}\ (1866)\ 0.307\right]$$

$$= 0.2864\left(\frac{\%\ C\ \text{in coal}}{\text{heat value}}\right) R.\ \text{in}\ T$$

$$\left(\frac{200 + \%\ CO_2}{\%\ CO_2 + \%\ CO}\right) \qquad (6)$$

This equation (6) gives values which are about 0.5 per cent. low, for it does not take into account the loss of heat due to the formation of water vapor from the hydrogen in the coal. And so the results found by the foregoing equation should be increased by this amount.

When the same kind of coal is being used right along, the values for the per cent. carbon and heat value of the coal will disappear into the constant, giving the expression:

Per cent. heat lost =

$$\textit{constant}\left(\frac{200 + \%\ CO_2}{\%\ CO_2 + \%\ CO}\right) R.\ \text{in}\ T \qquad (7)$$

For average coals of the four classes mentioned in the following table, the corresponding constant may be used in formula (7) with very close results:

Kind of Coal	% C	Heat Value	Constant for Form. (7)
Lignite	51	5500 cal	[illegible]
Bituminous	[illegible]	7500 cal	[illegible]
Semi-bituminous	[illegible]	8400 cal	[illegible]
Anthracite	83	7700 cal	[illegible]

One calory equals 3.97 B.t.u.

A direct-current shunt dynamo will only self-excite and develop pressure for one direction of rotation corresponding to the remanent magnetism. A German electrical engineering firm makes use of this fact to provide a means for obtaining a unidirectional current irrespective of the direction of rotation. Two shunt machines are coupled in any suitable manner and connected in series. The shunt coils are wound in opposite directions, so that for either sense of the rotation only one machine develops pressure. It is advisable to supplement the remanent magnetism by an auxiliary winding separately excited. The two machines may also be combined in a single machine.

It is stated that in the oil fields of Baku, Russia, engineers are studying the use of natural gas for firing instead of using crude oil as before. A simple centrifugal apparatus consisting of a centrifugal fan working through pipes leading to the wells, thus creating vacuum, is more generally employed. In this way the natural gas issuing from a well is collected and stored, to be used either under boilers or in gas engines.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT McKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 Shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y.
Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 *we printed and circulated* 1,836,000 *copies of* POWER.

Our circulation for May, 1909, *was (weekly and monthly)* 152,000.

June 1 42,000
June 8 36,000
June 15 36,000
June 22 36,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

Contents

Removes all the Carbon

Henry Duncan, of Spring Valley, Ohio, has got it now. According to the Dayton *Daily News* this gentlemen has invented "a chemical preparation which, poured upon the coal, removes every particle of carbon; hence, smokeless combustion." We wonder that the suggestion has not occurred to somebody before. The cobbler of Altoona has shown (?) that ashes will burn as well as coal, if you sprinkle salt and oxalic acid upon them, and won't smoke; ergo, add something to the compound to kill out the carbon, sprinkle it upon the coal and when the carbon is gone, burn the ashes.

The Twelve Hour Shift

The engineer of an electric-light plant was found asleep one night while on duty. That by itself may not have amounted to much but the cause of his going to sleep is significant. Five 300-horsepower cross-compound engines and a twelve-hour shift with an engineer and an oiler on watch—these were the conditions, which are doubtless duplicated in many instances.

It is no wonder that the engineer was asleep. A twelve-hour shift is enough to render any man physically unfit to perform his duties with justice to himself or his employer. This is a fact, however, which many power-plant owners and managers fail to appreciate, assuming, apparently, that a man is as "fit" after working twelve hours as when he first went to work. Such long hours are injurious to the engineer's health and dangerous to those around him because of the liability of accident resulting from error in judgment on the part of a man with a tired brain.

The power-plant owner who will deliberately sacrifice the health and mental development of his engineering force can adopt no more systematic method of reducing the efficiency of his men than by employing the twelve-hour shift. Few men, after working twelve hours in a hot, stifling engine room, care to do other than plod home like an overworked truck horse when released, eat supper and go to bed, knowing that the same conditions will be encountered on the morrow. Can any plant owner or manager imagine a man going home in such a condition and spending much time in mental development, reading up on engineering matters, or figuring on problems pertaining to his plant? Furthermore it is not reasonable to expect that an engineer will subject his energies to any extra taxation in order to keep his plant in the best condition when his regular working hours cover almost the entire period out of bed.

In the fireroom, a fireman who knows he will have to shovel coal for twelve hours, besides attending to other duties such as blowing tubes, cleaning fires, oiling the feed pumps and keeping the boiler room clean, is not going to exert himself in seeing how little coal he can burn. His greatest aim will be to get through the day's work as easily as possible, without a care as to the money he throws away because of inattention to his legitimate duties. Can he be greatly blamed?

The net result of this sort of policy is that the economy of the plant falls far below what it should be and the owner pays the bill, meanwhile laboring under the silly delusion that he is saving the expense of the third set of men which would be required to operate the plant on eight-hour shifts.

Heat Loss of a Steam Engine Cylinder

As Watt has been credited with inventing everything connected with the steam engine, and saying about all the epigrammatic things that have been said about the steam engine and its management, it is possible that he said: "Keep the cylinder as hot as the steam which enters it," and it is also possible that he invented the steam jacket in order to carry out this injunction. But, as the steam jacket only transfers condensation from the inside to the outside of the cylinder, its use, in a great many cases, is at least of doubtful economy.

If a perfect nonconducting cylinder covering could be found, most of the losses from radiation could be prevented, and whether used on the outside of a steam jacket or in place of it it would, if not too expensive, be rapidly adopted. "Dead air" has long been regarded as a most efficient insulating substance, but no air at all is generally thought, whether rightly or otherwise, to be the best insulation. Whether the Thermos bottle jacket is lined with dead air or with more or less of a vacuum, the question arises: Why would not the insulation used on the Thermos bottle be just as efficient if applied to the steam-engine cylinder?

From data obtained in a rather crude sort of way, the operating engineer in a large pumping station estimated that a gain of four per cent. in the amount of water delivered per pound of coal burned was realized by substituting a vacuum jacket for a steam jacket on one of the engines. In this case the jacket was connected directly to the condenser of the engine and the cost of maintaining the vacuum was slight.

With a higher vacuum and special means of guarding against slight leaks of air into the system the gain might be greater. Who knows? Engineers would like to know. Designers should know. Who will find out and tell?

Priming and Foaming

Everybody has seen the pot boil over. That is what happens when a boiler foams or primes. The term "to prime" is usually applied to the mechanical entrainment of moisture in greater or less quantities, while "foaming" implies the formation of suds.

The lifting and carrying over of water are favored by rapid ebullition, by tortuous and constricted passages for the steam to follow before being liberated, by the liberation of a large quantity of steam from a small amount of water surface and by a tendency to form small bubbles or suds, which is produced by the presence of soapy substances or by the concentration of salts in the water.

In the old days, when boilermakers used to strive to get as many square feet of heating surface as possible into a given shell, it was found that the tendency to raise the water was much reduced by leaving out the central vertical row of tubes, a practice which is now quite generally followed. Steadiness in steaming will be favored by a large and free disengaging surface for the steam, and the avoidance of constricted passages for the steam to pass through beneath the water line. Of course, the more steam bubbles there are beneath the water line the higher will the water line be, with a given amount of water in the boiler, and the more rapid the rate of steaming the more violent the ebullition, and the greater the volume in which the steam escapes into the steam space the greater the tendency to carry the water along with it.

The likelihood that priming will result from the use of any given feed water should be taken into consideration in the design of the plant. The boilers selected should be of such type and capacity that there will not be a great inherent tendency to priming. It has been stated, for instance, that the locomotive type of boiler is three or four times more prone to priming than the ordinary horizontal return-tubular boiler. Aside from the type of boiler and the rate at which it is driven, however, there are many things in the operation of a plant that have an influence on the tendency to priming. One of these is whether the boilers are washed out regularly and kept clean. Mud, precipitate, or other matter in suspension will increase the tendency to foam. Another agency is the water level that is carried. In many boilers a change of water level results in considerable variation in disengaging surface and also in steam-storage space. The greater the disengaging surface and the greater the steam-storage space, the less likelihood there will be of particles of water being carried into the steam pipe.

Another point is the extent to which impurities are removed from the water before it enters the boiler. Mud and other impurities in suspension can be kept out by a filter, but impurities in solution must be removed by suitable chemical treatment. Carbonates, it is true, can be precipitated by an external heat treatment, but sulphates, chlorides, etc., require the addition of some suitable reagent which, in nearly all cases, whether the purifying process be of the hot or cold type, or whether a boiler compound be used, is some salt of sodium. This sodium combines with the sulphate radicles of calcium sulphate to form sodium sulphate. Sodium sulphate is very soluble and will not precipitate even though the water be boiled down to the consistency of a syrup. Any great concentration of this sodium salt in the boiler has a tendency to produce foaming, which should be prevented by frequent and regular blowing down. It has been found in many cases that where the blowing down is faithfully attended to the boilers can be driven far above their normal rating without trouble from priming.

The presence of oil in the boiler also has a tendency to produce foaming, even where some compound containing soda or other alkali is employed to prevent its baking onto the plates. Alkalies combine with the organic part of the oil to form soap. The remedy is, as before, to blow down frequently.

Mention was made in the foregoing of the fact that solid impurities in the water are conducive to foaming, and this applies not only to solids brought in with the water, but also to those precipitated from the water in the boiler, either by heat or by compounds, and even to old scale loosened from the shell or tubes of the boiler as a result of the use of scale preventatives. These particles are sometimes very fine, especially where magnesia is present in the water, and they do not settle readily while the water is in rapid motion from boiling. They have a tendency to collect on the surface, which can to some extent be removed by the use of the surface blowoff. Another factor in producing priming not mentioned is the intermittent action of the engine in withdrawing steam. Inasmuch as the carrying power of gaseous currents increases more rapidly than the increase in speed, it will be seen that if a given amount of steam is supplied intermittently there will be much more likelihood of water being carried away with it than if the same amount of steam were drawn out in a steady current. This can be remedied to a large extent by the use of receiver-separators on the steam lines. The better to effect the latter purpose, the separator should have a large volume, should be a separator-receiver and be located near the engine, while from the point of view of preventing water hammer and unsightly and annoying leaks at joints, etc., and a quick and easy return of the water, a separator with less receiver capacity should be used at the boiler. When a superheater is used the use of a separator between the boiler and the superheater will relieve the superheating surface of the work of evaporating the moisture and leave it free to do the work for which it was designed. The heat required to dry out ten per cent. of moisture from 120-pound steam would superheat it some one hundred and fifty degrees.

Initiative

In an orderly power plant, where all the proper tools and appliances are at hand and set rules are followed in the performance of daily tasks, initiative is not of vital importance. Any man ordinarily skilled in his trade or profession should find no serious difficulty in superintending or working in such a plant. There is usually little or no call for inventive ability and no adaptation of means or materials necessary, so that a lack in this quality would not be a serious handicap. An enviable record may even be made. But take the same man and put him in a plant where the initiative of another has not left it in such excellent shape and the materials and tools are not at hand to do every job in a hurry, then observe the result. His ingenuity and ability will be taxed to the limit and he will find it necessary to exercise his brain to a much greater extent than was ever necessary in the model plant.

An inventive mind making it possible to take the initiative in every instance is not a case of inheritance. It comes from broad experience in the various lines of work pertaining to power-plant operation, and is acquired in no other way. To show a man how to scatter coal or spray and properly to handle the slice bar requires previous experience in this line. Knowing how to use a hammer and chisel, to file a piece of metal flat or round, to turn off a commutator, or even handle a pick and shovel are small things in themselves, but all go to make the thoroughly competent and all-round man. A chief engineer may never have to do such work, but it is to his advantage to have practical knowledge of all these things gained by experience, so that, when occasion demands, he may take the initiative and train the unskilled hands. Without these qualifications and the ability to devise ways and adapt means, the job is apt to get muddled and sooner or later the "boss" will find himself in a sorry plight. As a minor example, if a bolt three inches long is needed for a repair or replacement, and the nearest ones on hand are two-inch and four-inch bolts, the man of initiative would promptly cut an inch off the four-inch bolt, smooth up the end and use it. The other sort of man would let the job wait a week or a month, until some three-inch bolts could be got in stock.

New York N. A. S. E. Convention

The fourteenth annual convention of the New York State Association of the National Association of Stationary Engineers was held at Syracuse, June 11 and 12, with headquarters at the St. Cloud hotel. The executive sessions of the delegation were held in the New Onondaga courthouse.

Promptly at half-past 9 o'clock on Friday morning, the convention was called to order by the chairman of the local committee, Harry Bache, and after the Rev. E. L. Waldorf offered prayer, Mayor Alan C. Forbes made a pleasing address of welcome. President J. C. Roberts responded for the engineers. Past National President Herbert E. Stone's witty and interesting speech was well received. The convention then went into executive session and the several necessary committees were appointed.

During the progress of the meetings resolutions were adopted concerning the death of the late Ira Watts, secretary of the Life and Accident Association. A special fund was voted for the use of the legislative committee to help in the efforts to secure a State license law. An invitation was extended to the State association by the secretary of the Chamber of Commerce to make Syracuse its permanent convention city, and Superintendent Fischer, of the Onondaga county courthouse, extended to the delegates the use of the courthouse for exhibition purposes at any time. Mr Fischer will be made an honorary member of Syracuse Association No. 34 at its next meeting.

The following State officers were elected, and were installed by Past National President Herbert E. Stone: Grover H. Worden, president; Charles Schabecker, vice-president; E. E. Pruyn, secretary; Winfield C. Graham, treasurer; Harry Bache, conductor; Joseph M. Gregory, doorkeeper; Stewart Warner, chaplain. Either Albany or Buffalo will be the next meeting place.

The manufacturers' exhibit was the largest ever held in connection with the State convention. The exhibit hall was in the basement of the courthouse, convenient to the convention hall, and was very tastefully decorated with the national colors. The following occupied booths: Home Rubber Company, Garlock Packing Company, Edward Joy Company, V. D. Anderson Company, Syracuse Supply Company, Jenkins Bros., Mechanical Rubber Company, Syracuse Rubber Company, Peerless Rubber Manufacturing Company, Eureka Fire Hose Manufacturing Company, Carbohydride Company, C. H. Trumble, Chapman Valve Manufacturing Company, Stewart Heater Company, Penberthy Injector Company, Winegar Boiler Compound Company, C. E. Mills Oil Company, Geo. S. Herrick, McLeod & Henry Company, Direct Separator Company, Albany Steam Trap Company, Dearborn Drug and Chemical Works, Underfeed Stoker Company, Greene, Tweed & Co., Syracuse Gas Engine Company, *Practical Engineer*, W. B. McVicker Company, Neemes Bros., Keystone Lubricating Company, *National Engineer*, Fairbanks Company, Strong, Carlisle & Hammond Company, S. H. North, Fulton Company, POWER.

On Saturday evening a banquet was served at the Hub café, at which fully 300 attended. At the close of a splendid menu, Herbert Self, of the Peerless Rubber Company; William Murray, of Jenkins Bros., and John W. Armour, of POWER, entertained. During the evening Harry Bache, the toastmaster, introduced the following speakers, who made short, snappy and interesting addresses: Rev. E. L. Waldorf, J. E. Reagan, Prof. John E. Sweet, J. C. Roberts, Giles Stillwell, H. E. Stone, T. W. Meachem, Joseph Griffin and E. E. Pruyn.

There were trolley rides to places of interest in the city, a visit to the Syracuse University and an excursion to Long Branch park.

Kentucky N. A. S. E. State Convention

With eleven delegates seated and a total of sixty members and friends present, the sixth annual convention of the Kentucky State Association convened in Liederkranz hall, Henderson, Ky., June 4. Vice-President Draper presiding. After preliminary remarks, Mr. Draper introduced Hon. S. D. Harris, mayor of the city, who paid high tribute to the National Association of Stationary Engineers. The

DELEGATES AND VISITORS AT NEW YORK N. A. S. E. CONVENTION, AT SYRACUSE, JUNE 11 AND 12, 1909

DELEGATES AND VISITORS AT KENTUCKY N. A. S. E. CONVENTION AT HENDERSON, JUNE 4 AND 5, 1909

objects of the order are well known to Mayor Harris, as this was the second time the State body had been entertained at Henderson.

Mayor O'Brien, of Owensboro, an honorary member of the association, was the next speaker. He referred to the occasion of last year's meeting at Owensboro, when Mayor Harris was in attendance. This year he was returning the compliment, and hoped that each of the cities would be further favored with the State meetings.

F. W. Raven, national secretary, then addressed the convention. He took a strong position in favor of a State license law for engineers, not only for the benefit of the organization itself, but also for humanity in general, and deplored the fact that political pull is so often able to defeat the best of measures. He also showed how the N. A. S. E. was working for education and for the public in getting only competent men in charge of power plants. J. H. Van Arsdale, national trustee, of St. Louis, was then introduced, and in a talk on the welfare of the association outlined several plans whereby individual members could help in its advancement.

Following this talk, a paper on "The Aims and Objects of the N. A. S. E." was read by State Deputy R. Baumgarten, of Ashland, Ky., who covered completely the grounds upon which the association was founded and on which its affairs are conducted. This paper was greatly appreciated and a rising vote of thanks was tendered to its author. State President August Pohl, of Louisville, then took the chair, resuming the regular order of business. Among other matters it was decided to furnish a streamer representing Kentucky, to supplement the American flag owned by the National body. After the business session, F. V. Gantt, of Cincinnati, delivered an interesting talk on steam turbines. He brought out their advantages as compared with reciprocating engines and went into considerable detail with regard to low-pressure turbines which, he predicted, would have a large application in the near future. Details of construction were also taken up, with special reference to the Curtis type of machine.

Hopkinsville was chosen as the next place of meeting.

J. N. Draper, of Henderson, was elected State president; F. L. Roy, of Louisville, vice-president; A. S. Smith, of Henderson, secretary; J. H. Cobe, of Owensboro, treasurer; C. Carroll, of Louisville, conductor, and R. Baumgarten, of Ashland, doorkeeper.

Installation of officers was by F. W. Raven, assisted by J. H. Van Arsdale. Immediately following adjournment a trolley ride was taken to Henderson's beautiful park overlooking the Ohio river. Here refreshments were served and a group photograph was taken. The social events wound up in the evening with a banquet in Backerkamp hall. This was served by the ladies of the local committee and was a grand success. Several members from Evansville, Ind., came over with their wives and joined in the festivities. F. W. Raven was toastmaster and the speakers were Mayor Harris, of Henderson; J. H. Van Arsdale, J. N. Draper, James Yeaman, Emil Hoegel, Edward Krampwirth, Isaac Dunn, B. S. Morris, C. O. Harris, Paul Marin, Dr. Graham and Joseph Wanrath.

American Order of Steam Engineers

The twenty-third annual convention of the American Order of Steam Engineers was held at Reading, Penn., during the week beginning Monday, June 7, the headquarters being at the Penn hotel. The sessions were held at Rajah Temple, there being about 50 delegates in attendance.

On Monday morning the assemblage was called to order by Past Supreme Chief Hiram M. Trout, chairman of the local committee, who introduced Mayor Rick, who gave the delegates and guests a hearty welcome to Reading. He spoke approvingly of the principles which govern the American Order of Steam Engineers, and wished the organization continued success. He also complimented the American Supplymen's Association on its splendid display. Supreme Chief Frederick Markee responded for the engineers.

During the several sessions of the convention considerable business was transacted, various committees were appointed and the following supreme officers were elected:

Frederick Markee, chief engineer; John Rost, 1st assistant chief engineer; T. J. Armbruster, recording engineer; W. S. Wetzley, corresponding engineer; T. J. Dunnam, treasurer; W. J. Courtney, senior master mechanic; Walter Lord, junior master mechanic; W. Rush, inside sentinel; W. J. Keller, outside sentinel; James Lightfoot, chaplain; H. Dubson, trustee.

The association was reported to be in a flourishing condition. Philadelphia was

OFFICERS OF PENNSYLVANIA STATE ASSOCIATION, N. A. S. E.

selected for the next convention, in June, 1910.

The American Supplymen's Association held its exhibit on the second floor of the Rajah Temple. The exhibition was the most successful ever held by the association and the arrangement of the hall and booths, under the supervision of H. G. McConnaughy, was the best we have ever seen at a convention exhibit, and the committee in charge is to be congratulated on the results attained. The following exhibited: Garlock Packing Company, McLeod & Henry Company, *Practical Engineer*, Jenkins Bros., Dearborn Drug and Chemical Works, Scully Steel and Iron Company, *American Journal of Steam and Electrical Engineering*, Keystone Lubricating Company, Griscom-Spencer Company, Berry Engineering Company, H. B. Underwood & Co., Peerless Rubber Manufacturing Company, John R. Livezey, Home Rubber Company, Corbett Supply Company, H. W. Johns-Manville Company, Philip Carey Company, Engineering Equipment Company, Watson & McDaniel Company, American Steam Gauge and Valve Manufacturing Company, Allentown Rolling Mills, Birdsboro Steel Foundry and Machine Company, William H. Taylor & Co., Scranton Steam Pump Company, Wilkirk Electric Company, W. B. McVicker Company, *Southern Engineer*, Anchor Packing Company, H. Belfield Company, Hutchinson-McCandlish Coal Company, McArdle & Cooney, George W. Lord Company, Cancos Manufacturing Company, L. J. Wing Manufacturing Company, France Packing Company, Quaker City Rubber Company, O. F. Zurn Company, Crandall Packing Company, Cyrus Borgner Company, POWER.

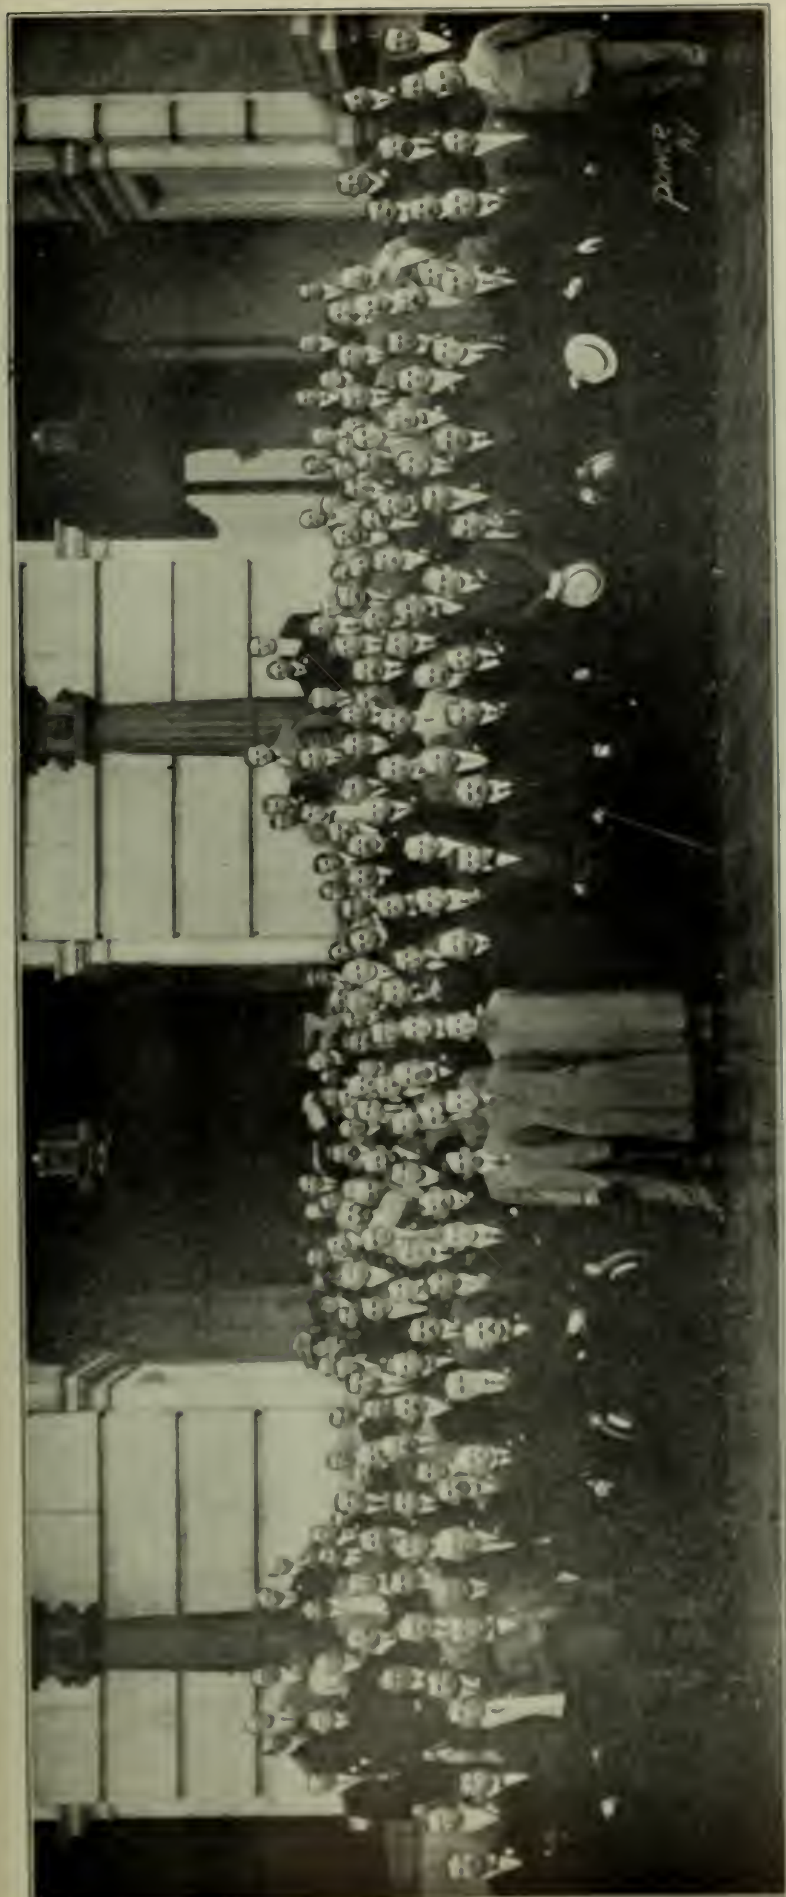
On Tuesday evening, at the Rajah Temple, a banquet was given to which the ladies were invited, and about 500 were seated at the tables. After the covers were removed, Past Supreme Chief Hiram M. Trout, toastmaster, introduced the following speakers: Frederick Markoe, the reëlected supreme chief; Charles E. Leippe, Judge H. Willis Bland, Noah R. Pierson, past supreme chief, and "Jack" Armour. Claude Miller entertained with a humorous monologue.

On Wednesday evening an entertainment was given in the exhibition hall by the New York "bunch." Every number was generously applauded, and the occasion was thoroughly enjoyed. During the evening Supreme Chief Frederick Markoe presented to each of the following gentlemen a handsome bouquet of American Beauty roses: William Le Compte, Charles Hopper, H. G. McConnaughy and Hiram Trout.

The other features of entertainment included trolley rides to Neversink and places of interest about the city, and a trip to Mount Penn.

At a meeting held by the American Supplymen's Association the following officers were elected: Charles Hopper, president; Nathaniel Kenny, vice-president; John W. Armour, treasurer; Frederick Jahn, secretary. "Bert" Williams was appointed director of exhibits.

DELEGATES TO THE PENNSYLVANIA N. A. S. E. CONVENTION, ERIE, JUNE 4-5, 1909



CONVENTION OF PENNSYLVANIA ENGINEERS' SOCIETY AT HARRISBURG, JUNE 9, 10 AND 11, 1909

Convention of Pennsylvania Engineers' Society

The Engineers' Society of Pennsylvania met at Harrisburg on June 9, 10 and 11. The sessions were held in the State Capitol. Mayor Ezra S. Meals welcomed the visitors and E. Herbert Snow responded for the society, of which he is president. The organization is composed largely of members of the Engineers' Clubs of Philadelphia, Harrisburg and Scranton and the Engineering Society of Western Pennsylvania, and the object of this union meeting was to take some action toward perfecting a State organization of all branches of the profession and the consideration of a code and draft of laws to support it. The call states that a bill providing for the examination and licensing of engineers and providing fees and penalties almost passed the general assembly at the last session, and it is thought well to see what better proposition the engineer has to offer. Some protection to the public is demanded.

A committee was appointed to draft a code and laws, and numerous papers upon general engineering topics were presented. Most of these dealt with civil and municipal engineering, but two were of especial interest to POWER readers: The first of these was a talk, illustrated by lantern slides, upon "Gas Engines," by E. T. Adams, of the Allis-Chalmers Company. He said that engines of 5000 horsepower are here and engines of twenty thousand horsepower are no farther off, looking forward, than engines of 1000 horsepower are looking backward. A station of one hundred thousand kilowatts capacity can be put into the same space with producers and gas engines as with boilers and steam engines, and in large capacities the prices are on comparable terms. The engines are of course much more bulky than turbines, but the saving comes in reduced coal storage and less room for producers, while the cleaning and scrubbing apparatus require very little more space than the turbine condensers. In gas engines directly connected to compressors, the greater masses involved result by their inertia the greater initial pressure and go far toward equalizing the effective pressure. Steel pistons can be used without trouble in cast-iron cylinders, because the piston is supported by tail rods outside of the cylinder and not allowed to bear. A station on railroad work near Milwaukee (probably Port Washington) [illegible] burned 2½ pounds of Pocahontas coal per kilowatt-hour. It is got down to a 50 per cent. load factor and a little over [illegible] pounds per effective kilowatt-hour on the line.

The other paper was that of J. G. Callan, on "Low Pressure Steam Turbines."

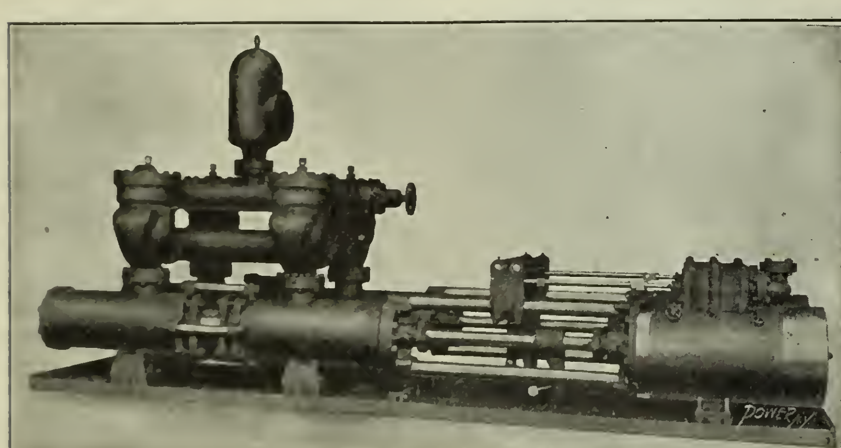
Power Plant Machinery and Appliances

Original Descriptions of Power Devices
No Manufacturers' Cuts or Write-ups Used

MUST BE NEW OR INTERESTING

Duplex Pot Valve Pump

The pump shown herewith has outside end-packed plungers and is designed for feeding boilers, pumping water containing sediment or grit, working on oil lines, or hydraulic presses, and for mining purposes. The only wearing part in the pump end is the packing of the plunger stuffing boxes. No leak can occur there without being observed, and it is easily stopped by setting up the packing. As the plunger does not touch the pump castings, there is no cutting or wear, consequently they require no reboring or refitting when working on gritty or sandy water. The piston rods do not enter the pump cylinders and are not exposed to the action of the water. Rods support the plunger slide in babbitted bearings.



DUPLEX POT-VALVE PUMP

The water-end valves are in pots and are quickly accessible by taking off the plates over them. The steam cylinders are of a new type, the steam ports being arranged on a novel plan. The method of steam cushioning is new, and the valves are of an original form. The pump will not short-stroke, it is claimed, which overcomes the most serious objection to duplex pumps. The valve gear is extremely simple and not liable to injury or wear, and can be replaced at very little expense or trouble. Rock shafts are abandoned and one-piece levers substituted. The levers swing on steel studs having extra long bearings. Both levers are alike and are easily removed and replaced. This pump is manufactured by the Dean Brothers Steam Pump Works, Indianapolis, Ind.

The Erie City Vertical Water-tube Boiler

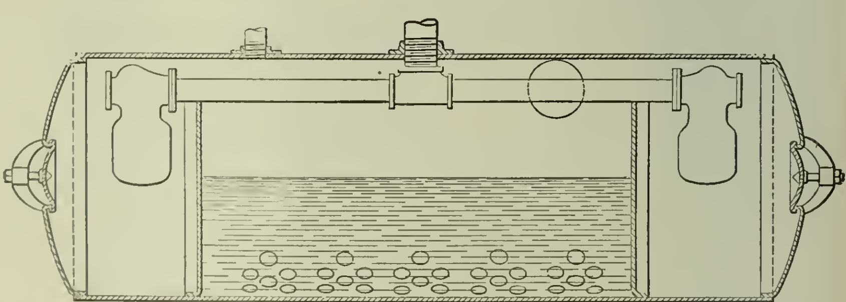
The Erie City Iron Works, of Erie, Penn., has added to its line of products the boiler shown in the accompanying illustrations, the reproduced photographs shown being from the experimental boiler at the Erie shops. It is not claimed that the type is novel, but that the Erie iron works will bring to its manufacture and exploitation refinements and improvement in detail and experience and facilities which should soon make a place for it among the standard types.

Unite the three banks of tubes of a Stirling boiler in a single upper drum, placed with its center directly over the center of the lower one, and you have the type. The furnace is an extension on the dutch-oven plan, allowing great flexibility in the adjustment of grate to heating surface and introducing the improved furnace conditions of the reverberatory arch. Additional capacity is gained by increasing the length of the drums and the number of tubes sidewise, carrying with it increased width of furnace and proportionate increase of grate surface, while the length of the grate may be made such as to give the desired ratio of grate to heating surface.

The tubes are so spaced that any one of them may be cut out, removed and replaced without interfering with any other. The entire boiler is suspended, as the engravings show, from the upper drum, giving perfect flexibility and freedom to adjust itself to varying conditions of temperature and stress. The sufficiency of the expanded tube joints in the upper drum to sustain the weight thus brought upon them has not only been tested out thoroughly in former boilers of this construction, but has been tried in the boiler illustrated by means of hydraulic jacks and found to be entirely adequate.

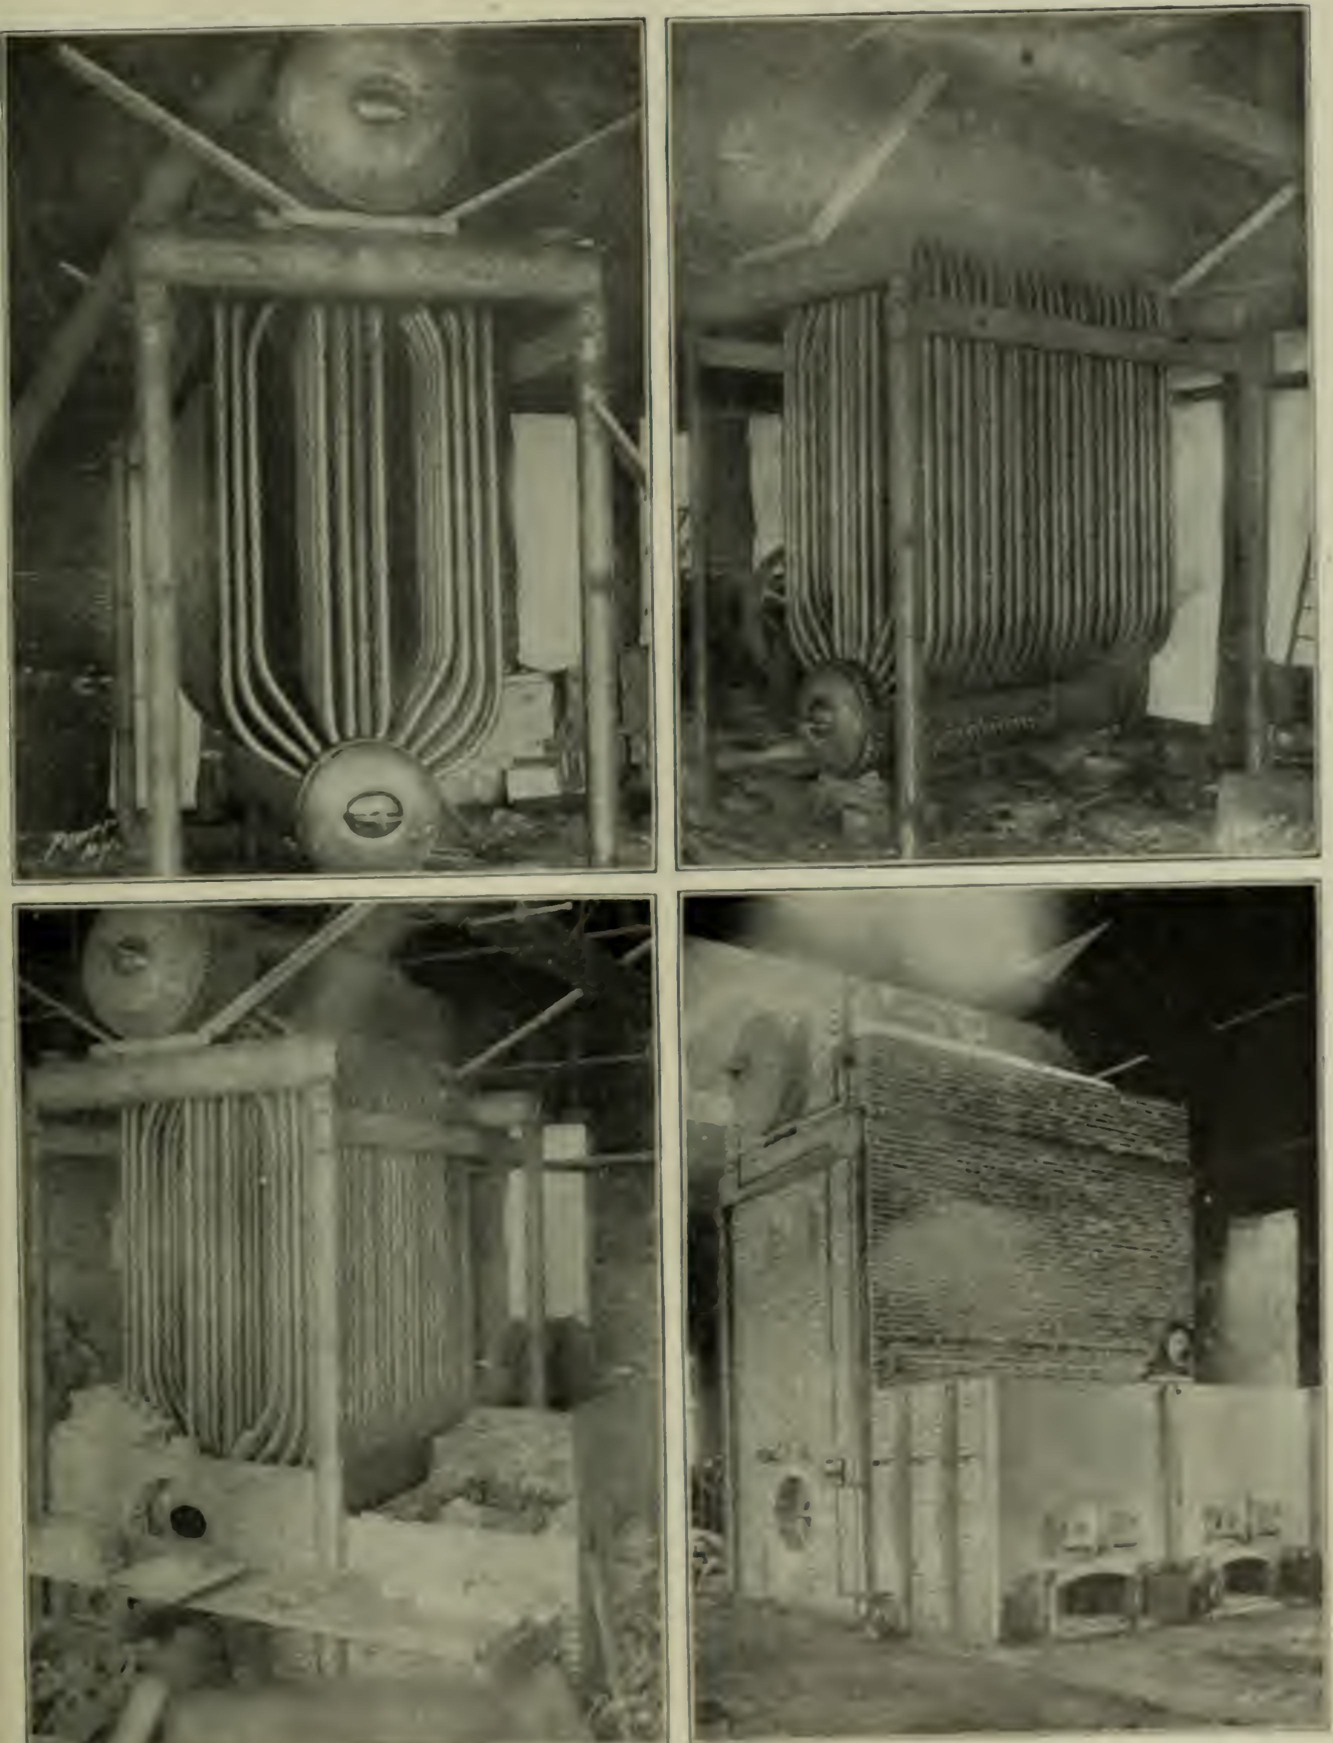
In this particular boiler the upper drum is 48 and the lower 40 inches in diameter, with 11 rows of connecting 3-inch tubes and, with 22 tubes in each row, furnishing 2377 square feet of water-heating surface. The front and rear groups contain 4 rows each, the central group, 3 rows.

The baffling is arranged to give three passes as shown, the gases passing longitudinally through each group of tubes. This gives a travel of the gas of something like 40 feet in contact with the heating surface, yet with such freedom of passage that there was little drop in draft pressure between the stack and the furnace when the boiler, nominally rated at 238 horsepower was developing over 500, and burning 36.7 pounds of coal per square foot of grate.

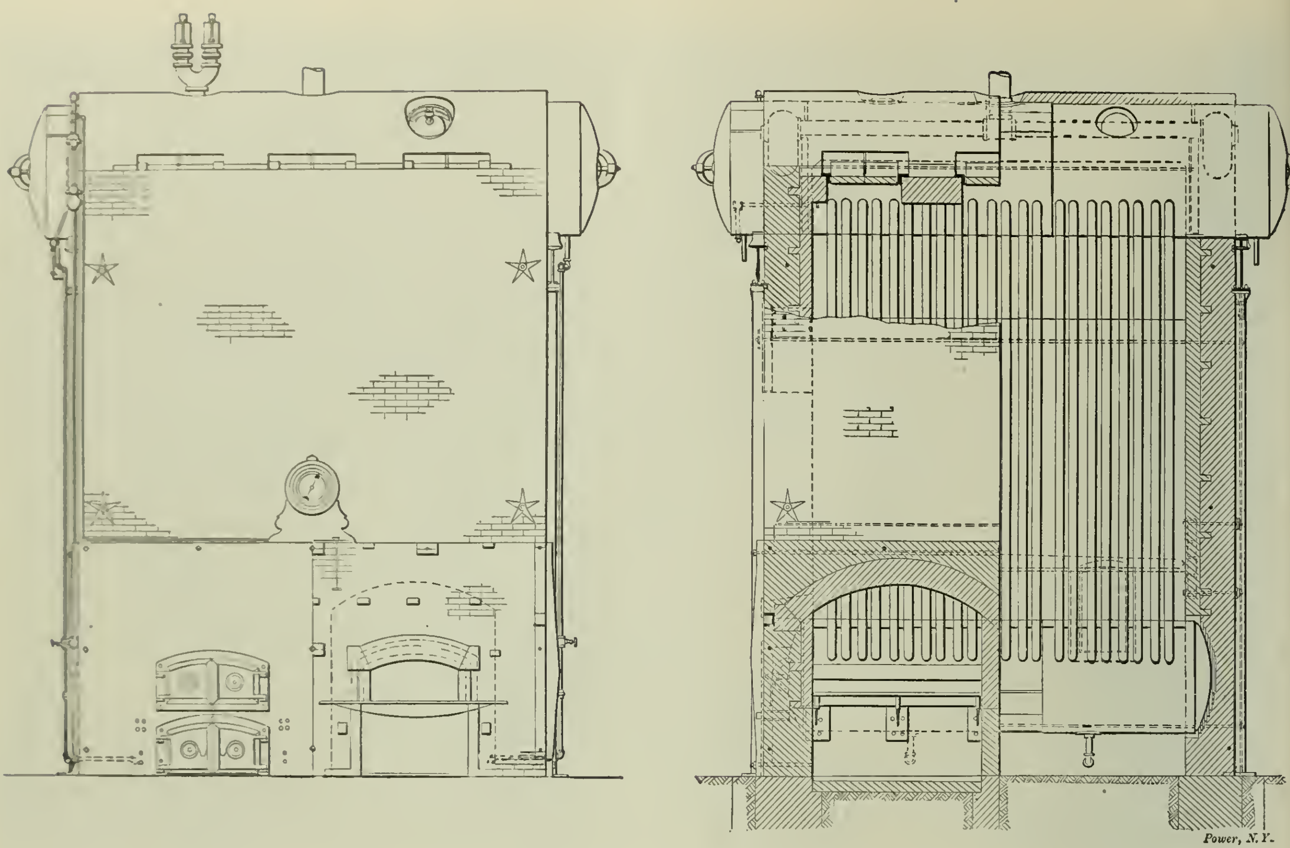


ENLARGED VIEW SHOWING SEPARATOR IN DRUM OF ERIE CITY BOILER

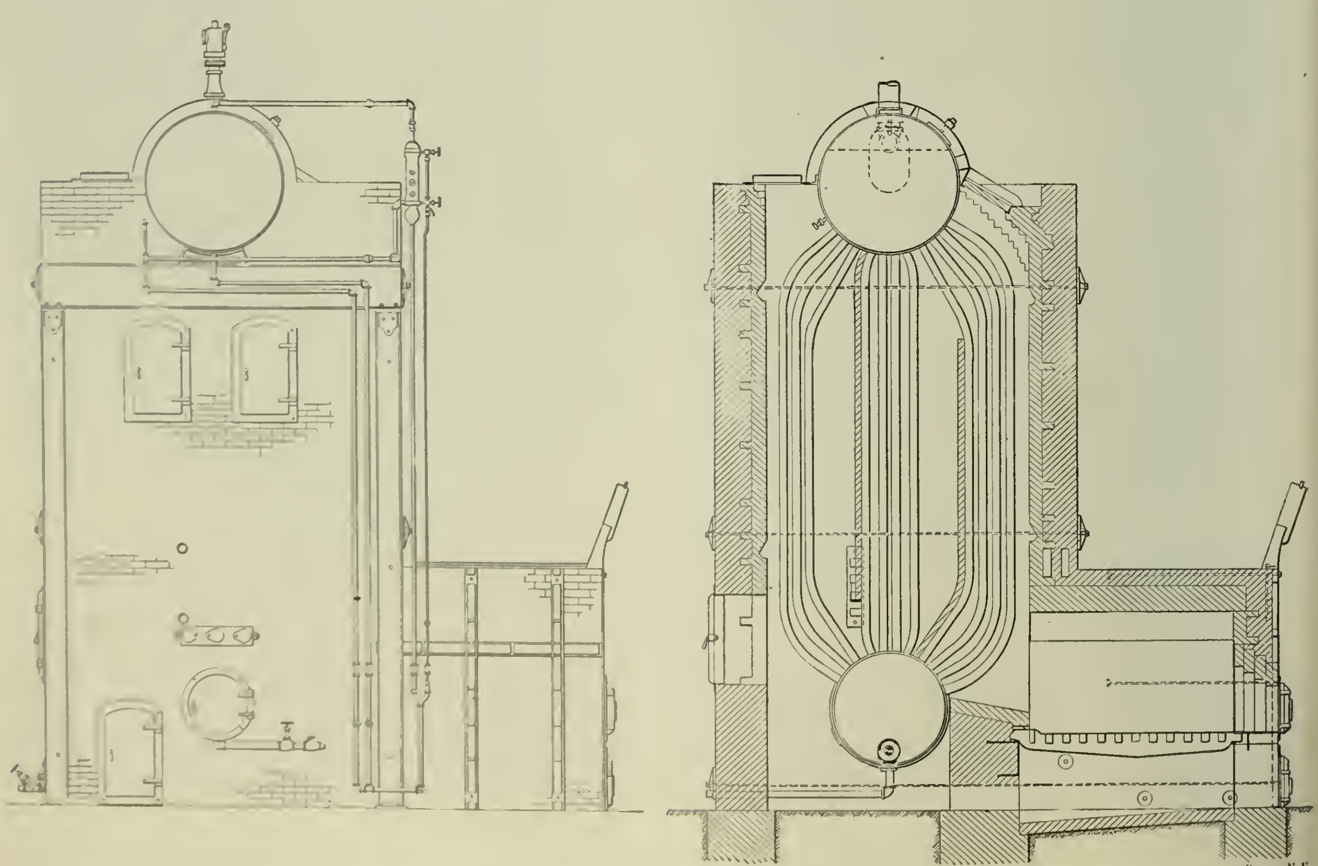
At each end of the upper drum is a dry chamber, as shown in the longitudinal section, in which is placed a separator upon each end of the steam-outlet pipe,



VIEWS OF ERIE CITY VERTICAL WATER-TUBE BOILER IN PROCESS OF ERECTION



FRONT ELEVATIONS OF ERIE CITY VERTICAL WATER-TUBE BOILER



SIDE ELEVATIONS OF ERIE CITY VERTICAL WATER-TUBE BOILER with the inlet facing toward the end of the drum and away from the steam-liberating surface. The boiler appears to be one which will be well adapted to the large units and intensive service demanded by the modern power plant, especially those in which large amounts of power are required for peak periods and where the ability to stand forcing is particularly desirable.

Feed Water Grease Extractor

The principal points in connection with this device are as follows: Two valves forming the inlet and discharge from the extractor, when seated as shown in the illustration, force the water into the shell of the extractor through the cartridges, and in this manner the grease is extracted. Where the valves are seated on the lower seat they form a bypass so that the shell of the extractor can be opened, the cartridges taken out and either replaced with an extra set or cleaned and put back.

The covering on the cartridges and form of applying are plainly shown at A, which is a somewhat reduced reproduction as to length when compared to the extraction shell. The ratio of the openings in the cartridges to the inlet of the extractor is as 48 to 1, and the cartridges are held firmly in place by resting on the lower seat by plate and spring washers at the top.

The pressure gages are applied to both the main chamber and base so as to note the difference in pressure and tell when the pressure in the main casing is increased due to the restricted flow of the water by the covering of the cartridges becoming filled with grease.

Provision is also made in the base, as shown at B, to connect a ½-inch steam pipe, driving steam into the inside of the cartridges and in this manner cleaning them so as not to necessitate taking the cartridges out as often as would otherwise be necessary. The shell of the extractor is small and compact. The shape of the cartridges, which are triangular, as shown at C, enables them to be placed in a comparatively smaller space.

The device is intended for stationary or marine practice and can be connected, as shown, directly to operating valves or to the valves in the pipe line. This extractor is manufactured by the American Steam Gauge and Valve Manufacturing Company, 208 Camden street, Boston, Mass.

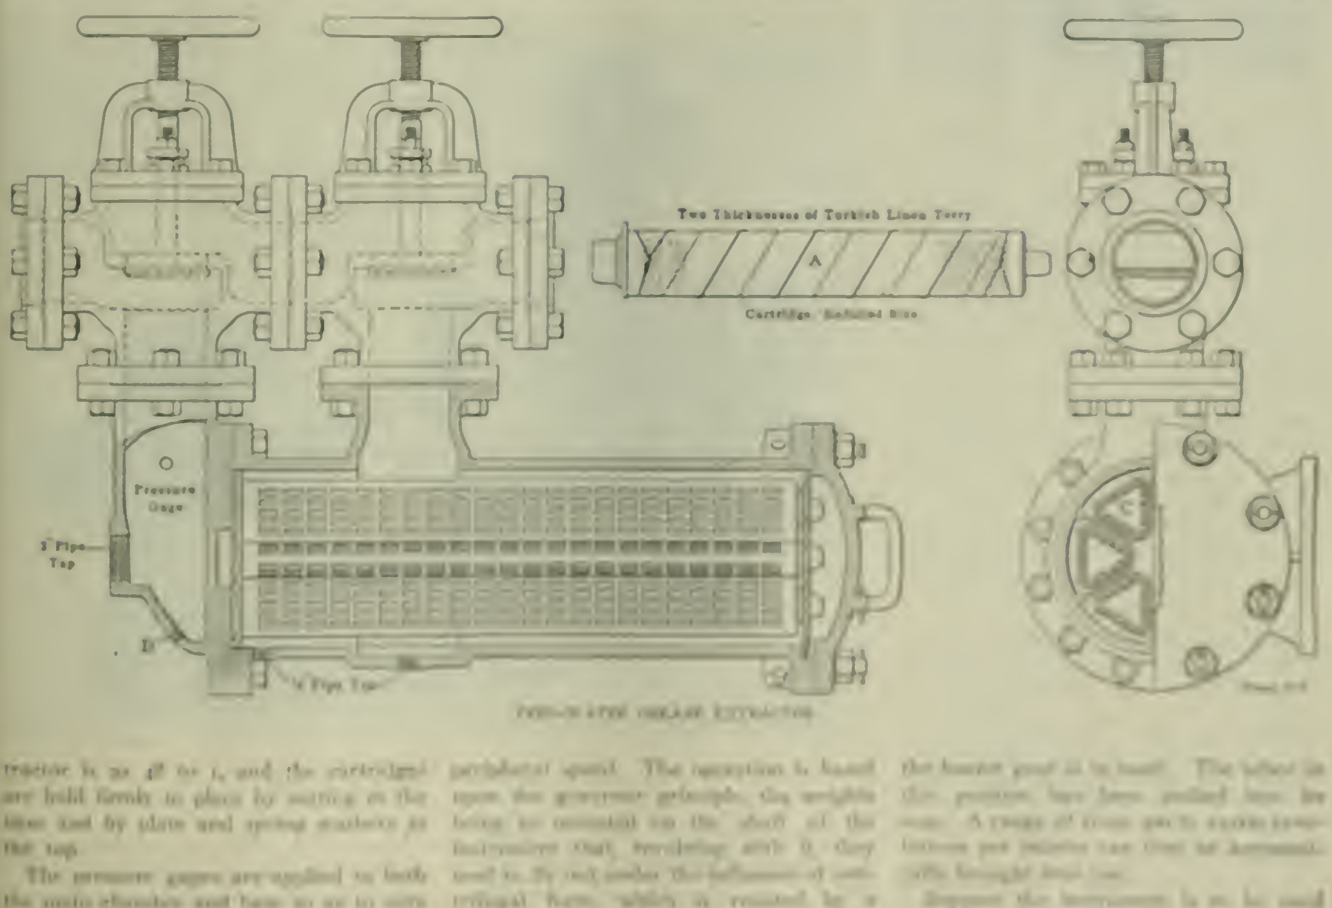
A Portable Tachometer

A portable single-spindle-type tachometer is herewith illustrated. It is manufactured by the Industrial Instrument Company, Foxboro, Mass. This instrument is designed for hand application to engines or any shaft or pulley, and shows at a glance the rate of rotation or peripheral speed. The operation is based upon the governor principle, the weights being so mounted on the shaft of the instrument that, revolving with it, they tend to fly out under the influence of centrifugal force, which is resisted by a spring. The resultant action of the weights relating to the shaft depends upon the rate of revolution and is indicated on a properly graduated dial by means of a suitable link and pointer.

The arbor is carried on a slide so that in this extreme position the highest speed is in gear. By pushing in on the arbor against the pressure of a spring, the next lower gear is brought in, and so on, until the lowest gear is in mesh. The arbor in this position has been pushed home by hand. A range of from 30 to 12,000 revolutions per minute can thus be automatically brought into use.

Suppose the instrument is to be used and the correct speed is not known. The operator pushes against the shaft until the

FIG. 1. PORTABLE TACHOMETER IN CASE



PRESSURE-TYPE GREASE EXTRACTOR

tachometer begins to register. The figures appearing on the sight aperture indicate the range in gear. If desirable, this arbor can be clamped in this or any other range position by means of the lock stud shown on the side of the case.

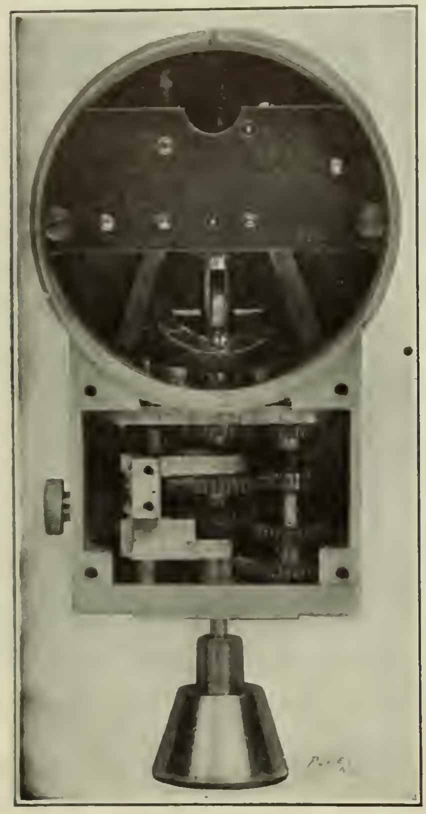


FIG. 2. MECHANISM OF THE TACHOMETER

If the speed of the shaft or pulley is within the range of the lowest number shown on the range register, which is from 300 to 1200 revolutions per minute, the instrument will register on the inner graduation of the dial, which figures read from 3 to 12. If the speed range is from 900 to 3600, the registration will be on the outside figures of the dial, which show from 10 to 35, the numbers indicating speeds of 1000, 1500, 2000, etc. If a still higher speed of from 3000 to 12,000 is to be registered, the readings are taken from the inner readings of the dial, but are read in thousands instead of hundreds, as in the first instance.

Each instrument is furnished with a leather case as shown in Fig. 1, in which is mounted one extension piece for the arbor, one steel and one india-rubber point for coupling to the shaft, one rubber-lined cone for coupling to a spindle and one disk for band drive if the shaft is inaccessible. Fig. 2 shows the interior mechanism.

Stationary tachometers are made in horizontal and vertical types for belt drive or direct connection to shafts.

Trenton "Type A" Gas Engine

A new type of gas engine known as "Type A" is now built by the Trenton Malleable Iron Company, Trenton, N. J., the illustration in Fig. 1 showing this type of engine direct-connected to a direct-current generator.

As to construction, all the surfaces within the combustion chamber are machined so that the heat losses from radiation and the tendency to accumulate carbon are reduced to a minimum. All valves are removable without interfering with any piping, it being merely necessary to remove one cotter pin, and slip out the stud, when by removing the cap screws the valve and valve seat can be removed without interfering with any other adjustment on the engine. By taking out the valve case, the interior of the combustion chamber can be cleaned and inspected at will. The cam shaft, main bearing and connecting-rod boxes are readily accessible through doors in the housing. One lever shifts all auxiliary cams and the engine is controlled from one position.

As indicated in Fig. 1, the bedplate is of box construction and supports the crankshaft bearings, shown at either side. The bearings are made of malleable iron and lined with Parsons white brass. As a means of lubrication to the bearings, oil

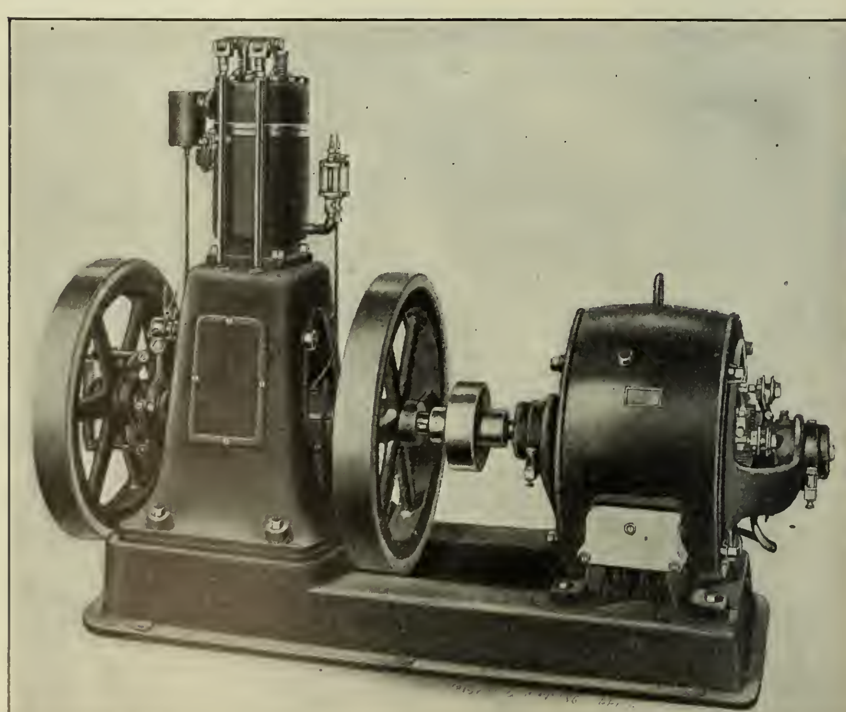

FIG. 1. TRENTON "TYPE A" GAS ENGINE

is delivered through an oil pump driven by a spur gear inside the housing. By removing the cap of the boxes and lifting the weight of the crank shaft, the lower halves of the boxes can be taken out by giving them one-half revolution on the shaft.

In Fig. 2 is shown the piston, which is of the trunk pattern, of ample length and packed with cast-iron rings. It carries a wristpin which is steeled, hardened and

FIG. 2. PISTON, SHOWING OILWAYS

ground. The sides of the piston are fitted with oilways which are filled with lubrication from the oil pocket, being fed from the inside through a suitable hole.

Both the inlet and exhaust valves are

of the poppet type, mounted in cases bolted to the cylinder head. They are operated from the cam shaft by means of push rods and valve levers.

The governor is of the centrifugal ball type mounted on the end of the housing and is so driven that the torsional disturbance of the cam shaft, due to the operation of the valves is not affected. It is simple and extremely sensitive which enables a very close regulation to be obtained. A simple mixing chamber and valve are fitted to the engine. At the center of the inlet manifold are the gas and air inlet valves and mixing chamber. The make-and-break type of ignition is used, being at all times under governor control. This engine is built in sizes up to 8½ horsepower and makes a compact, neat generating set where a limited amount of power is required.

Ladies' Night at Pawtucket

Saturday evening, June 5, was the annual ladies' night of Pawtucket Association No. 2, N. A. S. E., and in spite of the pouring rain a large number gathered at the association rooms in Cottrell block. Shortly after 8 o'clock the exercises were opened with a piano duet by Miss Marion Cooper and Ralph Daniels.

President Keene, in a racy preliminary address introduced F. L. Johnson as the "religious" editor of Power and also as the first speaker of the evening and toastmaster. Mr. Johnson gave a short description of his "missionary" life in New York and his domestic troubles in Lynn. He took advantage of his position as toastmaster to bring his remarks to an early close, and soon introduced Past National President P. H. Hogan, who spoke of the educational advantages enjoyed by members of the National Association of Stationary Engineers. He was followed by a character duet by the Misses Bessie Donohue and Bessie Ryan.

"Ed" Kearney, Massachusetts State deputy, told how the average engineer, instead of telling his troubles to a policeman, usually took them home with him. Alvin Martin, in a few apt remarks, presented to the winner, "Ed" L. Cheney, the prize which is given every year to the member furnishing the best question for discussion during the educational season.

Next on the program was a presentation of the balcony scene from "Romeo and Juliet," by the Misses Donohue and Ryan. This was followed by a few remarks by Columbus Hill, of America. W. M. Childers expressed his opinion that a woman's place was at home, not attending auxiliary meetings or ladies' nights.

Mrs. Canfield, past president of Rhode Island No. 1, Ladies' Auxiliary, in a few well chosen remarks gave Mr. Childers all that was "coming to him." Then the toastmaster remarked that had the committee of arrangements possessed more paper the program would have been longer.

The remainder of the session was given over to the refreshment committee, who served ice cream, cake, coffee and cigars.

As the last car left the square, in the wee sma' hours, the guests reluctantly took their homeward way, the out-of-town visitors going to Hotel Burke in Pawtucket.

Next day the visiting guests were taken on an automobile excursion to the various points of historical interest in and around Providence and Pawtucket.

The occasion will long be remembered by all who participated in it.

Personal

Karl M. Way and Perry Barker, formerly assistant engineers of the United States Geological Survey, have joined the fuel engineering department of the Arthur D. Little Laboratory of Engineering Chemistry, Boston, Mass.

Business Items

Herbert S. Crocker and Milo S. Ketchum have formed a partnership under the firm name of Crocker & Ketchum, consulting engineers, with offices at Suite 438, 811 Seventh street, Denver, Colo.

J. Proudfield Simpson has opened an office as consulting mechanical engineer at 541 Calvert Building, Baltimore, Md. Mr. Simpson would like to receive catalogs and hear from concerns wishing a representative in that section.

The Jacobson Machine Manufacturing Company, of Warren, Penn., builder of gas and gasolene engines, announces that it has engaged as foreman of its machine department John [illegible], who was for several years mechanical inspector at the Franklin works of the Chicago Pneumatic Tool Company.

The Stone and Webster Engineering Corporation, of Boston, recently placed an order with the American Ship Windlass Company, Providence, R. I., for three Taylor mechanical stokers for installation at the Dallas, Tex., electric light and power plant, for which six similar stokers were previously purchased.

An engineer's handbook has been published by the Erie Engine Works, Erie, Penn. It contains upward of eighty pages of useful information for operating engineers. It also, of course, illustrates the product of the Erie Engine Works and will be sent free to any engineer sending his name and address.

The Jackson Manufacturing Company, Nashua, N. H., awarded a contract to the [illegible] Construction Company, Boston, Mass., for the construction of a reinforced concrete trestle through its coal pocket. The track is to be supported by beams running under the rails. Large concrete columns with Y tops poured in place by concrete beams are to form the main supports. The whole construction is to be heavy enough to take the largest coal cars.

The American Blower Company, Detroit, Mich., has just issued a [illegible]-page booklet, 7x[illegible] inches, treating of "Sirocco" fans and other "A B C" specialties. The greatest interest, of course, attaches to the portion of the booklet which deals with "Sirocco" fans, several important installations being shown, and valuable engineering data given by emphasizing the claims for these fans, including increased efficiency and capacity, decreased space required and slower speed.

The Interborough Rapid Transit Company, of New York City, has adopted Keystone grease, manufactured by the Keystone Lubricating Company, Philadelphia, for all the escalators at its elevated-railroad stations. These machines are motor-driven and the largest escalators have several motors for the different parts. As these installations are a public-service proposition it is absolutely essential that they be kept running without fail, and therefore proper lubrication is all-important.

The Detroit United Railways recently placed a contract with the Westinghouse Machine Company for another turbine unit. This company already operates Westinghouse turbines in three of its power stations. The new turbine, which is of 1000 kilowatts capacity and is to operate at 150 pounds steam, 28 inches vacuum and saturated steam, will be installed at the Rochester station on the Detroit & Flint division. This station already contains engine-type units, but extensions of traffic have necessitated the installation of this new turbine unit.

The American Steam Gauge and Valve Manufacturing Company, Boston, recently furnished the following equipment for the three new colliers built by the Maryland Steel Company: Eighteen American-Thompson improved indicators, three 10-inch chime whistles, three 6-inch steam whistles, twelve 2½-inch duplex pop safety valves, three 2-inch single pop safety valves, 18 steam and water relief valves, 12 cylinder relief valves, 12 gages, 3 clocks, 6 counters. The company also furnished the following for the "North Dakota," built by the Fore River Shipbuilding Company: Six clocks, 108 steam and vacuum gages, 2 counters, 48 valves.

The Wisconsin Engine Company, of Corliss, Wis., reports increasing orders for both its Corliss engines and its complete-expansion gas engines. A recent gas-engine contract was received from the Bartlesville Electric Light and Power Company, of Bartlesville, Okla., and covers two engines of the horizontal tandem double-acting type, each to develop 800 b.h.p. and to be direct-connected to a 60-cycle alternating-current generator. These generators are to operate in parallel and very close regulation has been guaranteed. The complete-expansion principle, they say, embodies the expansion of the burning charge to a very low terminal temperature and pressure with the consequent balancing of the working conditions, simplifying the lubrication problem and decreasing the gas consumption by about 20 per cent.

The Industrial Instrument Company supplies data on its instruments in the form of engineering bulletins, each bulletin being devoted to a certain line or class of industry, or to those instruments of different classes that group themselves conveniently for a certain industry. This method saves much of the handling of loose-leaf catalogs without involving the trouble of their classification. It furthermore eliminates the formidable general catalog, only a small part of the contents of which is of interest to the average customer. The accompanying bulletins treat upon types or lines of instruments extensively, without including irrelevant matter. The various bulletins published by this company are kept on file and provided for binding together as convenience requires. These covers, or binders, and any bulletins will be sent to prospective purchasers for instruments upon application to the Industrial Instrument Company, Foxboro, Mass.

Much has been written and said concerning the [illegible] of lubrication and how much it is [illegible] efficient operation of any form of mechanism. Elaborate formulas have been given for testing different lubricants and literature has been prepared with a view of exploiting all kinds of products of this nature. It is not, however, essential that one should acquire an education of oils and greases, but it is imperative that a good article be used, for should this not be done the engineer is gaining very expensive experience. Then the primary object should be to select a product that has a reputation which has been gained because of satisfaction. Adam Cook's Sons, 313 West street, New York, state that Albany grease was the first lubricant in the field, being in practical use on all kinds of machinery for over 40 years, and that good results have been obtained under the most adverse conditions. Its use has been extended to every portion of the power plant where a solid lubricant may be employed. Albany grease is made in seven densities and is packed in one-, five-, ten-, twenty-five -and fifty-pound cans and kegs, half barrels and barrels.

New Equipment

A new power house will be erected at the Butler Hospital, Providence, R. I.

The Martin Dyeing and Finishing Company, Bridgeton, N. J., will enlarge power plant.

The American Silver Company, Bristol, Conn., is having plans prepared for the installation of a new steam plant.

The Great Western Electric Power Company has let contract for the construction of a substation at Oakland, Cal.

A new power house is being erected at the Hudson River State Hospital, Poughkeepsie, N. Y., to cost $125,000.

The Le Mars (Iowa) Water and Light Company is planning to install new generator, changing from 120-cycle to 60-cycle direct belted.

The corporation of Basic City, Va., will erect a hydroelectric light and power plant. Plans can be had of W. M. Page, city treasurer.

The Calvert (Tex.) Water, Ice and Electric Company has awarded contract for rebuilding and improvements to plant to cost $40,000.

Proposals will be received until 10 a.m., June 21, by Constructing Quartermaster, Fort Sill, Okla., for the installation of a central heating plant.

The Geneva, Waterloo, Seneca Falls & Cayuga Lake Traction Company, Seneca Falls, N. Y., will erect an auxiliary power plant at Cayuga Lake Park.

The Bettendorf Improvement Company, Bettendorf, Iowa, has applied for franchise for waterworks system, sewer system and electric light plant.

The Tulia Light and Ice Company, Tulia, Tex., has been incorporated with $10,000 capital. Incorporators, J. W. Schwarz, J. E. McCune, L. D. Smith.

R. P. Arnold and M. W. Gresson, of Prescott, Ark., and others are organizing a company to establish a ten ton ice plant, cold-storage plant, grist mill and cotton gin.

The Mound City Electric Light and Ice Company, Mound City, Mo., has been incorporated with $25,000 capital by F. M. Miller, R. W. Neill, T. W. McCoy, J. A. Crowell.

City of Gulfport, Miss., is having plans prepared for waterworks improvement to include the installation of an additional 1,000,000 gallon pump. M. F. Sullivan, city engineer.

The Commissioners of Waterworks, Newport, Ky., will arrange for improvements to cost $85,000. These will include two pumps of 5,000,000 gallons daily capacity. W. L. Glazier, superintendent.

The North Rose Cold Storage Company, North Rose, N. Y., has been incorporated to establish cold storage plant and warehouse. Capital, $20,000. Incorporators, John Hill, Frank Hill, Thos. B. Welch, Addison Weed.

A. M. Powell, candy manufacturer, Sullivan and Canal streets, New York, will erect a new ten-story building. Three Erie Ball engines, three Scotch boilers will be installed. Seventy-five ton ice machine, several pumps and elevators will be needed.

The Isthmian Canal Commission, Washington, D. C., will receive bids up to 10:30 a.m., June 21, for surface condenser, pumps, hose, rubber valves, packing, pipe covering, leather belting, pipe fittings, valves, ejectors, lubricators, etc., as per Circular No. 514.

Bids will be received by W. T. Kelly, Borough Clerk, Bellefonte, Penn., until June 1 for construction of complete electric power-plant, as per plans and specifications on file in clerk's office and at the office of D. C. & W. B. Jackson, 84 State street, Boston, Mass.

The Bureau of Yards and Docks, Navy Department, Washington, D. C., will receive bids until 11 a.m., June 26, for one 1000 and two 1500-kilowatt turbo alternators for New York, Philadelphia and Boston navy yards. Specifications can be had at the bureau or navy yards.

Remarkable Plant of the St. Clair Tunnel

Turbine Plant Enabled to Carry a Load Varying Instantly from Zero to 100 Per Cent. Overload by Novel Method of Controlling Combustion

BY OSBORN MONNETT

A study of the power problems involved in the recent electrification of the St. Clair tunnel at Port Huron, Mich., and their method of solution, serves to show to what extent a modern steam plant may be designed to meet special conditions. It is safe to say that there is no other electric power plant in the country where the load conditions are so extremely unusual. Large variations in load are, of course, no novelty, but in this case the fluctuations represent the entire range of generating capacity, with no-load periods of indefinite duration, the load coming on without the slightest warning and dropping off with equal rapidity.

Consisting of a single-track iron-lined bore 19 feet in diameter, the tunnel proper, which was built in 1890 and operated with steam locomotives of special design up to 1908, extends a distance of 6032 feet, in addition to the two approaches of 2500 feet on the American side and 3300 feet on the Canadian side, connecting the Port Huron and Sarnia terminal yards of the Grand Trunk railway.

Operated as a single-track division of the railway system, there is offered no opportunity for "recuperative working." The heavy Westinghouse single-phase locomotives pull direct on the power house through their pantograph trolleys for the full amount of power necessary for the movement of the trains. In Fig. 1 the grades and distances involved are given. Assuming that a train is passing from the American to the Canadian side, the load factor may be said to follow approximately the profile of the tunnel; there will be no power used on the down grade, and owing to the momentum little or none on the 1700-foot stretch at the bottom of the tunnel, which is practically level, having a grade of only 1 foot in 1000 for drainage purposes, but at the end of this level stretch sufficient power must be instantly supplied to pull a 1000-ton train up a 2 per cent. grade for a distance of 1 mile at a minimum speed of 10 miles an hour, and be able to start from a standstill on this grade if necessary. It can be seen, therefore, that quick steaming capacity was of the utmost importance, and, on the other hand, of no less importance was the ability to take care of the no-load periods without distress, these periods coming on instantly after carrying for a short time loads varying anywhere from full load to 100 per cent. overload.

FIG. 2. POWER HOUSE OF THE ST. CLAIR TUNNEL COMPANY

FIG. 1. MAP AND PROFILE OF YARDS AND TUNNEL

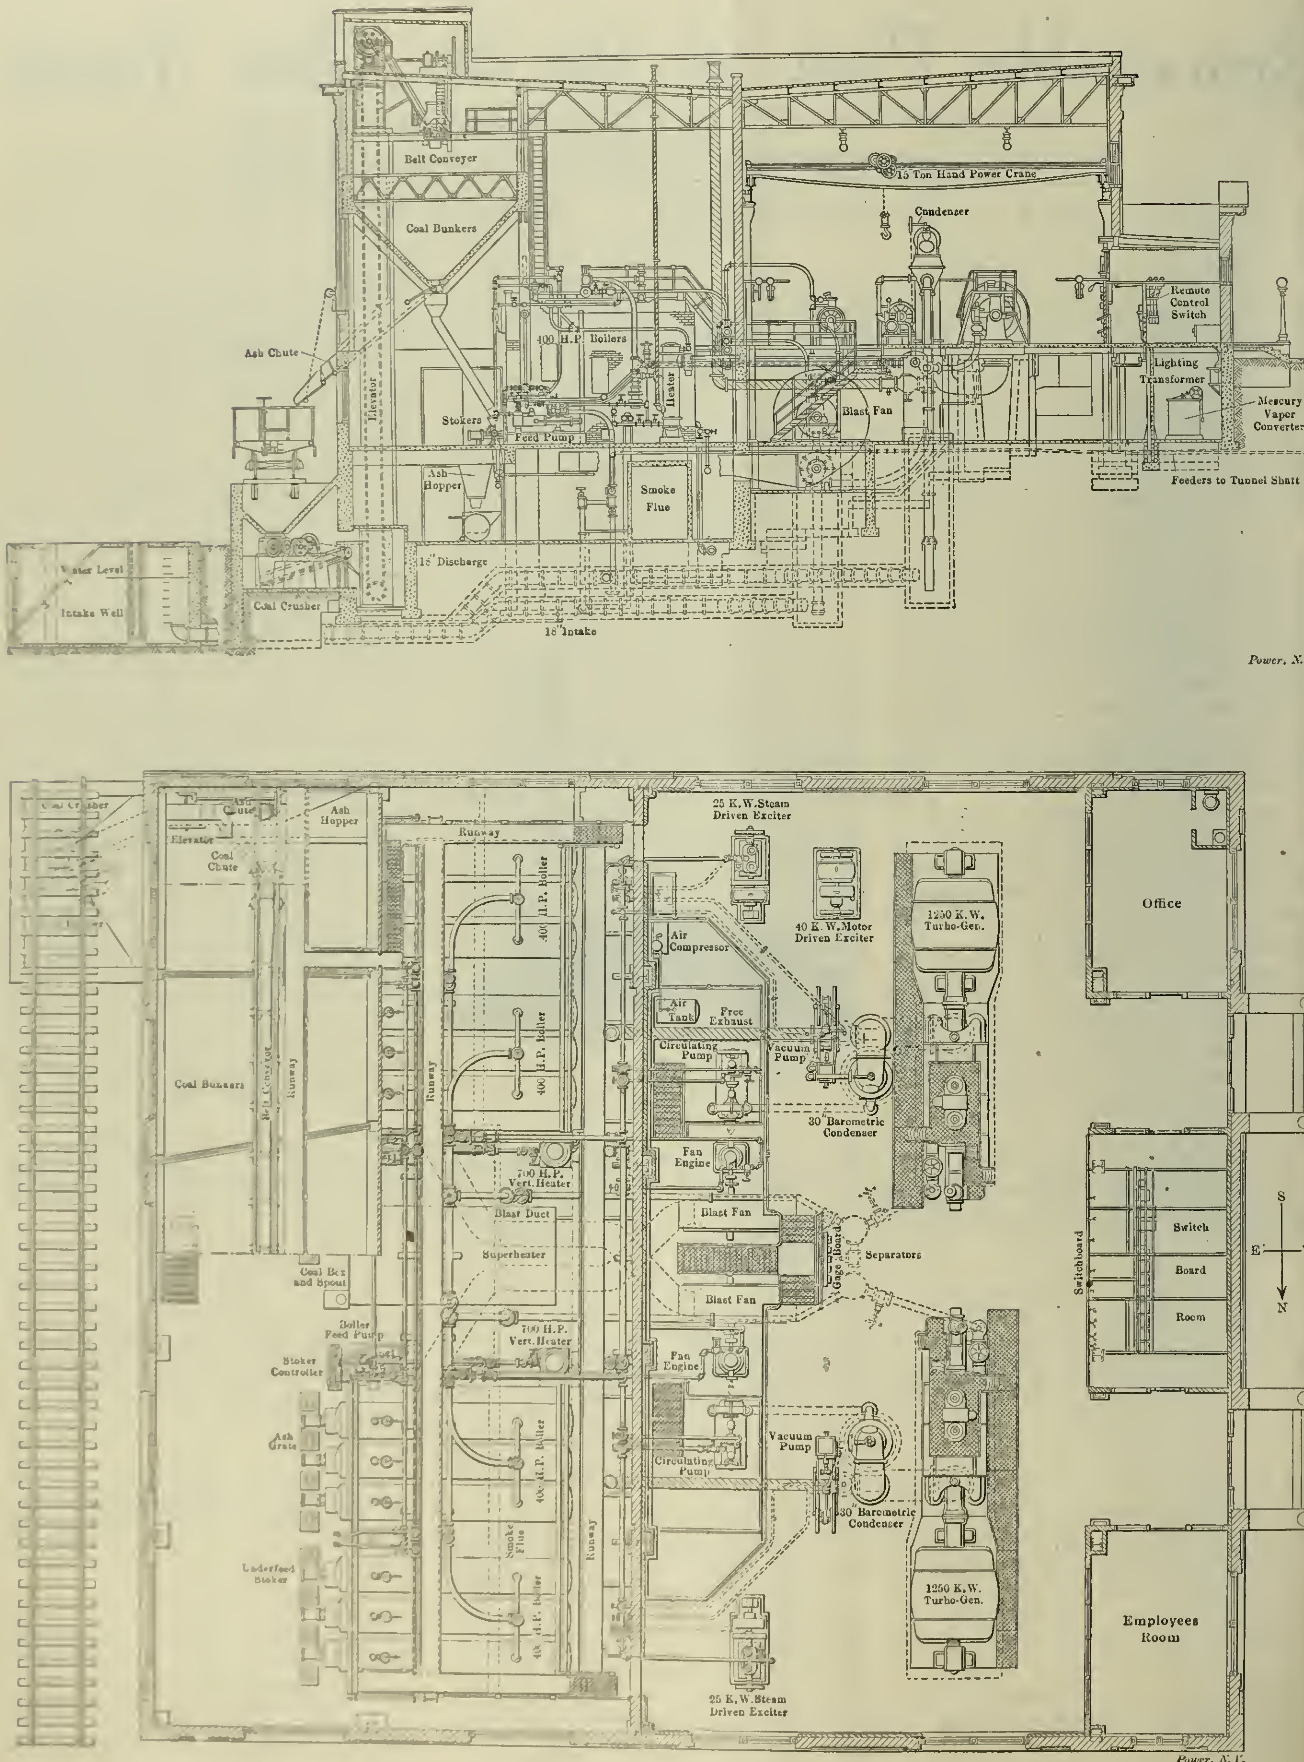
Located on the American side on the bank of the St. Clair river and slightly to the north of the center line of the tunnel, the power house, which together with the remainder of the system was installed under the direction of the Bion J. Arnold Company, of Chicago, consists of a substantial building with concrete foundation up to the grade line, and above this dark brown brick paving blocks, the trimmings being of stone and concrete. The stack, which is of Weber steel-concrete construction, rises 105 feet above the basement and is faced up to the roof of the building with paving brick to correspond with the general architecture. Fig. 2 shows the power-plant building and Fig. 3 the arrangement of the plant in plan and elevation. Owing to the slope of the river bank at this point there is considerable difference in level between the boiler and turbine rooms.

Coaling Facilities

Plenty of light and room are provided on the firing floor which overlooks the river, and there is sufficient space between the building and the water's edge to provide for a switch track by which coal may be delivered and ashes taken away. If desired, coal may also be unloaded directly from boats. After being dumped into the receiving hopper, the coal is passed through a crusher driven by a 20-horsepower three-phase induction motor, and delivered to a bucket elevator, from which it is distributed to reinforced concrete hoppers by a Robins belt conveyer and automatic tripper. Bunker capacity of 750 tons is provided. A desirable feature in connection with the coal bunkers is that metal lath concrete partitions extending to the ceiling completely close off the bunker space, thereby excluding the dust from the boiler room.

Boiler Installation

As the character of the load on this station imposes severe requirements on the steam-generating equipment, it is to be expected that some departure from standard sizes and dimensions will be found here. There are four Babcock & Wilcox water-tube boilers installed, having



Power, N. Y.

FIG. 3. PLAN AND ELEVATION OF POWER PLANT

ing wrought-steel inclined headers, and while rated at only 400 horsepower each, they have three horizontal steam drums 42 inches in diameter and 23 feet 4 inches long. This provides a considerable excess of water capacity which becomes available for steam making on lowering the steam pressure, and also enables the feed pumps to be used freely in reducing the steam pressure on no-load, should occasion require it.

Two boilers are set in a battery, and each boiler is equipped with three Jones underfeed stokers. In consideration of the load requirements it was desired to avoid any furnace construction calling for a large amount of firebrick walls or arches, which would have a retarding effect on the quick steaming action in case the brickwork should become cooled down during a no-load period, and which would also tend to give up a large amount of heat after the demand for steam had passed. Therefore, nothing has been interposed between the bank of tubes and the bare fires, and the boilers being constructed nine tubes high and as wide give a large amount of heating surface directly over the radiant heat of the furnaces, so that quick response is obtained to all conditions of the load.

As shown in Fig. 4, coal is conveyed to the stoker hoppers. Ashes are raked out onto the floor and passed through gratings into hoppers in the basement, from which they are loaded into push cars, dumped into the bucket conveyer and elevated to an ash hopper which can be unloaded into cars on the side track.

FIG. 4. BOILER ROOM

Novel Method of Controlling Combustion

The stokers operate with closed ashpits and forced draft, the draft being automatically controlled by the steam pressure and the speed of fuel feed being also regulated according to load conditions. Two forced-draft fans with galvanized-iron ducts leading to each ashpit are installed. By means of a special blast gate either fan may be used on the boilers. There is also a hand damper at each stoker to shut off the draft entirely if desired. As indicated in Fig. 1, the fans are located in the pit of the turbine room. They are of the American Blower Company's steel-plate construction, 11 feet in diameter by 3 feet 4 inches wide and are driven by its type B vertical center-crank engines.

Steam for these engines is taken from a 6-inch auxiliary header and the supply is controlled by Kitts regulating valves located in the boiler room. These valves have pressure lines tapping the main steam header just before reaching the turbines, and an increased load coming on the machines, the pressure will be reduced here before affecting the boiler pressure. Immediately the fan in use will be speeded up in direct proportion to the drop in pressure. At the same time fuel will be fed to the furnaces at a proportionately increased speed by a Cole automatic regulator, Figs. 5 and 6 giving the details of its construction. Belted to each fan engine is a line shaft running in self-oiling bearings and extending to the front of the boilers in the basement, where each shaft is connected through bevel gears with another shaft running at right angles, and by which the Cole automatic regulating valves are operated by belts. Either shaft may be cut out by a friction clutch when its corresponding fan is not in use. Situated on the boiler-room floor at each battery of boilers are the regulating valves, each of which controls six stokers. As is well known, the Jones stoker operates by forcing the charges of coal upward into the fire by means of a ram plunger operated by a steam piston, the return stroke of the piston allowing fresh coal to drop into the charging tube from the hopper above. In operation the function of the Cole regulating valves is to control the number of charging strokes of the stoker by turning steam alternately into each end of the stoker cylinders.

The Cole valves themselves, which are shown in detail in Fig. 7, consist of a rotating stem with a flat end, held to a valve seat by the steam pressure. The stem is turned by a ratchet attachment driven by a connecting rod receiving motion through a lay shaft and worm gear direct from the fan engine, as previously described. At each revolution, a steam port A, Fig. 7, is uncovered, causing a charging stroke of the stoker. At other times during the revolution the steam port is connected to the longer passage B, which causes the stoker piston to remain in the outward position ready to make a charging stroke. It can be seen then that the rate of feed will be proportioned to the number of revolutions of the controlling steam valves, which in turn are entirely dependent on the speed of the fan engines. In addition there is a further adjustment provided at the ratchet, as shown, whereby more or less notches on the driving mechanism may be engaged or disengaged, the more notches being taken up by the ratchet, the faster the steam valves will revolve. By means of the equipment described it is possible to provide a fuel feed which meets the peculiar load conditions in a most satisfactory manner.

Boiler Feed and Pumps

There are two Worthington tandem-tank pot-valve feed pumps provided and these are located between the two batteries of boilers. They take water from a sump tank which takes the overflow from the hotwell. Other connections are arranged so that water may be taken from the cold-water main of the condensers or from the city mains, giving three sources of supply. Each pump is connected to a Worthington-Cochrane open B vertical closed heater which utilizes the

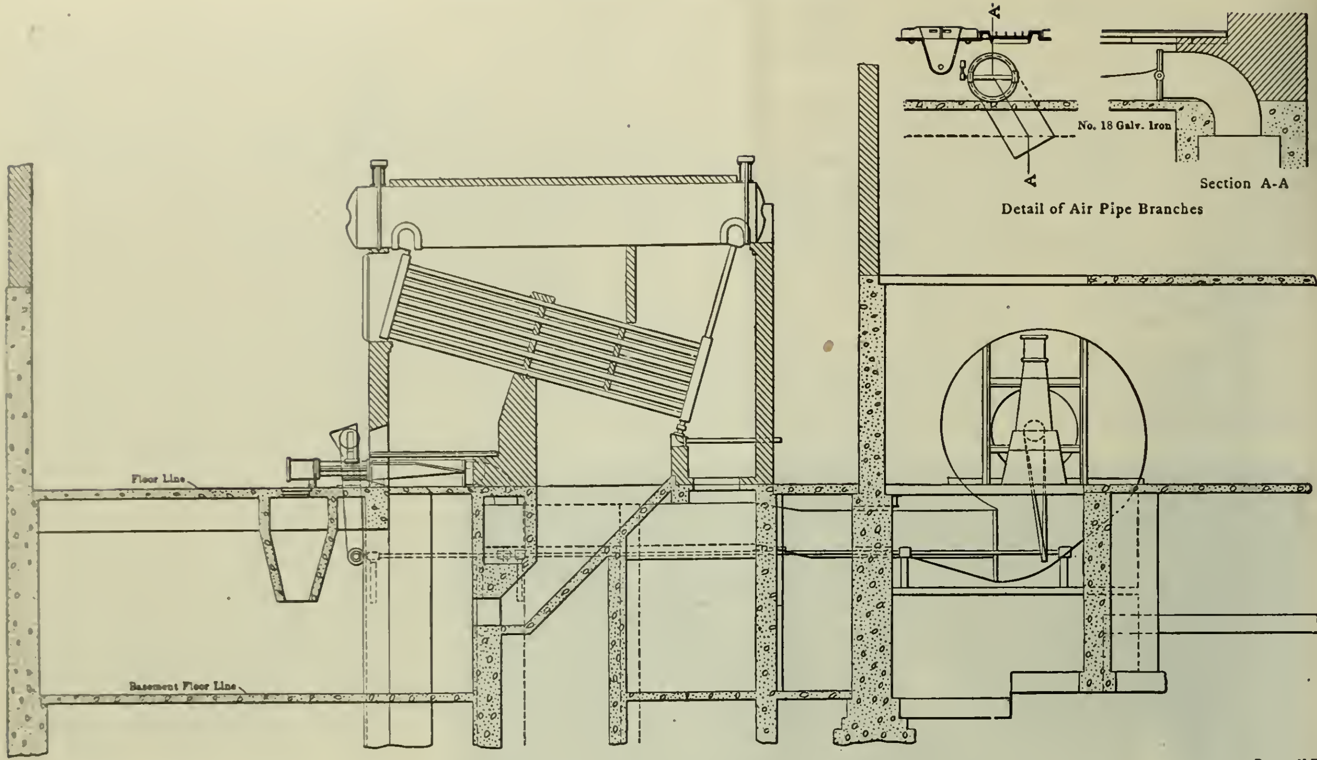


FIG. 5. BOILER SETTING AND DETAILS OF AIR BLAST

auxiliary exhaust. From the feed pumps the water passes through 3-inch Worthington water meters before going to the heaters. A thermometer is inserted in the feed lines both at the entrance and at the outlet to the heater. The average feed temperature is 200 degrees.

Referring to the sectional view of the boiler setting, Fig. 5, it is desired to call attention to the arrangement for cleaning the combustion chambers, the bottoms of which are really hoppers opening through doors into the basement, allowing the contents of the combustion chambers to be raked out into the small push cars. Anyone who has had to do with the cleaning of ordinary combustion chambers will certainly appreciate this arrangement. Vertical gas passes are used, finally leading to a flue under the boiler-room floor and passing to the stack.

Steam is taken from the boilers through 6-inch long-sweep bends and discharged into an 8-inch header leading down to a separately fired Foster superheater, located between the batteries of boilers. All high-pressure piping is of mild steel with welded flanges. Seven-inch lines connect the superheater with the turbine throttles, a bypass being arranged so as to run on saturated steam if necessary. Separators are installed at the turbines to take care of entrained moisture in this event.

Separately Fired Superheater

The superheater, a close view of which is shown in Fig. 8, is designed to superheat 36,000 pounds of steam per hour at 200 pounds per square inch to a final temperature of 587 degrees Fahrenheit, corresponding to a superheat of 200 degrees. It is of Foster construction, the

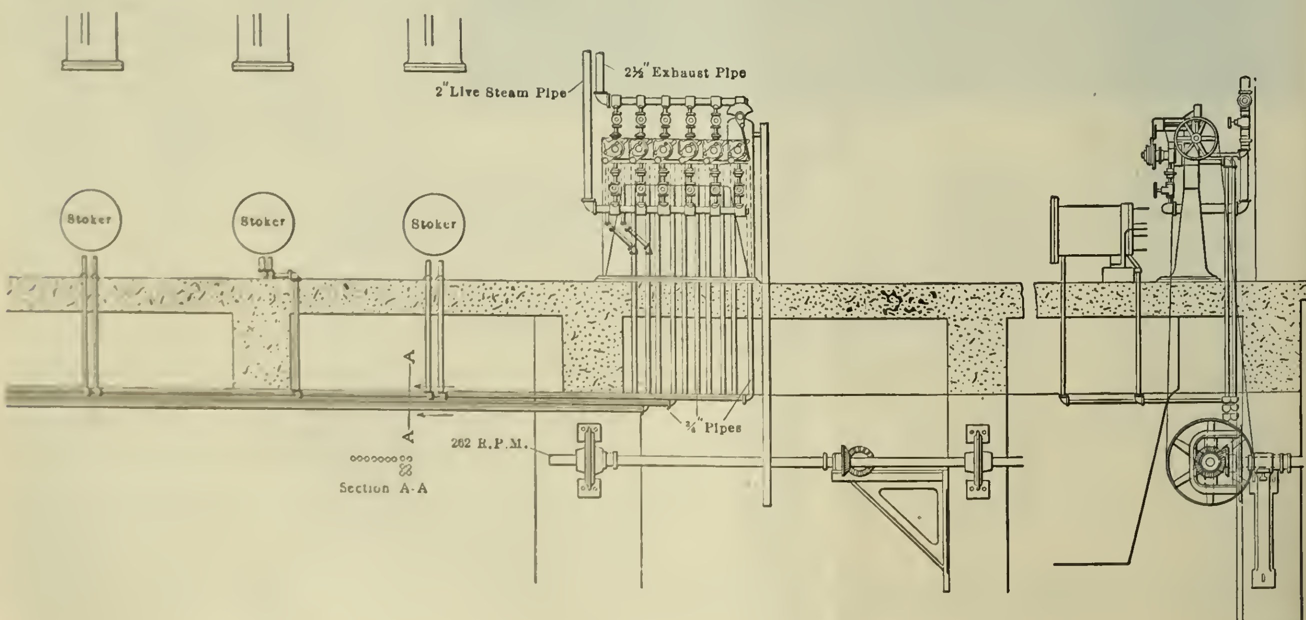

FIG. 6. SIDE VIEW AND END ELEVATION OF COLE REGULATING MECHANISM

lements consisting of cold-drawn seamless steel tubing upon which are shrunk ast-iron rings of special form, making a ibe of practically one metal, being steel n the inside for containing the pressure nd exposing only cast iron of special rade to the destructive action of the

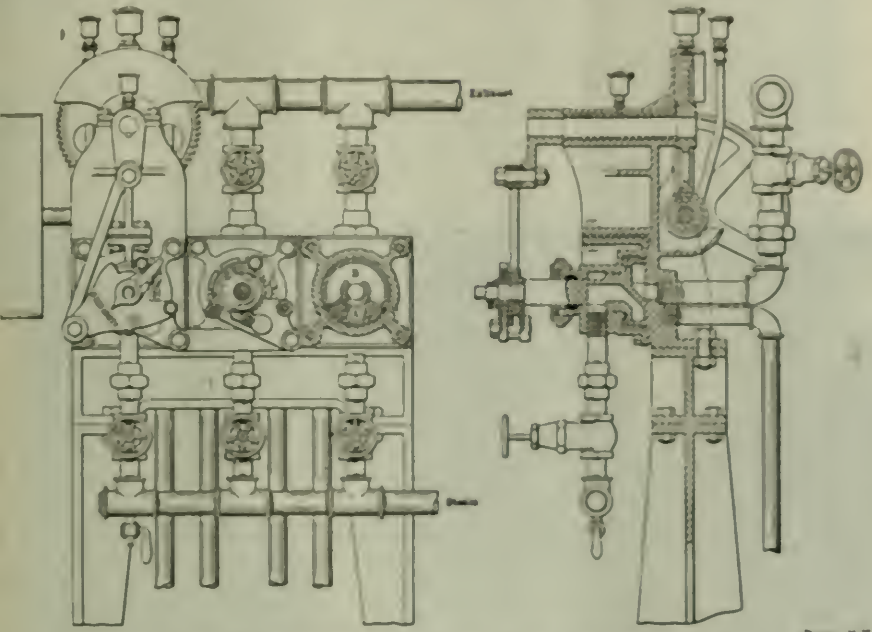

FIG. 7. DETAILS OF COLE AUTOMATIC VALVES FOR STOKER CONTROL

ot gases. The cast-iron rings, aside from rotecting the steel tube, give increased eating surface due to the corrugated ffect. The heating surface is so arranged that the entering steam is brought n contact with the cooler gases as they eave the superheater, the direction of the low of the steam being contrary to the irection of flow of the gases. The supereater is supported on a complete selfontained structural-steel framing, indeendent of the brickwork, which was fterward built into the frame.

In operation a fire is maintained on he grates by hand, and the temperature s controlled automatically by means of thermocouple in the steam outlet to he superheater, which is connected to a elay by which a large solenoid is operted. The solenoid opens or closes valves o a hydraulic piston, which in turn acts irectly on the dampers. A separate coal hute is provided for the superheater, and atural draft is depended on entirely, the ases passing into the main flue under he boiler room floor.

Turbine Room

The turbine room, which occupies about ne-half the power-house building, is ined with light colored pressed brick and urnished with an 8-foot wainscoting of hite enameled brick. Great pains have een taken with the painting and finishing f the machines, so that the plant presents n exceptionally neat appearance. A 15-on Northern hand-operated crane is installed here. About one-half the floor is cut away, forming the pit shown in Fig. 9, in which are located the fan engines and circulating pumps.

The Westinghouse Parsons turbo-units constitute the generating equipment. They deliver three-phase current at 3300 volts, 25 cycles, and are rated at 1250 kilowatts, with the further ability to deliver their full rated load on one phase. The steam ends have the standard bypass arrangement for overloads, and a speed-limiting device to shut off the steam in case of an excess of speed. The generators are completely enclosed and are ventilated by air drawn through the coils by vanes installed on the rotor.

While the requirement to deliver full load from a single phase results in a larger and more expensive generator, it also carries with it a number of advantages. There are a considerable number of shop motors and pumping outfits connected to the system, all of which may be operated advantageously on three-phase current. Again, there is always the possibility of wanting to use power at some greater distance, in which case three-phase transmission would be desirable. Finally, in case of general electrification of the road at any future time, the machines would be in shape to operate in parallel with the rest of the system without any change in equipment, and in this event considerably more than the present rating of the generators would be available on the three-phase circuits.

Barometric jet condensers are installed in connection with the turbines. They are of the Worthington type and have 30-inch exhaust connections, with 14-inch automatic relief valves leading to the atmosphere through spiral-riveted pipe of the same size. Condensing water is supplied by two 10-inch volute pumps, driven by 7x9-inch vertical engines taking the water supply from wells connecting with the St. Clair river through 18-inch tile lines which terminate in a concrete intake protected by a structural-steel grid and screen-wire screen at the dock line.

Another 18-inch tile pipe line carries the overflow from the hotwells to the sump under the feed pumps, the excess

FIG. 8. SEPARATELY FIRED FOSTER SUPERHEATER

water flowing to the river. On the main floor near the condensers are located the straight-line rotative dry-vacuum pumps, with 8x0x12-inch cylinders. One motor-driven exciter of 40 kilowatts capacity is installed for ordinary service, with a squirrel-cage 3300-volt induction motor taking current from the busbars. In addition each unit has a Westinghouse steam-driven exciter in reserve.

Switchboard

Ten switchboard panels, all of standard Westinghouse construction, are required to distribute the electrical output. The may be thrown on either the alternating-current busbars or on the 110-volt direct-current exciter circuits. All of these panels are equipped with ammeters, voltmeters and indicating wattmeters. In addition recording wattmeters are installed to measure the output on locomotive service, pumping service and lighting service.

A Tirrill regulator controls the voltage of the generator carrying the locomotive load, and this is mounted on a special instrument panel at the left end of the board. All lighting, including the mercury-arc circuit for illuminating the terminal cover of which is seen in Fig. 2, and conduits are laid in the tunnel on each side of the track.

Aside from the power and lighting load in the roundhouses and buildings at the Port Huron and Sarnia terminals, the greatest load outside of the traction service is for emergency pumping in the tunnel. It will be understood that the long open inclined approaches previously mentioned, occupy in the aggregate, considerable territory; in fact on the American side this amounts to approximately 11 acres, and on the Canadian side 13 acres. It is important to take care of

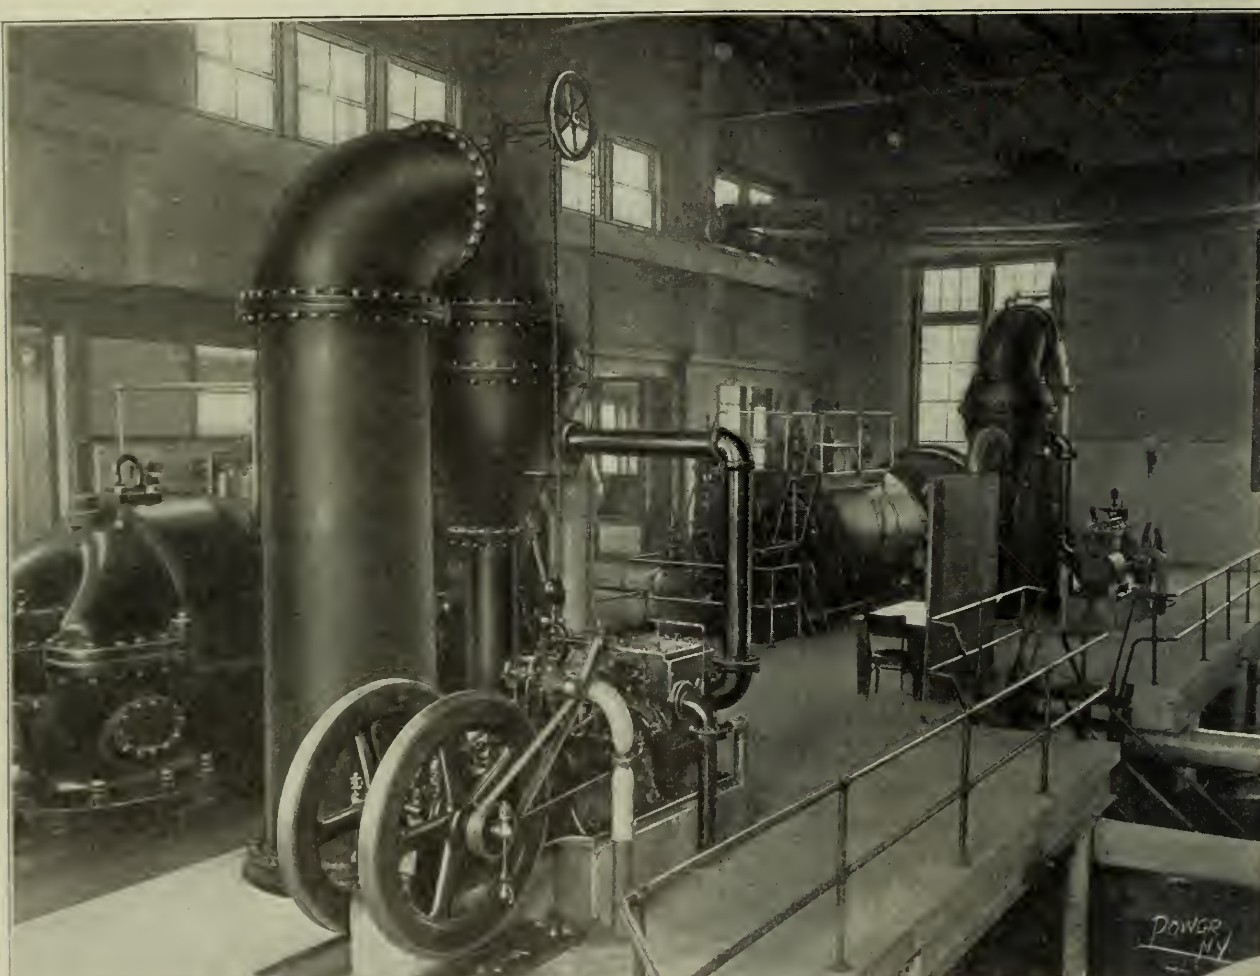

FIG. 9. GENERAL VIEW IN TURBINE ROOM

high-tension oil switches are located in an inclosed switchboard directly behind the board. There are two main generator panels located in the center of the board, as evident in Fig. 10; one for the locomotive power circuit, one each for three-phase power and pumping, and an arc-light panel. The output from the two steam-driven exciters is concentrated on one panel and that of the motor-driven exciter occupies another. One power-house panel takes care of the power and light in the engine and turbine rooms. Connections are so arranged that the lighting here, which is by Nernst lamps, yards, is carried by this machine to take advantage of the closer regulation. The station voltmeters, frequency indicator and synchroscope are also mounted on the same panel.

Facing the switchboard on the opposite side of the operating floor is a gage board carrying all necessary indicating and recording instruments for the boiler plant, so that in connection with the corresponding electrical data on the switchboard, everything is conveniently at hand for the operating engineer. Feeders from the switchboard enter the tunnel through a shaft in the power-house yard, the the rainfall on this area to prevent the tunnel from being flooded, and for this purpose centrifugal motor-driven pumps have been installed, operating at 3300 volts, 25 cycles and displacing the steam pumps formerly used. Fig. 11 shows the interior of one of these pumping stations.

At the Port Huron portal there are two pumps with a capacity of 4000 gallons per minute driven by 100-horsepower induction motors, and at Sarnia there are two of 5500 gallons capacity connected to 200-horsepower motors. In addition, each pump house has a small 150-gallon outfit for pumping out surface water which

FIG. 10. SWITCHBOARD

dinarily finds its way into the approach. Two similar pumps are located at the foot of the Sarnia grade to take care of condensation and seepage water in the tunnel. It is arranged so that water falling on the sides of the incline can be impounded in reservoirs, leaving only that falling on the central portion of the grade to be immediately handled by the pumps during a rainstorm. The reservoirs may then be emptied at leisure.

Operating Features

Fig. 12 gives in graphical form the operating data during a train movement, the total weight of which, including locomotive, was 1020.5 tons. A study of the chart will show the power required at any instant and the variation of temperature, pressures, etc., occurring simultaneously. It will be noted that there is really a remarkable ability on the part of the plant as a whole to maintain normal conditions regardless of load.

As the load comes on absolutely without warning, the first indication given to the firemen is usually the speeding up of the pulleys driving the Cole regulating valves. When this takes place about

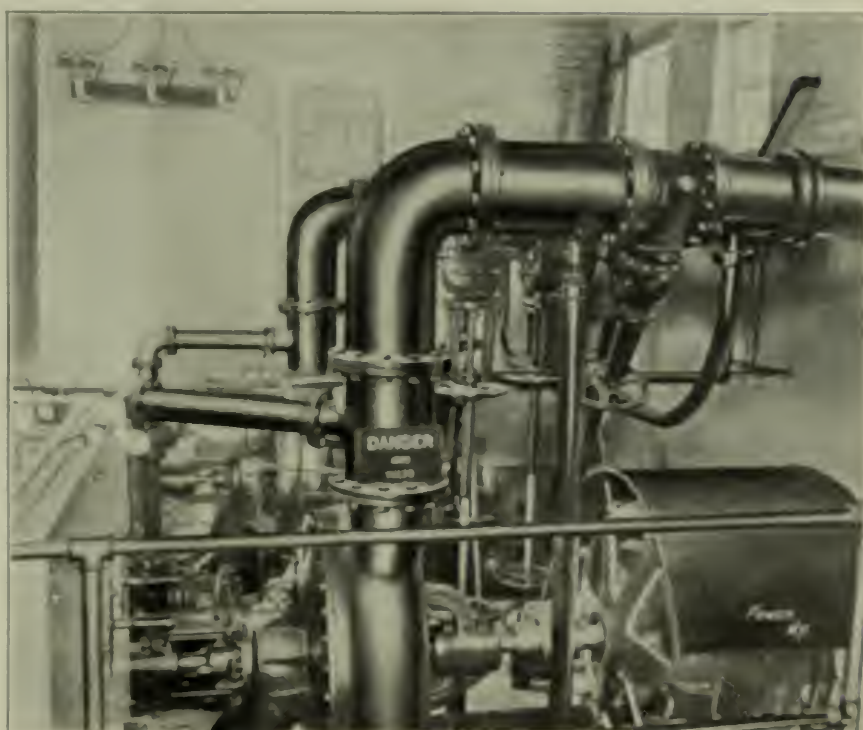

FIG. 11. INTERIOR OF ONE OF THE PUMPING STATIONS

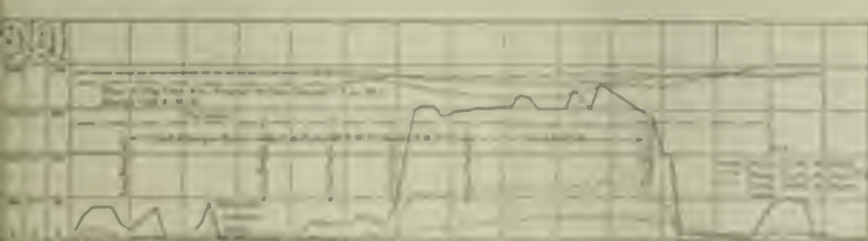

FIG. 12. GRAPHIC LOG OF OPERATING DURING ONE TRAIN CYCLE THROUGH TUNNEL

six shovelfuls of coal are thrown on the superheater fire. At the time of the writer's visit to the plant a load came on with the steam at 195 pounds. It fell very quite rapidly to 180 pounds, immediately starting to come back, and when it had reached 200 pounds the load dropped off. Meantime the superheater temperature dropped from 455 degrees to 420 degrees at a rate corresponding approximately to the drop in steam pressure. The temperature then gradually returned to 455 degrees, at which point it registered when the load went off, as indicated by the slowing down of the Cole automatic mechanism. When the load had completely subsided neither the steam pressure nor superheat rose appreciably above the figures given.

By consulting the recording gages in the turbine room it was afterward found that the peak load at this time was 1200 kilowatts, an overload of 65 per cent. The forced draft before the load was 0.3 inch of water and during load 2.5 inches.

The recording-gage charts at this plant are changed at midnight, and by a careful inspection of the variations for this particular day, it was found that the fluctuations had all kept within the limits given above, so that they may be considered as fairly representative of what the plant does under ordinary conditions. The largest momentary load ever carried up to the present writing is stated as 2045 kilowatts—more than 150 per cent. overload.

The forty-first annual commencement of Cornell University was held Thursday, June 17. Two hundred and twenty-five graduates received the degree of mechanical engineer, including seventy-five who have specialized in electrical engineering. Two years ago the electrical course was improved by the addition of a junior laboratory course, and the present class is the first to graduate with this complete course.

Manganese, the hardest of the common metals, is half as hard as the diamond.

Blowers as Breakdown Insurance

By C. M. Ripley

One difficulty the engineer meets with in dealing with "the boss" is due to the frequent inability to state a proposition of an engineering nature so that it will be fully understood by the commercial or financial mind of his employer. Many an engine room would contain much-needed improvements, for which the engineer could not obtain an appropriation, if he had pleaded his cause properly.

The president or treasurer of a company must not be dazzled by technicalities, nor must he be confused in a maze of engineering facts. He must be made to see the *commercial* side of the proposition. He must be made to realize that if a certain sum of money is *invested*, the improvement so purchased will yield him an annual return in reduced operating expenses. His mind always has been and always will be best appealed to by talking in dollars and cents and annual percentage income, rather than in pounds of coal, gallons of water, B.t.u., etc.

A Blower, for Example

Let us take, for instance, a blower. The engineer knows that if a blower were installed for, say, a plant with two boilers, the following results not only would be expected, but could be positively guaranteed:

A cheaper fuel could be burned, furnishing, say, 9,000,000 B.t.u. for a dollar instead of 6,000,000.

Any defects in the draft would probably be remedied.

When one boiler needed cleaning, the other could be forced to carry the load.

A breakdown in one boiler could be immediately repaired by forcing the other boiler to carry the load.

But the president of the company never heard of a B.t.u., and as for draft, little does he realize how the draft up the chimney vitally affects his bank account. The cleaning of the boiler means to him probably nothing more than does the cleaning of the marble wainscoting in the main hall.

What the Boss Wants to Know

The engineer would more frequently have his recommendations O. K.'d and new improvements put under way if he were to talk to the president or general manager in the following manner:

"If we were to spend a little money in a blower, I figure—and I am ready to back it up at the cost of my position—that it will bring a return to us of 200 per cent. per annum, if not more. I consider this to be a very wise move for the following reasons: (1) We burn 2000 tons of coal a year, costing $8200. (2) With blowers we could get along with coal costing $2.80 per ton instead of $4.10 per ton. (3) The difference is $1.30 on every ton that is delivered and will amount to over $1800 per year. (4) The cost of making such changes is less than $500. (5) Therefore this investment will annually save us over three times the first cost, i. e., return 300 per cent. per annum. (6) I have personally investigated in odd hours other plants (naming them) where this change has been made and conditions in our plant are almost identical with these. (7) Besides this great saving every year, a blower will almost serve as an extra boiler, and will be as good in case of a breakdown of either boiler as would a third boiler held in reserve. (8) Our fuel bills will be bound to increase unless I am able to close down each of the boilers every few months and remove the scale from the tubes. This I can do, if a blower is installed, with the least possible danger, and without the need of outside help, since the other boiler can do almost double work by merely starting the blower. (9) I hold the position of chief engineer for you and receive more salary than a mere engine man, because I am expected to keep the plant operating as cheaply as possible; because I am expected to furnish absolute reliability of service, and I am expected to keep the machinery modernized and with the least amount of depreciation. (10) It is my judgment that this change is necessary from my standpoint and will prove a splendid investment on the books of the company."

The blower is but one example of a great many valuable improvements. As soon as the engineer is better able to explain the financial side of the operating questions with which he has to deal, and present them as *investments*, not as expenses, then the efficiency of isolated plants will increase and there will be fewer men thrown out of employment by the central-station service.

Killed and Injured in Boiler Explosion

One man was killed, another probably fatally hurt and two others severely injured when the boiler of a portable sawmill in the woods near Parker's mountain, about 14 miles from the city of Rochester, N. H., exploded June 14.

The largest piece of the boiler was blown over 500 feet and sections were picked up at much greater distances. The fireman was blown into the air and died within a few moments. Another man was terribly scalded and was so near the boiler that part of the contents of the furnace were scattered over him, burning most of his clothes. His condition was considered serious and it was not thought he could recover.

The exact cause of the explosion is not known, but the boiler is believed to have burst under a high steam pressure.

Sizes of Fuses for Three-Phase Motors

By N. A. Carle

In selecting the sizes of fuses for three-phase alternating-current motors it is necessary to make some assumption as to the probable power factor of the motor in operation and, knowing the efficiency of the motor from the manufacturer's guarantee, calculate the amperes required to operate the motor at full load.

It is customary to install fuses with a capacity from two to three times the calculated amperes at full load to provide for the excess current demanded to start the load.

The formulas covering the various operations to be performed in calculating the amperes at full load are as follows:

$$\frac{\textit{Horsepower} \times 746}{1000} = \textit{Kilowatts Output}$$

$$\frac{\textit{KW. Output}}{\textit{Motor Efficiency}} = \textit{Kilowatts Input}$$

$$\frac{\textit{KW. Input}}{\textit{Volts} \times \textit{Power Factor} \times 1.732} = \textit{Amperes.}$$

Combined into one formula:

$$\frac{\textit{Horsepower} \times 746}{\textit{Motor Efficiency} \times \textit{Power Factor} \times 1.732 \times \textit{Volts}} = \textit{Amperes.}$$

The chart on page 1143 is designed to show the sizes of fuses to use for three-phase alternating-current motors up to 200 horsepower for the usual limits of the variable factors entering into the calculations in the foregoing formula. This chart is so designed that for motors above 100 horsepower, 400-440 volts must be used. Either 200-220 or 400-440 voltage circuits can be used in calculations for motors of less than 100 horsepower.

Examples

(1) If the efficiency and power factor of a 50-horsepower three-phase motor operating at 200 volts is 85 per cent., what size of fuse, with a factor of safety of 2.5, should be installed in each wire?

Starting with 50 horsepower read up to 85 per cent. motor efficiency, then across to 85 per cent. power factor, then down to 200 volts, then across to 2.5 factor of safety, and then down to 375 amperes as the capacity of fuses to be installed in each wire.

(2) If a 100-kilowatt motor operating at 440 volts has a power factor of 90 per cent. and an efficiency of 85 per cent., what size fuses should be installed in each wire, if the starting current is assumed to be equal to three times the operating current at full load?

Starting with 100 kilowatts read up to 85 per cent. motor efficiency, then across to 90 per cent. power factor, then down to 440 volts, then across to 3.0 factor of safety, and then down to 515 amperes as the capacity of fuses to be installed in each wire.

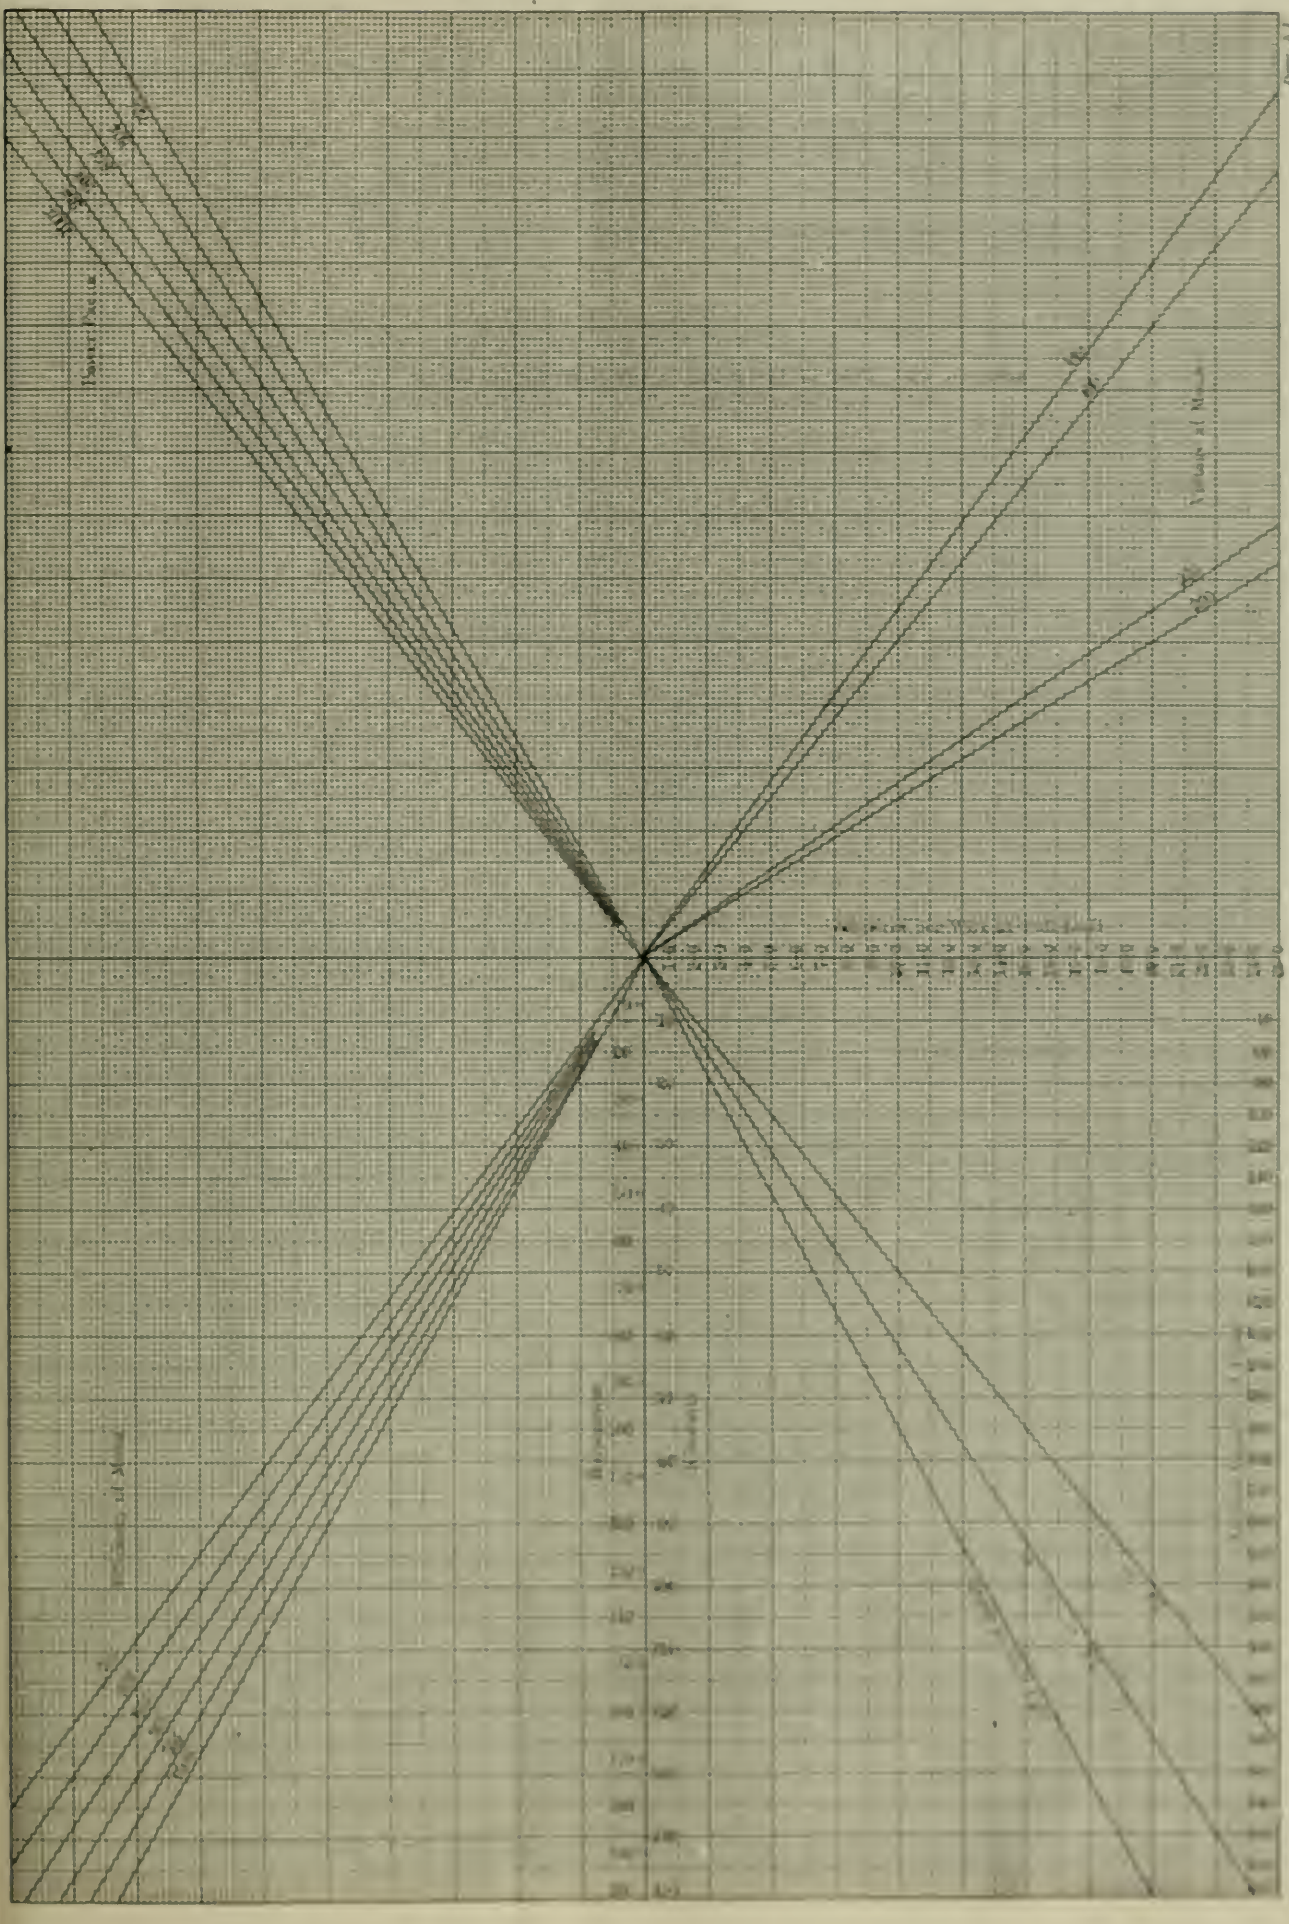

CHART FOR CALCULATING THE SIZE OF PLANT FOR THREE-PHASE ALTERNATING-CURRENT MOTORS

Heat Transmission into Boilers

Possible Ways of Utilizing More Fully the Heat Absorbing Ability of Steam Boilers to Obtain Better Economy and Higher Capacities

HENRY KREISINGER AND WALTER F. RAY

The investigations which are detailed in this article are the result of the study of one of the many problems growing out of the general plan of the United States Geological Survey to increase the efficiency with which the coals of the country are being used. Greater efficiency requires better boiler and furnace design and means the conservation of the fuel resources of the country. These special investigations have been undertaken by the Technologic Branch of the Survey, of which Dr. J. A. Holmes is the expert in charge, and H. M. Wilson, chief engineer. J. C. Roberts, engineer locally in charge of the Pittsburg plant, has given the work every possible encouragement. These experiments are directly under the charge of L. P. Breckenridge, consulting engineer, and D. T. Randall engineer-in-charge of tests, and are part of a carefully prepared plan of general investigations into fuels. The experiments are now being continued at the Geological Survey testing station at Pittsburg, Penn.

The object of this article is to treat of the heat-absorbing ability of steam boilers, and to point out possible ways of more fully utilizing this ability in getting both better economy and higher capacities from steam boilers. By a steam boiler is meant only the metallic vessel which holds water and steam and which absorbs heat, aside from the furnace whose function it is to liberate the heat from the fuel.

True Boiler Efficiency

The amount of heat a boiler will absorb per unit of time depends almost entirely on the amount of heat available for absorption. Not all of the heat which is liberated in the furnace nor all the heat which is delivered to the boiler is available for absorption. Heat flows of its own accord only from bodies at higher temperatures to bodies at lower temperatures, so that only that part of the heat which is above the temperature of the boiler will flow into the latter and therefore is available for absorption; heat below the temperature of the boiler will not flow into it and is not available for absorption.

For example, supposing 4 pounds of furnace gases at 2500 degrees Fahrenheit are delivered to a boiler operating under a pressure of 100 pounds by gage. The temperature of the water in the boiler is 337 degrees Fahrenheit. Assume that the specific heat of the gases is 0.25 and that it does not vary with temperature. The heat in the gases which is available for the boiler is then,

$$4 \times 0.25 \times (2500 - 337) = 2163 \ B.t.u.$$

Heat below 337 degrees Fahrenheit is below the temperature of the boiler and cannot be absorbed by it.

In practice no boiler absorbs all the available heat and the gases leave the boiler from one to several hundred degrees higher than the boiler water, according to how good or how poor a heat absorber the boiler is. The heat which the boiler does absorb, expressed in percentage of the heat available for absorption, is the true measure of the boiler's ability to absorb heat and has been given the name *True Boiler Efficiency* by the United States Geological Survey. The true boiler efficiency is then the ratio,

$$\frac{\textit{Heat absorbed by the boiler}}{\textit{Heat available for absorption by the boiler}}.$$

Thus, supposing that in the previously given illustration the 4 pounds of gases are cooled by the boiler from 2500 degrees Fahrenheit to 550 degrees Fahrenheit, we have then as the heat available to the boiler.

$$4 \times 0.25 \ (2500 - 337) = 2163 \ B.t.u.$$

The heat absorbed by the boiler is,

$$4 \times 0.25 \ (2500 - 550) = 1950 \ B.t.u.,$$

and the true boiler efficiency is,

$$\frac{1950}{2163} = 90.1 \ \textit{per cent.}$$

If the atmospheric temperature is 50 degrees Fahrenheit, then in the above case the heat in the gases above atmospheric temperature, delivered to the boiler, is

$$4 \times 0.25 \ (2500 - 50) = 2450 \ B.t.u.,$$

and the ordinarily used boiler efficiency is,

$$\frac{1950}{2450} = 79.6 \ \textit{per cent.}$$

The difference between the two efficiencies occurs in the denominators. In the true boiler efficiency the denominator is the heat available to the boiler, which heat has for its base line the temperature of the boiler water or steam, while in the ordinarily used boiler efficiency the denominator is the heat above atmospheric temperature delivered to the boiler, which, of course, has for its base line the temperature of the atmosphere. True boiler efficiency has the advantage over the ordinarily used boiler efficiency that it takes care of the variation of the temperature of the furnace gases as well as the temperature of the boiler due to different steam pressures. In other words, true boiler efficiency does not blame the boiler for lessened useful effect caused by low temperature of furnace gases, which is really the fault of the furnace, nor does it blame the boiler for absorbing less heat when the temperature of the boiler water is raised by raising the steam pressure.

Thus, for an example, supposing two boilers A and B are exactly similar in size, construction and setting and both are operated under a pressure of 100 pounds by gage. Suppose boiler A is supplied with 4 pounds of furnace gases per second at 3050 degrees Fahrenheit, while 8 pounds of gases are supplied at 1550 degrees Fahrenheit to boiler B; and also suppose that the temperature of the atmosphere is 50 degrees Fahrenheit. It is evident that the boiler getting gases at the higher temperature will absorb much more heat than the boiler getting them at the lower temperature, even if the gases supplied to each boiler contain the same quantity of heat above atmospheric temperature. Substituting these values, the heat above atmospheric temperature supplied to boiler A per second =

$$4 \times 0.25 \times (3050 - 50) = 3000 \ B.t.u.;$$

the heat above atmospheric temperature supplied to boiler B per second =

$$8 \times 0.25 \times (1550 - 50) = 3000 \ B.t.u.;$$

the heat available to boiler A =

$$4 \times 0.25 \times (3050 - 337) = 2613 \ B.t.u.;$$

and the heat available to boiler B =

$$8 \times 0.25 \ (1550 - 337) = 2426 \ B.t.u.,$$

Supposing further that the temperature of the gases leaving boiler A is 700 degrees Fahrenheit and that of the gases leaving boiler B is 470 degrees Fahrenheit. Many experiments made by the Geological Survey on large boilers and also on small models show that the temperature of the leaving gases would be about as assumed above. The heat absorbed by boiler A is

$$4 \times 0.25 \times (3050 - 700) = 2350 \ B.t.u.$$

and the heat absorbed by boiler B is,

$$8 \times 0.25 \times (1550 - 470) = 2160 \ B.t.u.$$

The true boiler efficiency of boiler A is

$$\frac{2350}{2613} = 90 \text{ per cent.},$$

and of boiler B,

$$\frac{2160}{2426} = 89 \text{ per cent.}$$

or very nearly the same as of boiler A. The ordinarily used efficiency would give boiler A credit for

$$\frac{2350}{3000} = 78.4 \text{ per cent.},$$

and boiler B credit for

$$\frac{2160}{3000} = 72 \text{ per cent.}$$

On comparing the efficiency in the two cases, it is seen that the true boiler efficiencies are very nearly the same, while the ordinarily used efficiency is over 6 per cent. lower for boiler B than for boiler A. It is apparent that the drop in useful effect of boiler B is caused by some defect of the furnace construction or its operation, and, therefore, should not be charged against the boiler, but rather against the furnace.

A moment's reflection will show that if the steam pressure is kept nearly constant and if the same quantity of heat is put into twice the weight of gases at half the temperature, twice the quantity of heat is below the temperature of the steam and, therefore, not available for absorption. It may be asked why the true boiler efficiency has been devised. The answer is, to study the heat-absorbing ability of a boiler independently of the operation of the furnace. In studying any complicated problem such as a steam-generating apparatus presents, it is necessary, if any general deductions are to be drawn, for as many of the variable factors to be eliminated, or fixed, as possible, leaving only the ones (preferably two in number) which it is desired to study. In studying the function of the steam boiler proper, the first step was to eliminate the furnace and devise the measure of the boiler's ability. This latter has been done by devising the true boiler efficiency, and it now remains to study the ways in which heat gets from the hot furnace solids and gases into the boiler water.

Modes of Heat Travel

Fig. 1 shows diagrammatically a section through a boiler heating plate and the modes of heat travel. It is shown that the metal of the plate is covered on the gas side with a layer of soot, and on the water side with a layer of scale. Next to the soot layer and entangled in its recesses is a layer or film of gas. This film of gas under ordinary conditions adheres so tightly to the soot or metal that it may almost be considered a part of the plate. It is, therefore, reasonable to assume that the dry surface of the plate is located somewhere within this film of gas. The wet surface of the heating plate is perhaps in a similar film of water and steam adhering on the inside of the boiler to the layer of scale or metal plate if the boiler is clean. Through the metal plate and its coatings the heat is transferred from the dry surface purely by conduction. For constant physical conditions of the coatings the rate of heat flow depends only on the *difference of temperatures* between the dry and the wet surfaces of the plate.

The heat is imparted to the dry surface of the plate mainly in two ways: (a) By radiation from the hot fuel bed and furnace walls, and (b) by convection from the moving hot furnace gases. The convection of heat is the process of the particles of the moving gas coming in contact with the dry surface of the plate and giving their heat to it. In a large majority of the boilers of the water-tube type the heat imparted to the dry surface

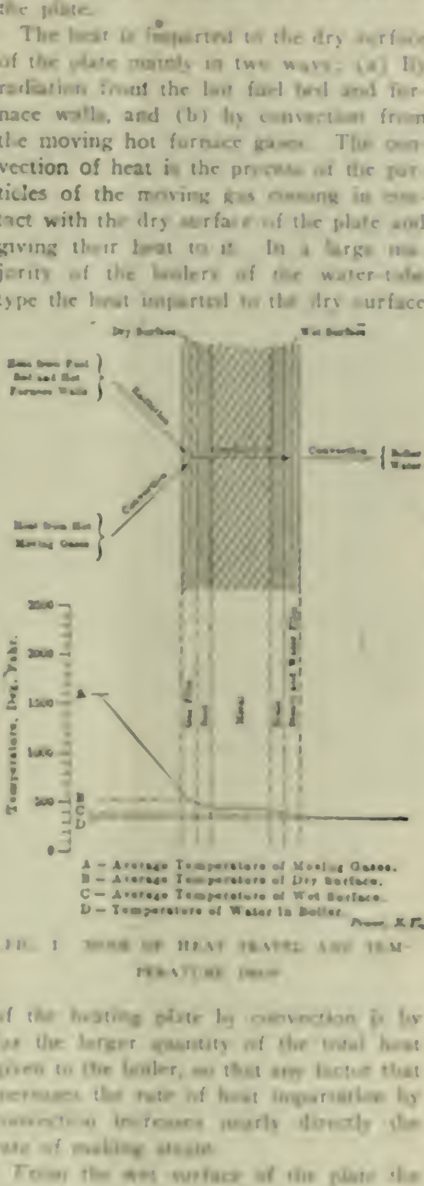

FIG. 1. MODE OF HEAT TRAVEL AND TEMPERATURE DROP

of the heating plate by convection is by far the larger quantity of the total heat given to the boiler, so that any factor that increases the rate of heat importation by convection increases nearly directly the rate of making steam.

From the wet surface of the plate the heat is carried into the boiler water mainly by convection. Here the conveying body is the circulating water which scrubs the bubbles of steam from the wet surface and puts more water in contact with it. It is reasonable, then, to say that the faster the circulation of water the faster the rate of heat transfer from the wet surface into the boiler water.

The heat which is communicated by radiation to the dry surface of the heating plate is approximately proportional to the difference between the fourth powers of the absolute temperatures of the fuel bed and furnace walls on one side and the temperature of the dry surface of the heating plate on the other.

According to this law the heat which the boiler receives by radiation increases rapidly with the temperature of the furnace. However, in modern water-tube boilers the heating plate exposed to radiation is so small a portion of the total heating plate that the rise in temperature affects the rate of making steam but little. Furthermore in well operated boiler furnaces the temperature cannot be raised much higher, so that there is very little hope of increasing the capacity of a boiler by raising the temperature of the furnace. The absorption of heat by radiation is aside from the aim of this article and will not be further discussed.

There is much more to be expected from convection. The quantity of heat imparted to the boiler in a unit of time can be increased by bringing more particles of gas into contact with the dry surface of the heating plate, thereby increasing the rate of making them. In fact, this is what has been done for years in locomotive and marine practice. In these types of boiler the capacity is increased by passing more gases over the heating plates, thereby bringing more particles of gas into contact with the dry surfaces of the plates.

Heat Imparted by Convection

Today it is a fairly well established law that the amount of heat imparted to a boiler plate by convection is very nearly directly proportional to the difference of the temperatures of the gases and the dry surface of the heating plate, times the velocity of gas passing over the plate, times the density of the gas. This law can be expressed by the equation,

$$H = C\,(T - t)\,v\,w$$

where

H = Heat imparted to a unit surface of heating plate per unit time,
C = Constant,
T = Temperature of moving gases,
t = Temperature of the dry surface,
v = Velocity of gases moving over the surface,
w = Density of the gas.

This law, originally proposed by Prof. Osborne Reynolds, was lately derived by Prof. John Perry of England. It is not hard to see why this law should be such as it is. If more gas is passed over the heating plate, more particles come in contact with the dry surface and, therefore, more heat is given to the surface in a unit of time.* Again, if these particles are at

*Strictly, this statement that the number of particles of gas striking the dry surface of the heating plate increases nearly directly with the velocity of gas passing over the [illegible] higher temperature, the heat will flow faster from these particles of gases into the surface and more heat will be given to the plate by each contact of each gas particle; also if the gases are denser, that is, if these particles of gases are closer together, more of them will come into contact with a unit of dry surface in a unit of time and, therefore, more heat is given to the plate. Unfortunately, when the temperature rises, the gases expand and the density drops, so that at high temperatures what is gained by the rise in temperature is nearly lost in the reduction of the density. This is the reason why in the two given examples the boiler receiving the gases at 1500 degrees Fahrenheit absorbs almost the same percentage of the heat available as the boiler receiving heat at 3030 degrees Fahrenheit.

By extending this law still farther, it can be seen why fire-tube boilers with small tubes are more efficient than those having large tubes, or water-tube boilers having small tubes close together are better heat absorbers than those having large tubes farther apart. For an example, take one fire tube 2 inches in diameter, and one 4 inches in diameter; in the 2-inch tube the particles of hot gas near the center of the tube are twice as near to the dry surface of the tube as the gas particles in the center of the 4-inch tube and, therefore, in the first tube the gas particles in the center can come in contact with the surface about twice as easily as in the second tube. Similar reasoning will show the same advantage for small air passages against large ones in water-tube boilers. If the 2-inch tube is of the same length as the 4-inch one and the same weight of hot gas is passed through both, the 2-inch tube will actually absorb more heat than the 4-inch, although the latter has twice as much heating surface. This explains why boilers of locomotives are more efficient than multitubular boilers used for stationary purposes.

In the locomotive boiler in the attempt to get larger amounts of heating surface, the tubes ordinarily used are much smaller (about 2 inches) than in stationary multitubular boilers. Within certain limits a 2-inch tube 10 feet long will absorb about the same amount of heat as a 4-inch tube 20 feet long, although the latter has four times as much heating surface as the former, provided the same weight of gases at the same temperature is put through both tubes. In fact, any tube whose ratio of diameter to length is (10 × 12) ÷ 2, will absorb approximately the same amount of heat under the above conditions. By making this ratio larger more heat in percentage of the total heat available for absorption can be absorbed by the tubes.

The quantity of heat imparted to a tube depends upon the number of contacts the particles of gas make with the dry surface of the tube.

In a small tube the particles of gas being closer to the surface make contact with it quicker and, therefore, the same number of contacts is made in a shorter length of the tube than would be the case in a tube of a larger diameter. Giving this law a full consideration, if all other factors were known, a boiler designer can design a boiler for any true boiler efficiency. It is not so much the amount of heating surface which determines the efficiency of a boiler, but the arrangement of it.

This law has been derived by Prof. John Perry, of England, from purely theoretical considerations and has been found to be very nearly true by laboratory experiments made by the United States Geological Survey.

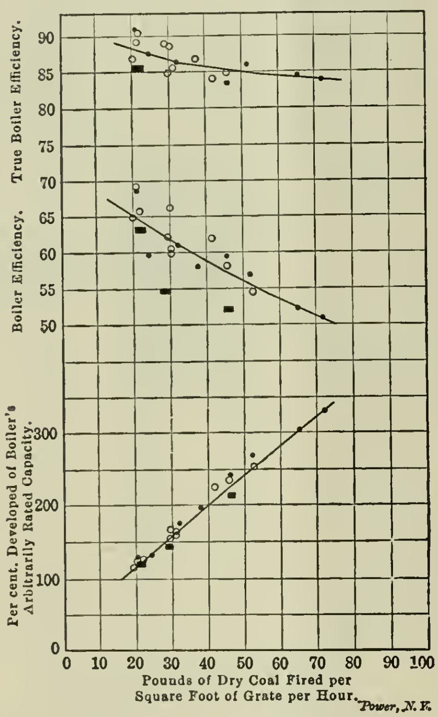

FIG. 2. RELATION OF CAPACITY AND EFFICIENCY TO RATE OF COMBUSTION

Rate of Heat Travel

It will be asked, can the heating plate of a boiler transfer any quantity of heat? The answer is, that it can transfer several times more heat than it does at present, especially in stationary-boiler practice. This answer, however, provides that the scale and soot are not unreasonably thick. The heat conductivity of iron at 400 degrees Fahrenheit given in the Smithsonian physical tables is about 0.0005. This means that if the two surfaces of a steel plate 1 inch thick are kept at a temperature difference of 1 degree Fahrenheit, every square inch of the plate will transmit 0.0005 B.t.u. per second; if the temperature difference is 10 degrees Fahrenheit, 0.005 B.t.u. will be transmitted, or if the thickness of the plate is 0.1 inch, the temperature difference of the surfaces being 10 degrees Fahrenheit, 0.05 B.t.u. are transmitted for every square inch per second.

The walls of the tubes of water-tube boilers are about 0.1 inch thick; the tubes of a locomotive are probably thinner. Let us figure what the temperature difference of the two surfaces of a tube 0.1 inch thick is at various rates of making steam. At the rate of 10 square feet of heating plate per boiler horsepower the heat transmitted per square inch per hour is,

$$\frac{34.5 \times 965}{10 \times 144} = 23.1 \textit{ B.t.u.},$$

or

$$\frac{23.1}{60 \times 60} = 0.0064 \textit{ B.t.u. per second.}$$

To transmit this quantity of heat requires a temperature difference between the two surfaces of

$$\frac{0.0064}{0.005} = 1.3 \textit{ degrees Fahrenheit.}$$

If only 1 square foot is taken to do the same work, the temperature difference would be 13 degrees Fahrenheit; if the same amount of work is required from 0.1 square foot, the temperature difference would be 130 degrees Fahrenheit.

These figures show that the resistance of the metal to heat transfer is very small, and that there is something else which is to be blamed for the low rate of steam production in steam boilers. Undoubtedly the soot and scale coatings are to be blamed for part of the resistance. However, even if the temperature drop through the soot and scale is assumed to be 10 times as much as the temperature drop through the metal alone, it will be found that the combined temperature drop through the soot, metal and scale is only a small fraction of the total drop between the moving gases and the water in the boiler. Thus, referring to Fig. 1, the lower portion shows the temperature drop or gradient through a portion of a heating plate and the coating. It is shown that the drop through the soot and scale is 10 times that through the metal.*

For the normal rate of making steam the temperature drop through the metal is 1.3 degrees Fahrenheit, and through the soot and scale 13 degrees, making the total drop 14.3 degrees. Now, as heat is transmitted through the plate only by conduction and as the conditions and the conduction of the plate and coating generally cannot be changed, the temperature drop through the plate must be increased if more heat is to be transmitted through the plate. Thus if the rate of making steam is to be twice the normal, the temperature drop must be increased from 14.3 to 28.6 degrees Fahrenheit, or if the rate is to be 10 times the normal the temperature drop would have to be 143 degrees Fahrenheit, and so on. It is ap-

*The authors have assumed "10 times" simply as a matter of convenience.

arent that even at 10 times the normal ate of making steam the temperature rop through the plate and its coatings is erhaps about one-tenth of the total temerature difference between the boiler ater and the gases.

In well-operated boiler furnaces the emperatures are 2500 degrees Fahrenheit, r higher; if the boiler works under a ressure of 150 pounds, the boiler-water emperature is about 365 degrees Fahrenheit. Assuming that the gases leave the eating plates of the boiler at 600 degrees ahrenheit, the total temperature drop etween the boiler water and the gases is t the furnace end of boiler,

$$2500 - 365 = 2135;$$

nd at the uptake end of boiler,

$$600 - 365 = 235.$$

he approximate average is 1180 degrees ahrenheit. If the boiler generates steam t a rate averaging one boiler horsepower er square foot of heating plate, which is

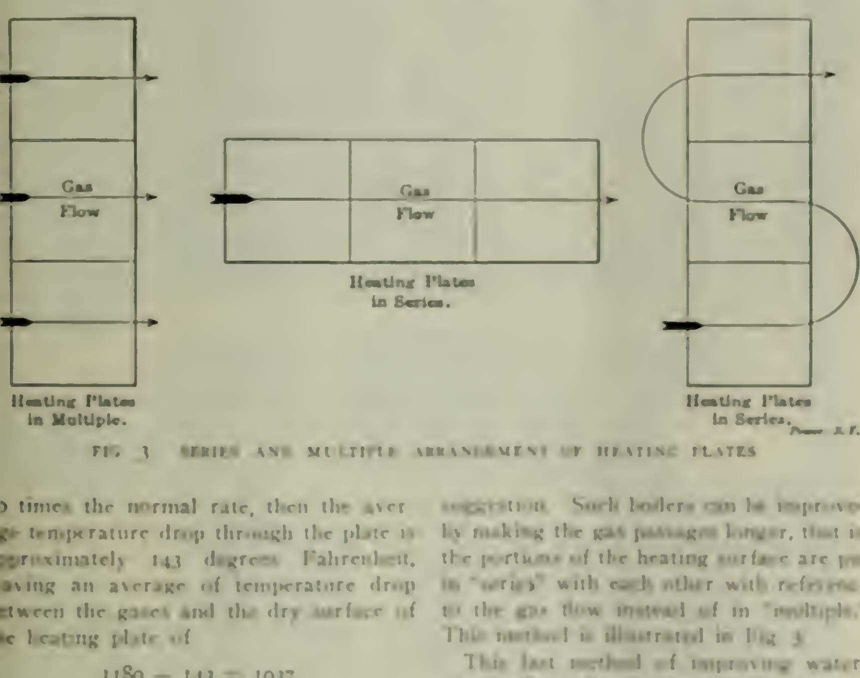

FIG. 3. SERIES AND MULTIPLE ARRANGEMENT OF HEATING PLATES

0 times the normal rate, then the average temperature drop through the plate is pproximately 143 degrees Fahrenheit, aving an average of temperature drop etween the gases and the dry surface of he heating plate of

$$1180 - 143 = 1037$$

Although these figures are only roughly pproximate, they serve to illustrate that *he slow rate of heat travel is not through he heating plate itself but rather from he hot gases to the dry surface of the eating plate.*

Temperature vs. Velocity of Gases

The logical conclusion, then, is that the late will take care of all the heat that eaches its dry surface, and this is where knowledge of Perry's law of heat imartation will be of service. It has been ointed out that according to this law he heat imparted to a unit of dry surace of heating plate varies directly as he difference between the hot gas and he dry surface, approximately directly as he velocity of gases flowing over the plate, and directly as the density of the gas. It has also been pointed out that when the temperature rises the density of the gas drops; that increasing the temperature beyond certain limits does not help much the rate of heat impartation; besides high furnace temperature is destructive to the materials used in furnace construction. It is the utilization of the velocity factor which offers a possibility of increasing both the efficiency and capacity of a boiler.

Improving Economy

As previously stated, the economy can be improved by making the gas passages smaller as compared to the length, that is, arranging the heating plates in such a way that the distance of the gas particles to the dry surface is the shortest possible. In some cases this arrangement is not practicable on account of difficulty in construction; water-tube as well as fire-tube boilers already installed cannot have the gas passages changed according to this suggestion. Such boilers can be improved by making the gas passages longer, that is, the portions of the heating surface are put in "series" with each other with reference to the gas flow instead of in "multiple." This method is illustrated in Fig. 3.

This last method of improving water-tube boilers already installed is successfully used by W. L. Abbott and A. Bement, of the Chicago Commonwealth Edison Company. A few years ago they rebaffled some of the Heine boilers at the Harrison street plant in such a way that the gases pass through the tubes three times instead of once, as they do in boilers with the usual standard baffling. Later, by the insertion of only one baffle, they made the gases flow twice through the tube chamber; with almost the same total draft they have obtained about the same capacity and from 6 to 15 per cent. higher efficiency.*

Increasing Capacity

The capacity of any boiler can be increased by forcing through the boiler larger weights of gases. If the weight of gases passed through the boiler per second is doubled, the velocity of the gas is doubled, with the result that the quantity of heat absorbed by the boiler per second is nearly doubled. It has been already mentioned that this method of increasing the capacity is used in locomotive and marine practice. In stationary boiler practice a good example can be quoted in the work of H. G. Stott and W. S. Finlay, Jr., of the Interborough Rapid Transit Company, New York City. They have added a stoker under the rear end of each of several Babcock & Wilcox boilers. This addition enabled them to burn nearly twice as much coal, resulting in twice the weight of gases of combustion being put through the boiler at nearly twice the velocity, and making the boiler absorb nearly twice as much heat as with a single stoker.**

It is true that when boilers are forced to make two or three times the usual amount of steam, the over-all efficiency drops somewhat. By using the methods for increasing the efficiency in connection with those for increasing the capacity, the latter could be increased without decreasing the efficiency, or even higher efficiency could be obtained.

Generally, when in locomotive or marine boilers the capacity is doubled or tripled, the over-all efficiency of the whole steam-generating apparatus drops several per cent., and it is said that the "boiler" is less efficient at higher rating. But when close examination is made of such results, it is found that at least two-thirds of the drop is due to incomplete combustion or other causes of low furnace efficiency. The true boiler efficiency, the true measure of the boiler's ability to absorb heat, changes but little. Fig. 2 shows results of 20 tests made by the United States Geological Survey on a torpedo-boat boiler. The true boiler efficiency is figured from the temperature drop of the gases while passing through the boiler. The method of computation was made as shown by the ratio:

[illegible]

The furnace temperature was taken with a Wanner optical pyrometer which was calibrated before each test. The flue-gas temperature was taken with a thermocouple.† The curves show that the com-

*For more detailed description of their work see United States Geological Survey's bulletin on "Heat Transmission in Steam Boilers." See also paper by present authors on "The Nature of True Boiler Efficiency," Journal Western Society of Engineers, Vol. XII, page [illegible].

**For a more complete description of this work see United States Geological Survey's bulletin on "Heat Transmission in Steam Boilers." See also paper by W. S. Finlay, Jr., read before the American Institute of Electrical Engineers, [illegible]

ery increases nearly directly with the rate of combustion; and that while the over-all efficiency drops 15 per cent., the true boiler efficiency drops only about 4 per cent. The true-boiler-efficiency curve indicates that the boiler keeps absorbing heat as fast as it is supplied. This fact agrees with the statement made previously that the faster the gases pass over the heating surface the faster the latter absorbs the heat.

In Fig. 2 the rectangles represent tests made on large square briquets, the solid circles represent tests made on small round briquets and the white circles represent tests made on run-of-mine coal.

New York's First Corliss Engine

By Thomas Wilson

One of the old vertical walking-beam type of engines made by Corliss & Nightingale in 1851 was the first Corliss engine to be installed in New York City. This engine is still in service and after its 58 years of almost continuous operation is practically as good as ever, and the probability is that it will be maintained in service for many years to come. The old engine, which bore the name "Enterprise," was exhibited at the World's Fair held in the Crystal Palace in New York in 1853, and was used to turn the shafting supplying power to other exhibits. The engine cylinder has a diameter of 20 inches and a stroke of 5 feet, standing 6 feet above the floor, and outside of the lagging has a cross-section 2 feet 1 inch by 3 feet. The top of the beam is approximately 15 feet above the floor, and from the center of the piston-rod pin to the center of the crank-arm pin measures roughly 14 feet. The crankshaft is 9½ inches in diameter, the crankpin 3¾ inches and the flywheel with a 2-foot space has a diameter of 18 feet.

In Fig. 2 it will be noted that the governor is hung from a bracket bolted to the frame of the engine, and from its lower end operates a bell crank, which in turn controls the movement of the steam valves. The dashpot for one of the valves is suspended from the cylinder, and the other rests on the floor. The valve gear itself is of the old familiar type used on early Corliss engines. It will be more apparent in Fig. 1 that the governor is driven by belt from the main shaft, with a gear connection interposed at the cylinder end. The beam is partially shown in Fig. 3, it being impossible to obtain good photographs of the engine in its present location on account of the limited space and the loft running immediately below the beam. The journal or pin projecting from the beam at the left in the photograph, was originally intended for connection to the air pump, but the condenser was never used with the engine.

In 1856 the engine was bought by Hall, Cornell & Co., afterward known as Hall, Bradley & Co., manufacturers of paints. It was used to supply power to their factory, and also some power to manufacturers in the immediate vicinity. Some time in the sixties G. F. Hall was engaged as chief engineer and remained a number of years with the firm until they moved to Brooklyn, their change of location being due to widening Elm street, now known as Lafayette. The additional width of the street cut off a portion of the engine room and made it necessary to seek other quarters. The engine was then sold to the chief engineer, G. F. Hall, who moved it to a basement in the immediate vicinity and continued to manufacture power for sale, only on a more extensive scale. The manufacturers in the entire block on both sides of the street were supplied from the one engine by means of long lines of shafting. The hardest work required of the old-timer was the rolling of lead block into thin lead sheets. This duty taxed it to the utmost and had to be performed at noon hours and after 5:30 when the other power was off. The engine continued in this service until 1897, and during all this time the only repair of any note required was a new cylinder, the original cylinder having been smashed by the beam, which had accidentally been allowed to fall on it.

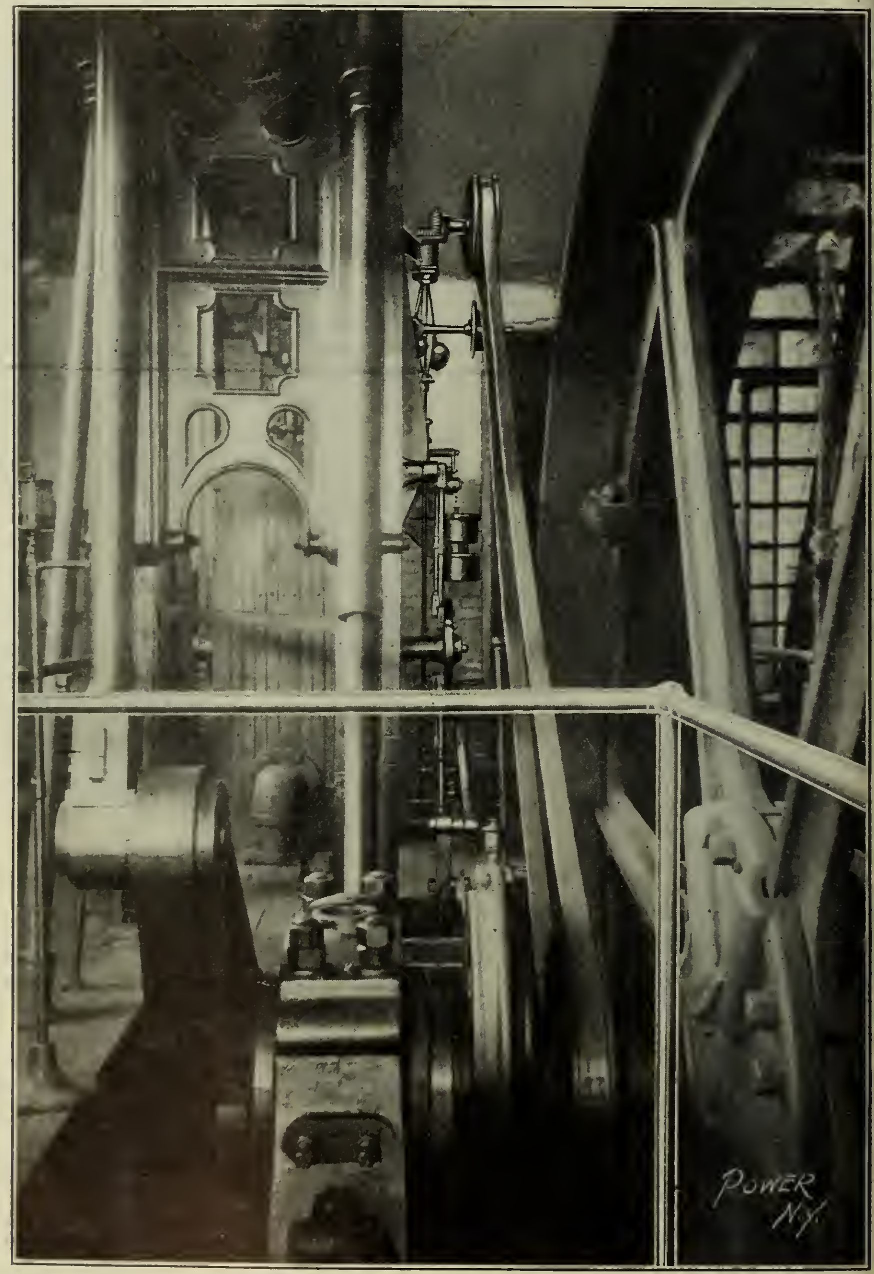

FIG. 1. THE "ENTERPRISE" AS SHE APPEARS AFTER 58 YEARS OF SERVICE

At the latter date the engine was sold by G. E. Hall, son and successor to G. F. Hall, to Wilson & Roake, of New York.

City, who had it in their possession for a few months. During this interval it was offered to the Stevens Institute and also to Cornell University as a relic of the early days of the steam engine, but as neither institution had space to store it, the engine was eventually sold in October of the year noted to the Raymond Rubber Company, of Titusville, N. J. This

FIG. 2 VALVE GEAR AND GOVERNOR

FIG. 3 THE BEAM

firm is a manufacturer of rubber goods from reclaimed rubber, and the engine is required to do the heavy work of the mill on 120 pounds steam pressure and at 35 revolutions per minute. It has been run almost continuously since its purchase, and frequently 22 hours a day. Nevertheless, it has given first-class satisfaction.

In 1905 the anchor bolts holding the main bearing to its foundation gave a good deal of trouble, and it was decided to put in new pillow blocks and an entirely new and heavier bearing of the same design. In the following year a new piston rod and cylinder head were required, as the former broke, due to imperfect alinement, and smashed the top of the cylinder to some extent. These are the sum total of the repairs made in 58 years. The engine now appears to be in good condition, and the present owner, who perhaps may be a little optimistic on the subject, claims that the "Enterprise" is good for 20 or 30 years more.

There are no data on the steam consumption of the engine, but a test performed by J. E. Holmes, director of machinery at the Crystal Palace, immediately after the fair may be of interest, although it is not nearly so elaborate as the tests of present-day practice. It appears that tests were conducted on December 17, 1853, on three engines, all of which were belted to the shafting and used for general power purposes in the Palace. The first was the engine under description, which was rated at 60 horsepower under a steam pressure of 70 pounds gage; the second

FRICTION AND REGULATION TEST

was a double horizontal engine, 15x32 inches, with the two cranks set at right angles to each other and working a single-belt flywheel. This engine was rated at 60 horsepower under 60 pounds steam pressure and was built by the Lawrence Machine Shop under the agency of Gordon McKay. The third was a horizontal engine, 13x60 inches, known as the "Southern Belle," and was designed and constructed by J. S. Winter of the Winter Iron Works, Montgomery, Ala. The tests were conducted to show the regulation and friction of the engines, but the data relating to the "Enterprise" will be given only.

At 7 o'clock of the day of test the engine was started under load, with a pressure of 12 pounds gage; the number of revolutions made per minute were 37. At 7:20 the pumps were uncoupled from the Corliss-engine shafting without making any visible increase in its speed. One minute afterward the pumps were coupled again to the shafting, and with a pressure of only 27 pounds gage the speed of the engine was not retarded more than one-quarter of a revolution. At 8 o'clock the pumping machinery was detached, and with a steam pressure of 7 pounds gage the engine turned the long line of shafting, belts, loose pulleys, etc., 14 revolutions per minute. At 8:45 the engine made 7 revolutions per minute under 3/4 pound steam pressure, and four minutes later stopped. The complete data of the test of the "Enterprise" are given in the accompanying table, from which it will be noted that the friction of the engine and shafting apparently had but little effect, and the regulation under the existing conditions was exceptionally good.

Government Publications Relating to Water Power Development

By H. H. Clingerman

The extent to which publications by the Government assist in the preliminary investigations for the development of a water power is hardly anticipated by anyone about to enter this field for the first time. In many cases a good general idea of the amount of power available can be secured from Government publications.

From the "List of Publications of the United States Geological Survey Relating to Water Resources" can be selected various water-supply papers which may have a direct bearing upon the stream under consideration. These papers are available through application to the director of the United States Geological Survey. If the free supply has been exhausted, they can usually be secured at a nominal price from the superintendent of documents, Government printing office, Washington, D. C. The papers giving the stream measurements for each year are of particular importance since these records frequently cover long periods of time.

The relative stages of a stream are observed either from a rod or gage extending into the water at the lowest stage or a chain suspended from a fixed support on a bridge and lowered until it touches the surface of the water. That part of the chain extending above the point of support is measured by laying it out horizontally on a fixed scale. The chain is of known length and will reach from the point of support to a point in the stream below the low-water level. Gage heights determined by a chain are subject to a slight error in a high wind or a stream having a high velocity. At times of different river stages, the flow of the stream is determined by a current meter and from these data the discharge curve for the stream is determined. Reference to the curve or its equivalent in the form of a table will disclose the flow of the stream for any gage height and these gage readings are usually reported daily.

Such data furnish the basis for tables showing the maximum, minimum and average flow of a stream in cubic feet per second for each month, the rate of flow per square mile of the drainage area and the runoff in inches. There are various ways for arriving at the amount of power available from these figures. In a report of the Government engineers on "The Relation of the Southern Appalachian Mountains to the Development of Water Power," it is stated that it pays to develop water power up to the minimum during the four high months of the year. Another rough approximation in use is to take the average monthly minimum for an average year. In the New England States, it is said, the rule is to take the minimum for the third driest month starting with the driest month for an average year.

The flow of streams as determined from these publications on "stream measurements," is subject to inaccuracies due to error in the gage reading and incorrect data for the discharge tables owing to a possible variation in the contour of the river bed at the point of measurement after the rate of flow has been determined. The results, however, are valuable for preliminary investigations.

In cases where such data are not available a general idea of the real conditions of flow can be arrived at by a careful study of the relation of rainfall to runoff. The section director of the United States weather bureau can supply statistics on the rainfall in the drainage area of the stream to be investigated which, together with the ratio of runoff to rainfall as determined for streams subject to similar climatic and topographic conditions, will give the average rate of flow for the year. The minimum and maximum, similarly, can be estimated.

Each section of the weather bureau publishes an annual climatological report giving the precipitation per month for the year at various stations and its departure from the normal as deduced from records covering a considerable length of time. By plotting in the form of a curve the normal precipitation, the average time and duration of dry and flood periods are evident.

In some cases the Government has made surveys of rivers and these show the amount of fall available. The contour of the watershed is shown on topographic maps for certain sections of the country. The United States Geological Survey has been engaged since its organization in making a topographic map of the United States and the parts covered from time to time are noted on index maps. The topographic maps or "Atlas Sheets" are of uniform size and drawn on a scale of one or two miles per inch. The contour intervals may be as low as five feet.

The amount of information secured by the Government and available to the public should be sufficient to define to a limited extent the possibilities of a proposed hydroelectric development.

Boiler Explosion at Copperhill, Tennessee

By George L. Fales

The right-hand drum of one of the four National water-tube boilers at the plant of the Tennessee Copper Company exploded on the morning of June 1, at 12:50 o'clock, causing a property damage of some $5000, but there were no personal injuries. The boiler on which the drum exploded was insured with the Maryland Casualty Company, of Baltimore, which allowed a pressure of 175 pounds per square inch. The boilers are about ten years old, and have seen constant service all that time, but are in excellent condition, being clean and free from scale, although the tubes are getting thin. Each boiler has two drums 36 inches in diameter by 17 feet long and 120 four-inch tubes; the headers are of the box type holding six tubes each.

As shown in Fig. 1 the rupture occurred in the solid sheet along side of the longitudinal seam of the middle course on the right-hand drum of No. 2 boiler. An examination of the rupture immediately after the explosion disclosed the fact that the sheet had been developing a crack for some time, as the metal part way through the sheet was old and rusty, and the remainder showed a clean fracture; the crack in places extended nearly through the sheet, and other places had from 1/8 to 1/4 inch of good metal. The only part of the sheet that appears to have been sound clear through is the part showed in Fig. 3, at the hight-hand corner. The crack was a little under the overlapping part of the seam, and it would have been almost impossible to detect it by internal or external inspecetion.

The drums were constructed of 3/8-inch steel plate, with 7/8-inch rivets 15/16 inch when driven, pitched 2 3/4 inches on the longitudinal seam and 2 inches on the girth seam. The rivets in the longitudinal seam were not disturbed at all, being tight, and the seam in good condition; the rivets in the girth seams were sheared off, as shown in Fig. 1, in some places, and the sheet gave way in others. The explosion carried away all the wooden part of the boiler-room roof and blew all the windows, sashes and all, out of the building. Practically all the piping over the National boilers was blown off, flanges and valves breaking off and letting the pipe free. No

VIEWS OF DAMAGE DONE BY BOILER EXPLOSION AT COPPERHILL, TENN.

FIG. 302. LARGE DIRECT-CONNECTED GENERATOR BUILT BY THE CROCKER-WHEELER COMPANY

ersonal injuries resulted, as the firemen nd other employees happened to be at the ther end of the boiler room near the Aultman & Taylor boilers, which were lso in service when the explosion occurred.

As soon as possible after the explosion he boilers which were not damaged were ut apart from the damaged section and ut on what good steam lines were left. The plant was in normal operation again ten hours from the time the explosion occurred, and measures were taken to ontinue its operation by repairing such amage as was immediately necessary.

Fig. 1 shows the exploded drum and sheet; Fig. 2 the damage above the boilers to the piping and roof, etc.; Fig. 3 hows a closer view of the ruptured sheet, lso the piece of sheet at the right hand hat had good metal all the way through it; Figs. 4 and 5 show views taken from bove the roof looking down on the oilers and piping from two different directions; Fig. 6 is a view taken from in ront of the boilers looking up, but does ot show much of the damage owing to the ight streaming through the roof.

At the time of the explosion the boilers were carrying steam at 160 pounds gage, and had 1½ gages of water in them. The oilers are inspected internally by the Maryland Casualty Company's inspectors very six months. The accident illustrates once more that the lap-riveted seam is dangerous, and emphasizes the fact that the butt-strap seam is none too good for joints of this character.

Catechism of Electricity

1071. *Illustrate and describe a large-size direct-current generator built for direct connection with the prime mover.*

Fig. 302 shows a generator of this kind built to give 600 kilowatts at 250 volts when run at a speed of 80 revolutions per minute.

The magnet frame *a* is of cast iron and is split horizontally, the two halves being aligned by dowel pins and held together by bolts *j*, *j*, etc. The lower half of the field-magnet frame is provided with feet drilled to receive the holding-down bolts and provided with leveling screws for adjusting the position of the magnet frame. The poles are of steel cast welded into the frame. Each pole is fitted with a cast-iron removable shoe *t*, which distributes the magnetic flux over the armature surface and serves also to retain the magnet coils in position. The air gap or clearance between the armature and pole faces is relatively large to reduce the bad effects resulting from a slight displacement of the armature from its true center.

The machine is compound wound and the magnet coils are separated from each other and the frame by spacers *n*, to provide free circulation of air between and around the coils. The series coils are wound of copper strip, connections between them being made by interleaving the multiple strips.

The arms *d*, attached to the hub *k*, support the toothed laminations of steel which form the armature core, and there are ventilating ducts in the core and end flanges. The armature conductors consist of flat copper ribbon, heavily insulated and retained in the slots by means of wedges. The commutator spider *h* is mounted on an extension of the armature spider and is therefore independent of the shaft *l*. A sectional clamping ring *r* permits removing a few bars of the commutator without disturbing the others.

The cast-iron rocker *s* is rigidly supported at *w*, *w*, from the magnet frame and has a tangential screw and hand wheel *w* for shifting simultaneously the position of all brushes. Each set of brushholders is supported on a bracket *o* clamped to the rocker ring and insulated from it. All the positive brush holders are connected to a copper bus-ring *u* mounted on one side of the rocker ring, and all the negative brush holders are similarly connected to a similar ring *v* on the other side of the rocker ring.

The Absorption Refrigerating Machine

The Different Parts and Their Functions Explained in a Simple Manner, with Practical Advice as to Its Care and Operation

BY W. E. CRANE

The absorption refrigerating machine is thought by many to be complicated and, therefore, it does not get the credit its merits deserve. When run by steam from the boiler it is simply a condenser, the heat being taken up by the machine and the resulting condensation going back into the boiler at the temperature it leaves the machine; while with the compression machine there is the loss of the exhaust steam, as with any engine.

About ten years ago a hotel proprietor wanted to put in a refrigeration plant and the writer introduced him to a refrigerating engineer. The hotel man had high-speed engines and lots of exhaust steam, but no excess boiler power nor room for more, and he wanted to do his refrigeration with exhaust steam. The engineer explained the relations of the temperatures to each other and showed by figures that it would never be possible to do the work with less than 65 pounds steam pressure. On our way home the hotel man said:

"I believe I can do it with exhaust steam."

Taking the proposition to absorption-machine builders they told him the same story the engineer did, and but one of them would consider the proposition, and then only on condition that the purchaser should be responsible for any failure. The machine was built and worked all right, at atmospheric pressure, on the exhaust, and since then many machines have been built along that line.

The action of the absorption machine is that of a double cycle (and more) and is apt to make a novice, or even a man skilled on a compression machine, nervous.

How It Is Done

Refrigeration is caused by the heat absorbed by expansion. If air is compressed it is heated. Cooling it under pressure and then expanding, or relieving the pressure, the air will absorb, or take up heat, either from surrounding objects or itself, and thus grow intensely cold, as can be seen in winter when using compressed air in drills, etc., the moisture in the air freezing. It is not of sufficient density to take up enough heat to be commercially useful and recourse is had to elements that liquefy under pressure.

Carbonic acid is one of these, but it requires a pressure of from 1200 to 1500 pounds, at which pressure, and cooled, it becomes a liquid. When expanded to 200 pounds it again becomes a gas and the heat expended in changing it from a liquid to a gas will change anything near it to a very low temperature.

Carbonic acid is odorless and is used in many places where odors are objectionable, as on shipboard. The objection to it is the exceeding high pressure necessary to liquefy it. It being odorless and no test being able to detect leaks, it is necessary to perfume it when looking for leaks. Wintergreen is one odor used and camphor is another. To use camphor dilute it with alcohol, put it into the system and the odor will be detected readily and at the leak there will appear a whitish substance.

Ammonia is the most-used medium in refrigerating systems. It will liquefy at 70 pounds, and at atmospheric pressure will boil at 29 degrees below zero. In a refrigerating system the ammonia under pressure is conveyed through the condenser, in which it comes in contact with coils of running water, is cooled and be-

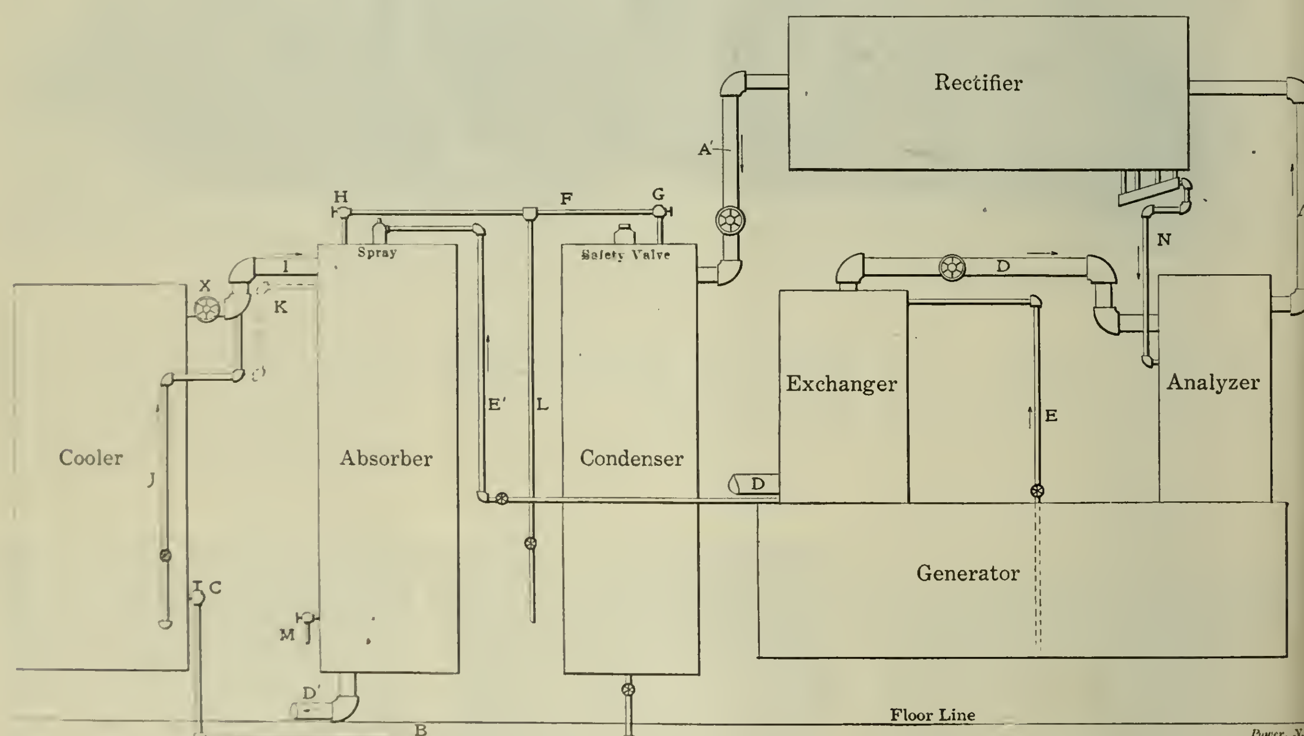

FIG. I. LAYOUT OF ABSORPTION SYSTEM

comes liquid and then passes to the cooler which contains the brine coils. It here passes through an expansion valve. This is a needle valve capable of very fine adjustment.

This valve being opened slightly, a fine stream of the liquid ammonia is injected into the cooler and, being at such pressure that it boils, it is soon turned into gas. This requires heat, and the changing to the gaseous state means that it becomes a valuable refrigerant.

In the compression machine the gas from the cooler must be kept at a sufficient pressure to cause it to fill the compression cylinder quickly, and it does not liquefy as quickly as in the absorption machine, where the cooler can be kept at atmospheric pressure and lower temperatures are obtained. For very low temperatures the absorption machine is the better.

The Machine Itself

In the compression machine only anhydrous, or pure, ammonia is used. In the absorption machine aqua ammonia is used and the anhydrous ammonia is distilled in a generator, a vessel containing steam coils.

Let us call the anhydrous ammonia "gas," and the aqua ammonia "liquor;" there being rich liquor and poor liquor. The gas, as it is distilled, goes up through the analyzer, a vessel filled with pans, through the pipe *A*, Fig. 1, to the rectifier. This is a vessel similar to a separator in a steam line; it dries out the moisture, or separates it, so that the gas goes to the condenser in a dry state, the moisture returning to the generator through the pipe *N*. (The water pipes and connections are not shown, in order to render the ammonia pipes clearer.)

For cooling, the water goes through the condenser, then the absorber and, last, the rectifier. From the rectifier the gas goes to the condenser, having been partially cooled in the rectifier. Here it is liquefied and passes through the small pipe *B* to the cooler, where it is changed back into gas.

Water has a great affinity for ammonia, and the colder it is the greater its attraction; cold water cannot be used, however, but a poor liquor will still have attraction for more ammonia if it is cool.

When the gas in the generator has been distilled it leaves the aqua weak, especially at the bottom, and this weak liquor is forced up through the pipe *E*, through the exchanger and through the pipe *E'* to the top of the absorber, where it is thrown over the incoming gas and the water coils in a spray, by means of a valve for that purpose at the top.

The gas in the cooler, passing up through the brine coils, is drawn into the absorber through the pipe *I*. This pipe should reach the center of the absorber and turn down, as if zero brine is carried the gas will be considerably below zero, and should it strike forcibly against the water coils, it might freeze them.

In the absorber the weak liquor absorbs the gas and it then becomes rich liquor and passes out at the bottom through the pipe *D'* to the ammonia pump, and from there to the exchanger through pipe *D*, whence it goes to the analyzer on its way to the generator.

The exchanger is the same as a heater for a boiler. The cold, rich liquor going to the generator meets the hot, poor liquor coming from it on its way to the absorber and they exchange heat, one being in the shell and the other in a coil. The hot, rich liquor, in passing over the pans in the analyzer, gives up any gas that may be found and this passes out through the gas pipe *A*.

On the generator, condenser, absorber and cooler are glass gages. It is a good idea to keep that on the generator closed except when the level of the ammonia is to be read. The gage on the cooler has to be kept closed, or it would become covered with frost; when used the valves have to be opened very slightly and even then not much can be told, as the ammonia in the cooler is pretty lively stuff. The gages on the condenser and absorber may be left open.

On top of the condenser and absorber is a crossover pipe *F*. The valve *G* is left closed and the valve *H* open. The pressure gage from the absorber is taken from this pipe. The vertical pipe *L* is for purging.

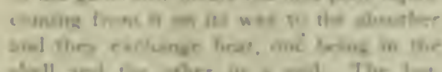

Fig. 2

The important features of the absorption machine are the expansion valve, the absorber and the strength of the liquor. The expansion valve should be handled very carefully, as it is delicate and will not bear rough usage. A monkey wrench should never be put on it. For small ammonia valves a wrench like that shown in Fig. 2 may be used judiciously, the handles to be not more than 4 inches long.

The expansion valve may be likened to a throttle valve on a full-stroke engine. If opened wide or more than is necessary to operate the machine a little above its capacity, it will draw on the generator as a wide-open pipe will draw on a boiler and it will take from the generator more liquor than can be separated in the rectifier; and when it passes the rectifier it must go through into the cooler. As this liquor cannot evaporate at that temperature, it will plug up the cooler. This is termed a "foul-over."

To get rid of this liquor, in the machine shown, it will be necessary to take it out from the bottom of the cooler through the purge pipe *J*.

The usual practice is to shut the gas valve *K* at the top of the cooler and, there being slightly more pressure in the cooler than in the absorber, the liquor will be forced over and can then be pumped back into the generator, afterward using greater care. With good care, even, dead liquor will collect in the bottom of the cooler after a time and must be taken out in the same way.

Now, shutting off the gas valve also necessitates shutting off the expansion valve and the machine stops working, with the consequent raising of temperatures. Also, when the machine is purged and the gas and expansion valves are opened, 10 or 12 degrees in temperature will be lost, as it will be an hour or more before the machine gets to work reducing temperatures again, and if there is still bad liquor in the condenser to come over, the machine will want purging again soon, with another rise in temperature.

Should the cooler need purging, leave the gas valve *K* open, and in some cases the expansion valve, and open the purge valve. Usually purging will start right away but, after a time, stop. Should this happen, close the purge valve for a few minutes and then open it.

It will take longer to purge by this method, but the machine will not lose the temperature, and after part of the cleaning is done the temperature will go down, and sometimes 1 or 2 degrees is gained during the purging. Refrigerating men will tell you not to do purging this way, but the engineer is interested in keeping his temperature down.

The condition of the frost on the purge pipe will indicate the stuff going over. If it is a sort of black frost and a wet finger does not freeze to the pipe, it is dead liquor. If the frost turns white and a wet finger freezes to the pipe, it is good liquid ammonia or gas and can be shut off.

When the liquid ammonia flows through the expansion valve it does not all vaporize at once, but some of it falls to the bottom of the cooler as a liquid and evaporates later. There should be an amount of this in the cooler all the time for the cooler to work on, the amount being indicated by the frost on the glass gage fittings; some coolers work best with only the bottom fitting frosted and others require both top and bottom to be frosted. Some require the bottom frosted in winter and both in summer. Only a trial on the particular machine can determine this point.

For purging, I have put in a pipe from the ell on the purge pipe *J* and connected it to the pipe *D'* between the absorber and the pump, and if there is a large amount of liquor in the cooler, I should open the valve in this pipe. It should be a globe valve so as to be readily regulated, and take the stuff direct to the pump. From one-quarter to one-half turn is sufficient, for if much ammonia goes through it will render the pump gas-bound and stop its pumping, as the ammonia pump will not work if the liquor gets too rich.

Instead of connecting the purge pipe *J* to the gas pipe *I*, as shown, and as is the custom, I should connect it as shown by the dotted line *K*, being careful to carry it inside and turn it downward in the center, as was done with the pipe *I*. Connected in this way the purging would be faster with the gas valve open.

Should the ammonia pump stop working from gas accumulation, place one man to watch the absorber pressure gage and slowly open the valve *G* at the top of the condenser until the pressure in the absorber gets up to 50 or 60 pounds, where it should be held until the pump starts working. Before doing this it would be necessary to close the gas valve *X*, opening it again after the pump starts. The expansion valve should never be opened above one-quarter of a turn, and then only to put extra ammonia into the cooler. With low pressure it will usually run with a turn of the rim of from 1/4 to 1/2 inch; at high pressure it will frequently leak enough to keep the cooler all right when apparently closed tight.

Never try to force an absorption machine, as it only results in partial or severe "boil-overs" and other trouble. For a short time I had a man who claimed that a machine has to be forced to keep up its work, and he would run with the expansion valve open a half turn and for a short time run the temperature down to 2 to 3 degrees per hour; then his cooler would be filled up and the shutdown for purging would follow, with the rise in temperature; and while he was supposed to keep the brine at zero, it would fluctuate from zero to 15 degrees above, he keeping at work ,all the time.

One should not expect the temperature to go down more than 1 to 2 degrees per hour. With the expansion valve opened just enough to maintain the temperature and the speed of the ammonia-pump set, the machine may not have to be touched for two or three days, and there is nothing to do but keep the log.

The Absorber

The efficiency of the machine depends upon the condition of the absorber. If the absorber is cool and free from air or poor gas, the cooler will give off its gas with ease. As long as the water and absorber are cool it is difficult to tell about the spray at the top.

This spray device is simply a valve with three oblique holes. If one side of the absorber gets warmer than the other, turn the valve slightly down, say one-eighth of a turn, and by a little manipulation the all-over temperature of the absorber can be maintained even. Sometimes a little scale or dirt will get over a hole and close so much of the valve.

This valve does not regulate the flow of the poor liquor, simply its distribution over the coils. The flow of the poor liquor is regulated by the valve near the exchanger, that at the generator being used only to shut off the poor liquor altogether. There should be only enough poor liquor thrown over to absorb the gas. More than this puts an extra load on the ammonia pump, exchanger and absorber. It is at this point that the expense of the absorption machine comes to be considered, as regards water, and also the capacity of the machine, all being limited by the amount of gas the absorber will take over from the cooler.

There is a great deal said about the relative temperatures, due to that of the water, and the pressure that should be carried on the generator. These points should be known when laying out and building the machine and determining the size of the condensing and generating coils; but when the engineer has a machine on his hands he wants to know why.

The practical point is just here: When the absorber is cold the poor liquor within it will have a large absorbing power and take gas from the cooler all right, even if it is gas of medium high percentage; if it grows warmer, it will have less absorbing power and do less work.

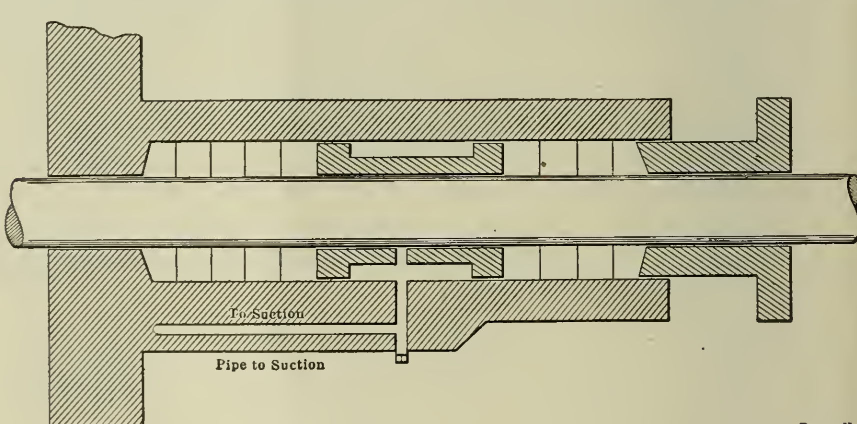

FIG. 3

If the temperature cannot be improved because of insufficient water or because of the high cost of the water, the liquor coming over must be made weaker, by turning more heat on the generator and distilling more of the gas over into the condenser, which will carry a large amount in storage. It will also be found that the cooler will need a little more gas under this condition. This weakens the whole charge in the generator, requiring higher heat in the coils and a higher pressure to distill the necessary gas from the weakened charge, and this is the reason a higher pressure has to be carried with a warm absorber.

With cooling water at or below 60 degrees, a low-pressure machine will run at atmospheric pressure; with water at 70 degrees, the steam pressure may have to be raised two or three pounds; and at 75 degrees it may have to be raised to 10 pounds. Some machines will require higher pressures, depending on the heating surface in the generator. With 60-degree temperature water the pressure in the generator may be from 90 to 100 pounds and at 75 degrees it will be necessary to carry it to 150 to 160 pounds. All these pressures are determined by the temperature of the absorber and whether coal or water costs the more.

If water can be obtained from driven or bored wells, an absorption machine can be run the year through with exhaust steam, and it will not act as a brake on the engine. Where there is lots of brine pumping by steam pumps it is possible to run a machine with the exhaust from the pumps.

It can be noticed at any time whether the absorber is taking hold well by the frost on the gas pipe *I*. If the frost continues white and keeps accumulating, the absorber is working uniformly; if the pipe begins to thaw, either the absorber has "let go," or the cooler has become foul.

At the bottom of the absorber is a valve *M*. The pipe from this should have a swivel joint so it may be swung into or out of a bucket. If there is air in the system it will usually be found at the bottom of the absorber and is to be drawn out through this valve. The valve should be opened occasionally to test the system for air. A clean machine ought to run from one to two months without trouble of this kind. To test it, get a bucket of cold water, and set it under the outlet to the pipe and open the valve from one-eighth to one-fourth turn. If air is present, bubbles will rise to the top of the water, nearly noiselessly. Should there be few bubbles, accompanied by a crackling sound, like water being heated with steam it indicates the presence of gas, showing that that part of the machine is all right.

When air bubbles are rising, if a match is held over the pail and a pale yellow flame results, it shows that there is some foul gas mixed with the air.

Half way up the absorber there is another purge pipe for drawing off foul gas. If this valve is slightly opened and the gas issuing therefrom is lighted and continues to burn of itself, it shows foul gas and the pipe should be turned into a pail of water until good gas comes, which can be told by the crackling sound. Do not make the mistake of holding a light under it only to light it. Ammonia gas will burn if a light is kept under it with a very similar flame. The pail of water tells the story.

The pipe *L* on the crossover pipe *F* can also be tested: The absorber should be pumped as low as possible without allowing gas to get in the pump, and the pressure should be kept as near a vacuum as possible. The pump should be kept at a uniform speed. The pressure in the cooler will be nearly the same as that in the absorber, as it is the absorber that governs the pressure. The makers' instructions will give the proper pressures to carry with relation to brine temperatures, but the poor fellow who has followed them and run up against the packing of a rich liquor rod under pressure will keep just as near a vacuum as possible and save packing, ammonia and the nervous system.

Every ammonia-liquor pump has, or should have, a long stuffing box and a thimble at the center of the box (see Fig. 3), with packing on both sides. This thimble should be central, as there is a recess in the thimble connecting, by a port, to the suction side of the pump and all leakage past the first packing goes back into the suction, the packing outside the thimble having to resist only the pressure on the absorber; but do not imagine that 5 pounds pressure on the rod of a rich-liquor pump is a simple thing, for it is the worst proposition in the packing line a man ever ran up against. Keep the pressure in the absorber as near vacuum as possible. The richness of the ammonia charge is determined by what the absorber will take care of.

There is no telling what the composition is after the machine starts, except by the operation of the machine. If you are running with exhaust and the absorber works all right, the rich liquor at the pump will show 26 degrees, but that only tells what it is at that point.

There should be sufficient anhydrous ammonia in the system for the cooler to have all it wants and allow the generator to keep a few inches in the condenser gage all the time, with the steam pressure down to the low point. This is with a cool absorber, and it is sometimes possible to have the liquor in a cool absorber so rich that the pump will not take it, the gas separating out in the pump, a condition which will be shown in the glass gage of the absorber, as when the pump lets go, the absorber fills up and the liquor in the glass will effervesce like soda water. The remedy is to weaken the charge by throwing more of the gas over into the condenser, as a reservoir, and start the pump by pressure from the condenser.

It will be necessary to have a little pressure on the absorber when purging at the valves *M*, etc.; just above atmosphere is all that is necessary. Never open these valves when there is a vacuum, as it would draw air in.

The Condenser

The gage on the condenser shows its condition. There should always be two or more inches in the glass. As the condensing water first passes through the condenser, and as the gas is cooled in the rectifier, there is not much trouble with the condenser. The liquid ammonia, if all right, will continue to effervesce. If it is quiet, like water, there is foul gas, which will collect at the top. In this case, shut the valve *H* at the top of the absorber and open the valve *G* at the top of the condenser. Then get a bucket of water and blow the pipe *L* into it. It will be impossible to do this without wasting some ammonia, and when the water is impregnated with ammonia, so as to be offensive, change it for more water. This may have to be done once or twice a day for two or three days.

When through purging each time, change the valves back again, as the absorber gage is on this line and during the time the pressure is on it the absorber gage will show condenser pressure. In one case the liquid pipe *E* at the bottom of the condenser became plugged, thus stopping the machine. Connection was made from the bottom of the glass gage to this pipe and the delay was short.

It is a difficult matter to get a safety valve that will be tight, so recourse is had to extending the casing and putting in a blank of sheet lead that will let go at the pressure that the safety valve is set for. When this happens, put in another blank.

The Generator

The coils for steam in the generator go in it about the center and return near the bottom. When starting up a generator cold, do so easily, taking plenty of time. If possible, the better plan is to turn steam on at the bottom and let it work its way upward. If it is a large machine with a flange joint in the center, by turning steam on strong at the top, the top will be heated and expand and spring the joint at the bottom. Should this occur, stop the heat and let it cool. Take off one nut at a time, oil it and put it back and pull it up tight. This may stop it once or twice, only do not hurry the heating of the generator.

As soon as there is sufficient pressure to raise the liquor over through the weak-liquor pipe *D*, open the valve and when the liquor shows in the absorber start the pump. This sets up a circulation in the generator and the danger is over. When the pressure is shown to be sufficient to liquefy the gas, which will be at 70 pounds, and it does not show in the gage in the condenser, open the expansion valve slightly so as to start circulation. The top of the steam coils are about at the center of the generator.

It is a good plan to make a gage from a pine strip marked in inches and half inches and fasten it to the gage fittings, with a mark showing the top of the coils. The charge in the generator should always be kept above the coils and usually near the top of the generator. This level will change, depending on the gas in the condenser and cooler and the liquor in the absorber. Sometimes, purging the cooler will raise the level in the generator 4 or 5 inches. When a lot of the anhydrous ammonia is sent over into the condenser the level will be changed.

If there is no leakage around the ammonia pump, all loss will be of anhydrous ammonia and it must be replenished with the same. Should there be leakage of liquor it can be replenished with aqua ammonia, or with water and anhydrous ammonia. If water is used, it should be pure, distilled water, as impure water would cause foul gases.

The troubles caused by allowing the charge to get below the generating coils are two: If allowed for more than a short time the ammonia will corrode the pipes, and the hot pipes in the gas will decompose the gas. This will be shown up around the cooler, the frost everywhere being excessively heavy, as though everything was frozen up, and the gage on the absorber will show about as good vacuum as a condensing engine. The temperature of the brine will be high, as that is the only thing that does not show any low temperature. The only remedy is a good charge of anhydrous ammonia and purging out the bad gas.

Rectifier

The rectifier is for drying out the gas and should be run cool enough to chill off the moisture but not cool enough to liquefy the gas, or any portion of it, as it would drain back into the generator and have to be distilled again. The last passage of water is through this vessel and there is a bypass around it for the water so that the temperature can be regulated. There are thermometers for the rectifier and water leaving it.

If considerable water is used because of the absorber, a large amount will go through the bypass. If water is economized and the absorber is active, all of it may go through the rectifier. The thermometer should not register above 110 degrees. The drain pipe *N* should feel warm to the hand.

Dirty Coils

The condenser and absorber coils are liable to the same trouble where the water becomes warm and the flow stopped. Corrosion, in the form of "barnacles," sets in and the pipes gradually become filled. [illegible] top and bottom and each coil has a valve at both ends.

There should be an air compressor on the premises capable of maintaining a pressure of 80 pounds through an open 3/4-inch pipe. The headers should be connected to the air line, and also to a water pressure, with 1/2-inch pipe; the feed line will do.

Once a week the ammonia should be shut off, or, rather, the machine should be stopped and the water drawn from the coils, the bottom valves closed and air turned on. There should be a valve for the bottom header, in the bottom of the flange, which should be opened and then the valves on the coils should be opened separately and the air allowed to blow through. The deposit will be soft and will easily clear out. After air has blown through, turn on the water in the same manner and wash the coils out. While the machine is idle, the brine temperature may have gone up one or two degrees, but it will readily come down again.

If the coils are badly coated the machine will have to be stopped for two or three days. The ammonia will have to be drawn from the condenser and absorber, as if warmed up the expansion would cause too much pressure. In drawing off the ammonia be careful not to reduce it too low all at once, or the freezing effect will be so great as to freeze the water coils.

Have prepared a sufficient quantity of a strong potash solution, draw the water from the coils, fill them with potash and let it stand for twenty-four hours, or longer if the machine can be spared. When the potash is drawn off, turn on the water from the small cleaning pipe and fill the coils. Close the valve to within one-half turn and turn on the air. Open one valve at the bottom of the coil header and keep it open until the water runs clear, then close that one and open another. After all have been blown, begin with the first and go over them again. They may require four or five blowings out before they will be clean.

When air and water issue from a pipe together, it will be noticed that it issues with a series of explosions, which appear to take place all through the coil and may be thought to do the cleaning, but this method has little effect without the potash. Water at from 125 to 150 degrees appears to do better work than cold water, as the vapor from the warm water makes the explosions stronger.

The gages should be looked at occasionally to see if pressure is being generated, and it is the better plan to cool the generator than to shut off the condenser, as there is no pressure gage on the condenser unless the valve *H* at the top of the absorber is closed and the valve *G* is opened, thus using the absorber gage for the condenser. Do not forget to change back again, however.

Weak-liquor Pipe

In regard to the weak-liquor pipe, it should be remembered that as the pressure in the generator is carried higher the flow through this line is increased unless throttled.

Brine

For brine, chloride of calcium should be used instead of chloride of sodium, because it cleans the pipes better, prevents corrosion and will carry lower temperatures. Care should be taken to get the purest, but even with this there is a sludge that will stop circulation in small pipes, and sometimes good-sized pipes are bothered. Place a steam pipe in the tank for dissolving purposes and do not fill the tank full of water after the calcium is placed in it. When the mixing tank is charged, turn on steam until tank is boils, then close the steam valve. Skim off the scum that rises. It will be necessary to wait until the brine cools before pumping into the system or it would raise temperatures. The skimming can be done without heating, but not as much of the impurities will rise as by heating, and not much time is gained, as the dissolving is so much slower. Heating saves lots of cleaning later, also.

Danger in Ammonia Fumes

In case of accident, ammonia is a bad thing, as it takes but a small amount to overcome a person. Acetic acid is an antidote and is found in ordinary vinegar. A sponge soaked in vinegar and put over the nose will enable anyone to work in a strongly impregnated atmosphere, as far as breathing is concerned, but the eyes would not be protected. To work under such conditions it is necessary to wear a helmet, which should be kept charged at all times at 125 pounds pressure and regulated so that it will take one-half hour to reduce the pressure to 25 pounds.

Should anyone be in danger of suffocation, breathing the fumes from vinegar will neutralize it. Drinking warm milk will relieve a person partly suffocated from ammonia or any gas.

Workers around ammonia should not forget the strong affinity it has for water and the absorbing power of water. When there is a small leak of even the gas under pressure, a piece of water-soaked waste put over it will remove all trouble until the water is thoroughly saturated with it.

It is a good idea to practice using water for even unimportant leaks so as to be accustomed to it. A 1-inch hose and a 2½-inch hose under water pressure should always be handy, as by their use a big leak could be drowned; and these would be thought of instantly if one were accustomed to the use of water to take care of ammonia fumes.

Detecting Leaks

There are various devices for detecting leaks, but the best is white litmus paper. This can be procured free from the dealer in ammonia. Take a strip ¼ inch wide and about 1½ inches long. With a thread, tie it onto a small stick 15 to 18 inches long. When using it, moisten it in water and hold it to the suspected place. If there is a leak the paper will turn red and the shade of red will show how strong the leak is. Litmus paper will detect leaks that cannot be smelled. Turn it away from the leak into pure air and it again becomes white. It can be used until completely worn out, all that is necessary, when using it, being to moisten it.

Fittings

For putting screwed fittings together, or for material to put on flanges, use litharge and glycerin; for sheet packing, use pure rubber. Do not get fittings intended simply to receive the pipe that is to be screwed into them; get special ammonia extra-heavy fittings, either with a stuffing box at each end of the fitting, in which rubber packing should be used or fittings with a lead ring in each outlet and with provision to put in shot and allow a plug to be screwed in the top to force the shot down on the pipe.

Care and Management of the Water-tube Boiler

By William Kavanagh

Water-tube boilers having straight tubes may be divided in two classes, those that employ ground plugs or caps for closing the holes through which the tubes are inserted and cleaned, and those in which small handhole and circular plates fitted with rubber or asbestos gaskets are used for the same purpose as the ground plugs or caps. The Babcock & Wilcox and Root boilers employ caps with ground joints or surfaces to close the tube openings in the headers, while the Heine and Oil City boilers use handhole and circular plates on which are placed asbestos or rubber gaskets to form a water- and steam-tight joint. Fig. 1 illustrates the method of closing the hole in the tube header of the Babcock & Wilcox boiler. Fig. 2 shows the method adopted by the Heine boiler builders for closing the tube connection in the header or water leg, a gasket being used, as shown at *A*, to insure a water-tight joint.

Fig. 3 is a longitudinal elevation of the Babcock & Wilcox boiler showing doors *D* located in and connecting with the different chambers, the object of the doors being to afford access to these chambers for the purpose of cleaning and blowing the dust off the tubes, for removal of ashes and for repairs to the deflecting arches, walls, etc. Fig. 4 is a view of the Heine boiler and the cleaning doors *D* are for the same purpose as the doors in the Babcock & Wilcox boiler.

When blowing the dust off and from between the water tubes and around the drum two nozzles, shaped as in Figs. 5 and 6, should be used. The straight nozzle may be used in blowing the dust off the tubes in a horizontal and crosswise direction, while the bent nozzle can be used for blowing the dust off the tubes in an upward and downward direction, and also from the bottom of the drum. Both nozzles can be used while steam is on the boiler, and they may be lengthened by adding a piece of pipe or steam hose, thus affording access to parts remote from the cleaning doors.

Wrong and Right Ways to Shut a Boiler Down

A boiler properly shut down is easily cleaned; if improperly shut down, it means long, tedious and unnecessary labor to overcome mistakes that should not occur. The wrong way to shut a boiler down is to haul the fire, blow the boiler down and allow it to cool as rapidly as possible. This method requires plenty of labor after the boiler is opened to scrape and clean off the hard-baked scale and mud that would otherwise be carried off through the blowoff if the boiler was properly shut down.

The right way to shut a boiler down is first to see that there is the usual amount of water in the boiler before hauling the fire. Good results are obtained by not hauling the fire, but allowing the fire to cool in unison with the boiler, the water and surrounding brickwork. Second, close everything that may have a tendency to admit cold air through the tubes and around the drum; let everything cool together, and when the boiler is opened for cleaning a strong stream of water will wash off all the scale and mud that did not run out when the blowoff was opened. In nearly every case when a boiler is shut down in this way the scale remains soft and is easily removed.

FIG. 1

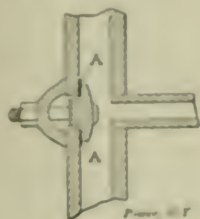

FIG. 2

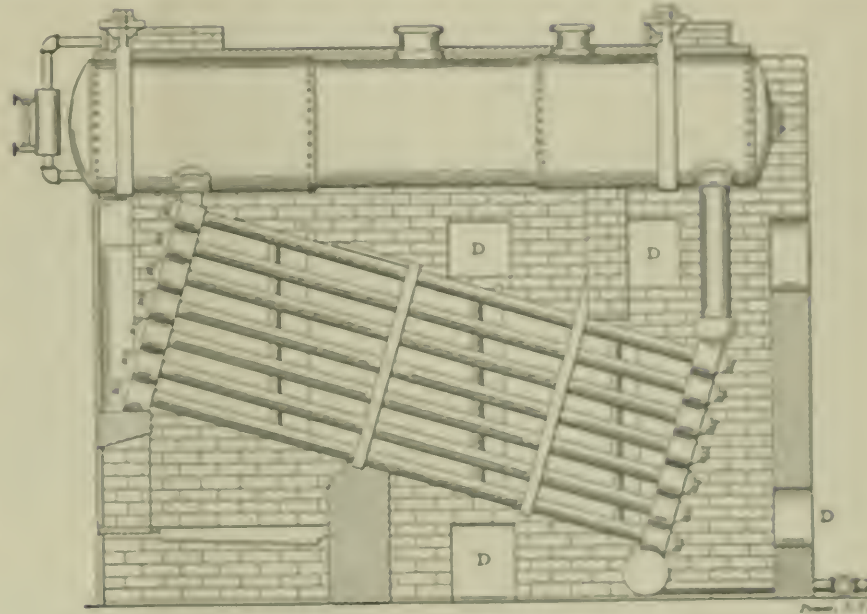

FIG. 7

FIG. [illegible]

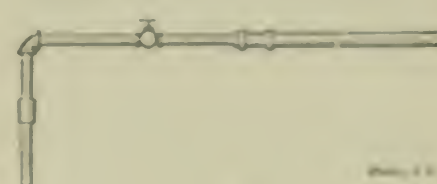

FIG. [illegible]

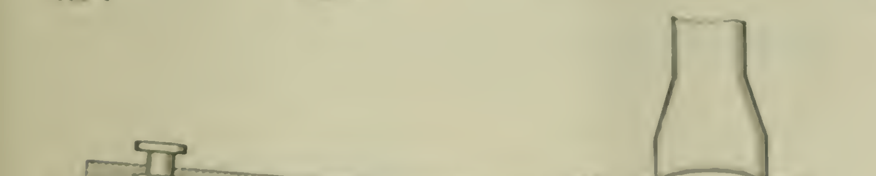

FIG. [illegible]

Another great mistake usually made in cleaning water-tube boilers is to open all the tubes. This is unnecessary. Where there is an open heater, and filtered water, or water not impregnated with scale-making properties, water that might be called good "steaming water," is used, it will be found that the opening of the "fire row" and one or two rows above the fire row will generally be sufficient to ensure a good job.

The cleaning of the caps with the Babcock & Wilcox type of boiler requires time, especially when all the caps are removed. Engineers acquainted with this type of boiler adopt various methods to clean the caps. Some scrape off the scale from the caps, others immerse the caps in kerosene oil and when the scale becomes soft, it is easily removed, leaving the ground joint intact. In some cases, however, it becomes necessary to use emery cloth in which case a fine grade of emery cloth should be used. By attaching it to a buffing wheel and revolving the wheel about 500 times per minute a quick job can be done on the caps. Sometimes it becomes necessary to apply emery cloth to the ground surfaces on the headers. A quick way to polish these surfaces is to make a wooden buffer or cleaner, as shown in Fig. 7, to fit the opening in the headers, and by attaching some fine emery cloth to the disk at *A* and inserting the plug *P* in the opening, the whole can be rotated by means of a carpenter's or similar brace; by placing the plug *P* in the tube opening, the plug acts as a guide and insures an equal amount of wear on all of the polished surfaces, which cannot be obtained if the emery cloth is used by hand. In this way all of the headers that are to be cleaned can each receive a polishing in a very short time.

Straight Water Tubes Easily Cleaned

The water tubes in this type of boiler are straight and are more easily cleaned than curved tubes. A turbine tube cleaner is attached to a hose. A stream of water flows through the hose, rotating the turbine at a high velocity. The rotative speed throws out cutters or scrapers (by centrifugal action) against the interior of the water tube, and by feeding the turbine and hose into each tube the scale is partially or wholly removed, depending on the thickness and density of the scale. Sometimes it will be found necessary to make more than one trip with the turbine through a tube, but in general one trip is sufficient, provided the scale is not too heavy and the cutters on the turbine are sharp.

In replacing the caps particular attention should be given to the cleanliness of the ground surfaces, and the mistake should not be made of plastering over these surfaces with a heavy coating of graphite and oil. Metal to metal insures the best joint. If graphite is used it should be used very sparingly. When the caps are in position it is an excellent idea to test them for tightness by pumping a water pressure equal to the steam pressure carried in daily operation. If any cap leaks and it cannot be made tight with an ordinary pull on the cap wrench, then the water should be lowered below the leaking cap, the cap taken off and the surface thoroughly cleaned before again putting the cap on. Sometimes it is necessary to change a cap and even do a little grinding before making a tight joint. After the caps are all in position the boiler should, if possible, be filled with warm water and allowed to remain so for at least twenty-four hours, when the blowoff can be opened and the water lowered to its regular hight, when steam can be raised as slowly as possible. After steam is raised it will be found a first-rate idea to go all over the caps with the wrench and try out the nuts for tightness. In most cases after steam is up and the boiler hot, half a turn and sometimes more can be given each nut. If this is not done, when the boiler cools there is sure to be a leaky header or cap. All that has been written about the Babcock & Wilcox boiler is equally applicable to the Heine boiler, with the exception of the caps. With the Heine boiler small handhole and tubehole plates and gaskets are used to close the tube connections, instead of ground joints. When inserting these plates care must be taken to see there are no lumps on either surface of the plate, header or water leg. The tubehole plates are round and cannot be placed in position like handhole plates, therefore the tubehole plates are first entered through a handhole opening and then zigzagged into place. A better plan than this is to use a string having a small weight attached to one end. By dropping the weighted end through a hole ready to receive a plate, the plate can be fastened to the string and by pulling on the string the plate can be hauled into place quickly.

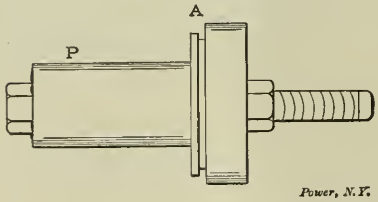

FIG. 7

When using this plan one should begin at or with the highest row first and then work downward until the handhole row is reached, when this row can be closed in the usual manner.

Inspecting the Water-tube Boiler

While inside the drum, the feed pipe, dry pipe and drum blowoff should receive attention. If there is a mud catcher attached to the feed pipe it should be cleaned out, and the blow-down cocks can receive new lining, if necessary. Water-column connections should be looked after and the drum inspected for corrosion along the water line. The portion of the tubes lying directly over the fire should receive particular attention, as these tubes become flat on their sides from the action of the heated gases and draft. They should receive the hammer test and all weakened tubes should be discarded. The neck or connection between the water leg and drum should be inspected for corrosion and leakage, and the point where the tubes enter the water leg should receive the hammer test. The deflecting arches and walls should be inspected, because waste of fuel can occur if the heat is not properly dispersed among the tubes.

Marking Valves of Refrigerating System

By Lewis C. Reynolds

It is quite usual to find the valves in a power plant marked in their running position so that the operator may know how to set them for certain conditions. The rheostats and voltage regulators will have a pencil mark on the marble panel, the valves have a chisel mark on nut and stem and probably the boiler-feed valves have a string tied on the wheel corresponding to some stationary point. Each man operating has his own mark or perhaps several relating to a different set of conditions. In a refrigerating plant with its numerous valves requiring at times the most exact adjustments some scheme of marking becomes absolutely necessary and can be accomplished by a system of dials with pointers which will intelligently indicate valve positions without disfiguring the valves.

Provide a disk of sheet brass say, 1/16 inch thick and 6 inches in diameter, for a 1-inch valve; divide the outside edge into a suitable number of divisions depending on the fineness of adjustment desired, and stamp each division with a figure punch, or if graduated close, at intervals, so that the figures will not become confusing. Attach the dial to a small brass collar which is secured to the valve stem by a small setscrew. The marking of the dial can best be done by fastening the disk to a wooden block attached to the faceplate of a lathe, and moving the carriage with a pointed tool across the disk so as to take a light cut. The spacing can be done by placing a suitable gear on the spindle and moving the faceplate after each cut until the next tooth comes in line. Set the dial on the valve stem so that the pointer will be at zero when the valve is closed. If the valve is opened more than one turn, it will be necessary to count them and read the fraction of a turn directly from the dial.

This device has proved of great advantage in operating a refrigerating plant. It has been placed on the expansion and weak liquor valves, also the steam valves to the retort pump and the condensing water valves. Any change made in their position is noted on the log sheet and also the reason for the change. A monthly memorandum sheet is ruled up with the first column for the day of month, the second column for the hour of day and the following columns for the different valves. Once each day a reading of the valve position is taken and the time noted. This is filed for future reference, and comparisons of valve positions can be made for different months and years. The men in the station become accustomed to referring to the valve positions by number, and the engineer when visiting the plant can tell at a glance if any changes have been made.

WE PAY FOR USEFUL IDEAS

An Original Remote Control System

Recently an engineer was called upon to devise an economical method of controlling a direct-current 220 volt, 3 horsepower pump motor from his still room.

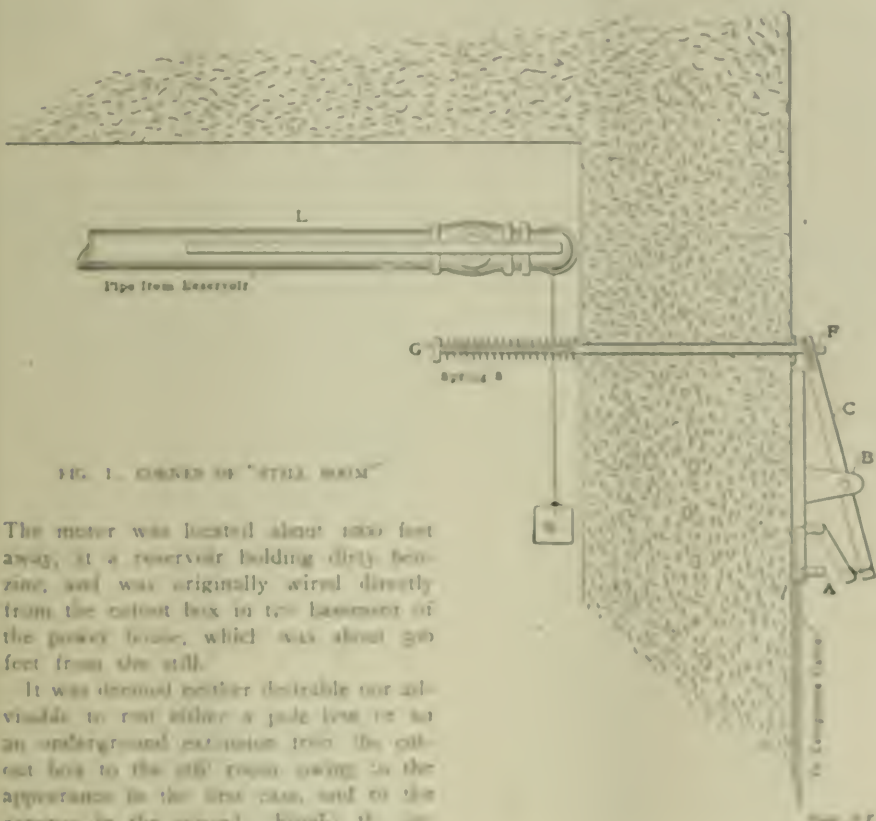

FIG. 1. CORNER OF "STILL ROOM"

The motor was located about 1200 feet away, at a reservoir holding dirty benzine, and was originally wired directly from the cutout box in the basement of the power house, which was about 500 feet from the still.

It was deemed neither desirable nor advisable to run either a pole line or an underground extension from the cutout box to the still room owing to the appearance in the first case, and to the expense in the second. Finally the engineer decided to make use of an extra pair of telephone wires in a cable which ran from the power house to the warehouse.

The extra wires were extended to the rear wall of the still room. At a point about 5 feet from the floor, and one foot from the corner of the room, a 1/2-inch hole was drilled through the wall. A double-pole single-throw switch was installed, having a pivot point at B, Fig. 1, a lever arm C pivoted at B and connected to the switch at A through a short link. A rod about 20 inches long and one-half inch in diameter was then run through the wall and connected to the lever arm C at the point F. A spring was put on the other end of the rod, and held in place by the flange G. The telephone wires were then connected to one side of the switch and a source of electric energy to the other. The switch, as required by the fire underwriters, was thus located outside of the still room.

By pressing on the end G of the rod, the switch A was closed. On removing the pressure, the spring S would immediately force the switch open again.

On the feed pipe leading to the still, an automatic self-closing valve was installed, also required by the underwriters. This valve was closed by means of a weight W, Fig. 1, hung from a lever L and was so located that when the valve was widely opened the lever would press on the flange G and close the switch. The lever would then be held against G until the still had as much benzine as required, and then be released, closing the valve automatically and opening the switch.

In the basement of the power house, close to the cutout box, the switchboard shown in Fig. 2 was installed. At the top of the board are two magnets connected in series to the telephone circuits, and energized whenever the switch A, Fig. 1, is closed. The cores of these magnets are connected to a steel frame F, which fits lightly around a 4-inch steel disk pivoted at P. This disk, instead of being controlled by a spring, is rotated by means of a long cord which is wound on a spool on the axle of the disk in the rear of the board, passed over several pulleys and attached to a heavy weight. The degree of rotation is limited by a projection on the disk, which makes contact with the catches H or O on the frame F, depending on whether the switch T is being opened or closed. Pivoted at the point x is a 6-inch lever P, which is connected at its lower end to a double-pole single-throw switch. The upper end is slotted half an inch to give play. When the magnets are energized, the cores are drawn up, lifting the frame F and allowing the disk to rotate with great speed

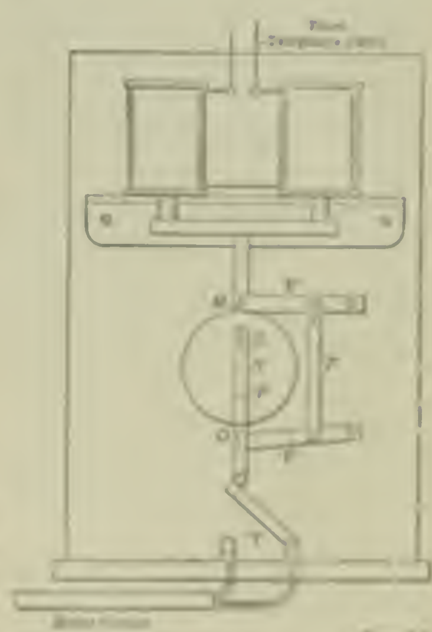

FIG. 2. STARTING DEVICE

until stopped by the catch O, the lever acting as a plunger closing the switch T and closing the motor circuit. When the magnets are deenergized by the opening of the switch A, Fig. 1, the cores drop, and frame F releases the disk, which turns until stopped by the catch H, opening the switch and thus opening the motor circuit.

cuit. Fig. 3 gives a rough diagram of the circuit.

The sump motor is thus quickly and conveniently operated from the still room in a manner that conforms entirely to the underwriters' specifications, and is reliable and inexpensive.

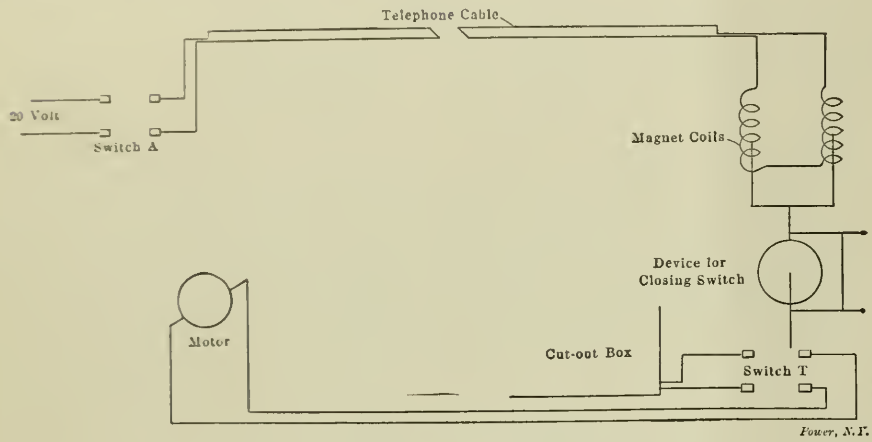

FIG. 3. DIAGRAM OF CONNECTIONS

Are Inside Screw Valves Unsafe?

On page 811 of the May 4 number, Thomas Sheehan has a letter on "State Inspection of Boilers," wherein he states that an inspector condemned one of the valves on a new boiler because it was not of the outside screw-and-yoke type.

Also on page 863 of the May 11 number is an editorial entitled: "Are Inside-screw Valves Unsafe?"

A person reading these articles, who is unacquainted with the Massachusetts laws on boiler construction and inspection, would very naturally condemn the boiler inspector for refusing to accept a new boiler simply because one of the connecting valves was not of the outside screw-and-yoke pattern. If, however, those who are interested in the matter will look at the "Boiler Rules," which are not made by the inspectors, they will find the following: "All stop valves 2 inches and over in diameter shall be of the outside screw-and-yoke type."

Therefore, the boiler was not "set up and connected as per law," as Mr. Sheehan claims, and neither was the inspector "guided by what he believed to be his duty in the matter" alone. There was, of course, no alternative whatever but to refuse to grant the certificate until the valves were installed in accordance with the "Boiler Rules."

The comparative safety of the two types of valve is another matter, but for convenience the outside-screw valve is far preferable to the other type. This may not make so much difference in the small plant, where one or two men alone handle the apparatus, but in the large plants, where momentum changes must be made rapidly, it certainly makes it much more convenient if the engineer can see at a glance whether certain valves are open or shut.

S. J. SMITH.

Lawrence, Mass.

Take a cross-section of a valve of the type alluded to and note the thread when the valve is closed. This is the point where all the strain comes when the valve seats and also when starting to open. There is no possible chance for lubrication, and if the thread begins to cut there is no knowledge of it, and no help if there were; there are but from one to three threads and they are right at the end of both stem and disk.

I consider them very dangerous, where the valve is important, and for many years have never put in one of this type over 2 inches in diameter.

W. E. CRANE.

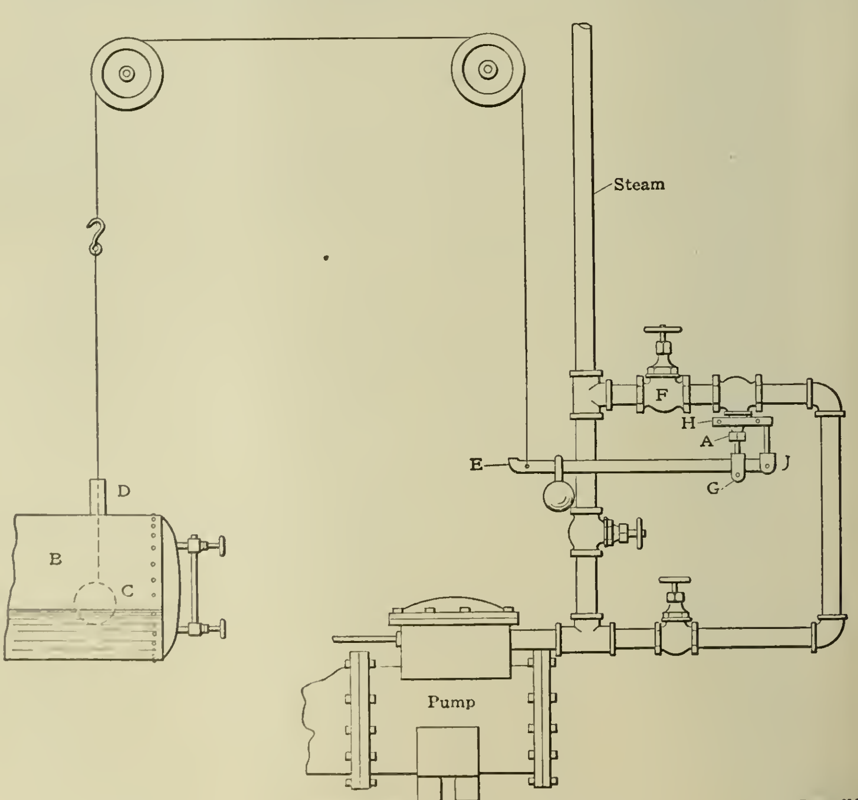
Broadalbin, N. Y.

Homemade Automatic Pump Regulator

After having connected up a reducing valve, extra valves, fittings, traps, etc., to overhaul an old 2-inch two-pipe heating system of 4000 square feet of cast-iron radiation, which has been operated many years without any of these appliances, I thought of completing the job at very little expense, by making a homemade pump regulator, as per the accompanying sketch.

It has worked for the last two years, needing only an occasional packing of the automatic-valve gland *A*.

The return tank *B* is directly connected with the heating system, and also through the traps; it also has connection with the pump suction. The float *C* is a seamless copper one, to which was fitted a ¼-inch brass rod. The tank *B* was drilled and tapped for ¼-inch standpipe, and a ¼-inch



HOMEMADE AUTOMATIC PUMP REGULATOR

nipple *D* long enough to serve as a guide for the rod was screwed in.

The float while separated from the rod, duly weighted with water, was introduced through the tank manhole and screwed to its rod. A hook was screwed on at O and an arrangement of cord and pulleys put up leading to the lever E.

The high-pressure line to the pump was bypassed and the regulating valve F inserted, together with other necessary valves. This regulating valve, which for reason of space was put in upside down, was made out of an ordinary globe valve, the stem threads being turned down and a pulley fork fitted to the end of the stem. The lever rests on the wheel pin G.

The hexagonal part of the valve bonnet was turned round, so as to fasten on an old pump-rocker arm H trimmed to suit the case. The forked eye J was taken from an old pump valve rod. The working of this contrivance hardly needs any explanation.

ALEXANDER DOLPHIN.

Jamaica, N. Y.

Return Tubular Boiler Setting

The accompanying sketches are of two return-tubular boilers with practically the same conditions existing, except that the plan of setting is different.

In Fig. 1 the boiler is set 3 feet above the grate surface and the bridgewall is built up square and is 28 inches high.

In Fig. 2 the boiler is set 2 feet above the surface of the grate and the bridgewall slopes back from the rear end of the grate until it reaches a vertical hight of 16 inches. The top of the bridgewall in each furnace is horizontal, thus bringing the center up to within 8 inches of the boiler shell.

FIG. 1

FIG. 2

The boiler furnace set as shown in Fig. 1 burns its coal more quickly and cleanly, requires less work and provides better combustion than can be secured in the furnace shown in Fig. 2.

Why does the furnace in Fig. 1 burn its coal with better results than can be obtained with the furnace shown in Fig. 2?

E. W. JACKSON.

Muddy, Ill.

A Blast Pressure Gage

The accompanying illustrations are of a pressure gage and telltale in use at the plant of the Tennessee Copper Company, Copperhill, Tenn. Six blowing engines discharge into one main receiver, at a pressure of 30 ounces per square inch. Each engine has a Crosby recording chart and draft gage to record the pressure, but as the chart is small and the gage set high, it is impossible for the oilers and engineers to keep the pressure even.

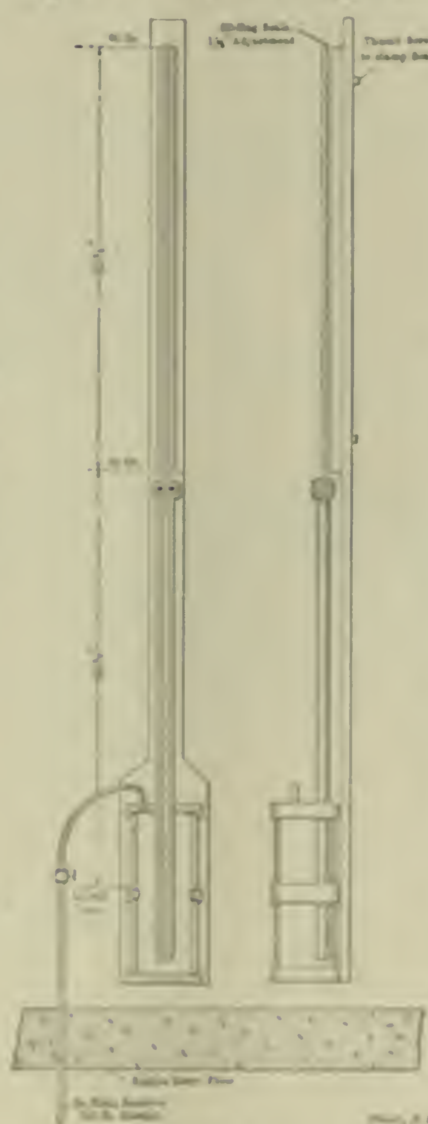


FIG. 1

A water gage was constructed as shown in Fig. 1. Two oil-pump glasses constitute the reservoir, clamped together on packings by some old oil-pump caps. A ½-inch pipe screws through the cap and extends to within 1 inch of the bottom. This pipe extends upward to a graduated scale, where a ¾-inch glass tube enters the pipe through the packing gland. The scale is made adjustable for 1½ inches to allow for evaporation of the liquid and difference in level.

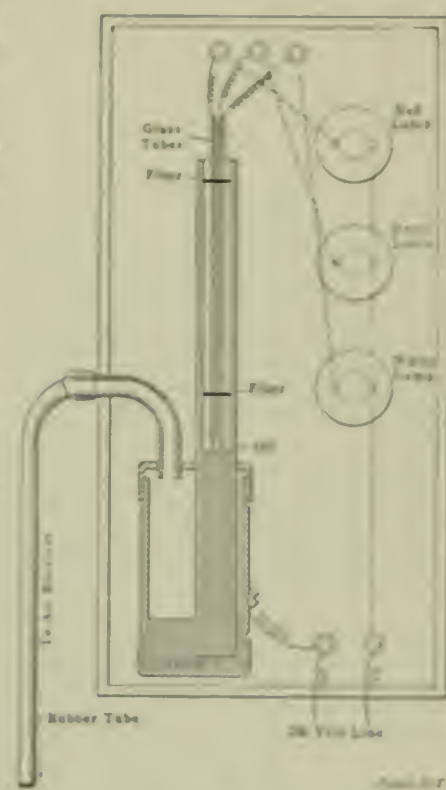

FIG. 2

From the top of the center ring on the reservoir, which is the point chosen to start from, to the beginning of the scale measures 59¾ inches, and is equal to 30 ounces pressure, based on the fact that one ounce pressure will support 1.73 inches of water. From this point the scale is graduated in ½-ounce graduations up to 40 ounces.

The liquid is colored red and the graduations are red and black on a white scale; the indicated pressure may be read 20 or 30 feet away. The gage is placed in the center of the engine room on the wall and is connected by a pipe line to the main receiver, some 300 feet away. Beside the water gage is fastened the electric telltale which is shown in Fig. 2.

This consists of a small reservoir and pipe similar to a water gage, but on a smaller scale, all constructed of iron. Three glass tubes, supported by two rings of fiber so they can neither touch each other nor the pipe containing them, have a platinum wire sealed in each tube at one end which projects through the tube ¼ inch; the other ends connect to a copper wire which extends to lamps as shown. The glass tubes have a difference of ⅛ inch in length on the bottom ends. The gage is filled with mercury so that with the water gage showing 49 ounces, the bottom light will burn; the other two lights are each 1 ounce apart in lighting up, and burning at 50 and 51 ounces. A bell could be used instead of lights if desirable.

A small amount of oil is used on the top of the mercury to break the small arc when the mercury recedes from the wire tips.

These gages have been very satisfactory in keeping the blast pressure even.

We use a similar water gage to adjust and test the recording gages on the blast pressure.

G. L. Fales.

Copperhill, Tenn.

Heating by Exhaust and Live Steam

Fig. 1 shows the piping arrangement where exhaust steam is used during the day when the engine is running, while at

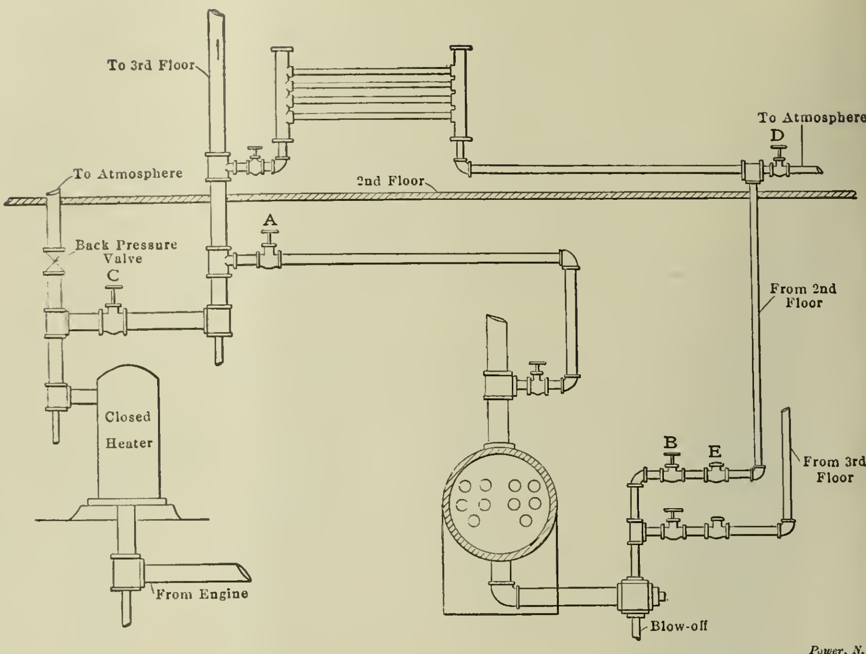

FIG. 1

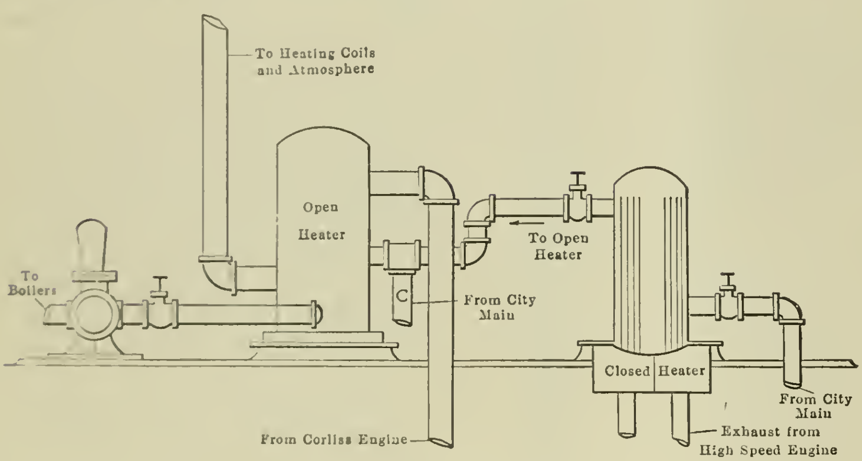

FIG. 2

night or when the engine is not running, live steam is used. This system is operated in the following way: In the morning, before the engine is started, the valve *A* in the steam line from the boiler and the valve *B* in the return pipes from the heating coils are closed, and shortly after the engine is running the valve *C* is opened and the back-pressure valve in the exhaust pipe is nearly closed, while the valve *D* leading to the atmosphere is opened just enough to let the water of condensation out of the heating coils. At night, after the engine is shut down, the valves *C* and *D* are closed, while the valves *A* and *B* are opened and left this way until the next morning, the night-watchman keeping the steam up.

It would have been an improvement if the pipe from the valve *D* were connected into a receiving tank, thereby saving the water of condensation from the exhaust steam during the day, or whenever the engine is running, and using this water over again for boiler feeding, as the water had to be paid for at meter rates.

The check valve *E*, which is in use when live steam is used and the water of condensation returned direct to the boilers, must be tight at all times, for if this check valve leaks, the system will not work satisfactorily.

There are many steam plants where no use is made of the heat in the exhaust steam, and it is hard to say whether the

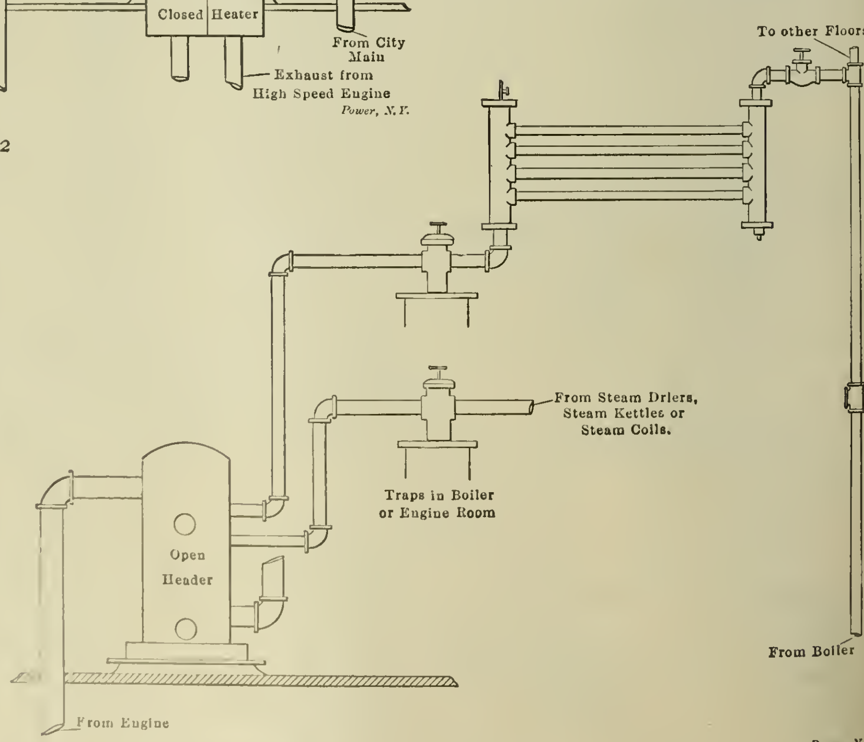

FIG. 3

owner or engineer is at fault for not making use of it for heating the building or heating the feed water for the boiler. Many steam-plant owners do not see any real gain from installing the necessary appliances for making use of the exhaust steam. The writer has in mind one plant where this is done. There is a large Corliss engine and the exhaust passes through an open heater. Some time ago a high-speed engine was installed for driving a dynamo for lighting the building, and the exhaust steam was run direct to the atmosphere. The reason it was not run through the open heater, as was that from the large engine, I think was because this heater was too small to take care of the exhaust from both engines.

It would have paid the owner to install a larger heater, or a small closed heater could have been installed in the exhaust line of the high-speed engine and, as water was taken under pressure from the city main the water could be first passed through the closed heater and then into the open heater, as shown in Fig. 2, making the water much hotter before it went to the boilers, resulting in a saving in the coal bill. Should the high-speed engine be shut down for any cause, the valves A and B could be closed and the open heater fed with cold water through the pipe C from the city main, or the piping could be arranged so that if the open heater got out of order the water could be passed by this heater to the pump from the closed heater, thereby making it unnecessary to supply cold water to the boilers.

Fig. 3 shows a plan where live steam is used in heating coils, steam driers and steam kettles, and water of condensation is returned by means of steam traps to an open heater. The steam traps can be placed in any convenient place in the engine or boiler room, or on the wall on shelves, as shown.

Fig. 4 shows a plan where exhaust steam is used and water of condensation returned to an open heater in the engine room. In this plant the exhaust steam is carried to the fifth floor with a back-pressure valve in the exhaust pipe at the ceiling on the fifth floor. There are also tees in the exhaust pipe at each floor, as shown at A and B, and from these tees pipes are branched off to each coil of heating pipe on this floor.

Compound Engines

Regarding G. W. Harding's contention in the April 20 number, that we can get twice the work out of an engine by compounding, whereas he says: "If the diagrams show, say, 100 horsepower in the high-pressure cylinder and 100 horsepower in the low-pressure cylinder, we have a 200-horsepower engine, do we not? Suppose we remove the low-pressure cylinder, do we still have a 200-horsepower engine?" To the first, yes, to the second, no; but by removing the low-pressure cylinder and other impediments, and running it as a simple engine about 120 horsepower would be developed, for the principal reason that there would be no receiver pressure to exhaust against.

Now, if we can gain from 20 to 40 per cent. in power by compounding, it would certainly be the sensible to do so, if steam consumption is taken into consideration.

Let us look in what light Mr. Harding regards a triple-expansion engine. According to his reasoning a triple-expansion engine would develop three times the power of a simple engine, and so on.

A. L. Anderson.

Douglas, Alaska.

G. W. Harding seems to be somewhat mixed in his article on the compound engine, in the April 20 number. He does not state clearly what he means by a compound engine having twice the power of a simple, but one would presume that he means that by compounding a 100-horsepower simple engine it would develop 200 horsepower, all other conditions remaining the same.

Suppose we have a 200-horsepower compound engine, with the work equally divided, or nearly so, between the two cylinders. He would say that we have only a 100-horsepower engine left if we remove the low-pressure cylinder with the steam pressure and revolutions remaining the same.

When we remove the low-pressure cylinder, we also relieve the back pressure on the high-pressure piston, thereby increasing the power developed in the high-pressure cylinder, say, 25 horsepower, with the same cutoff on the high-pressure cylinder, or a total of 125 horsepower, which the high-pressure cylinder of a 200-horsepower compound engine will develop if run as a simple engine.

Take a 100-horsepower simple engine of the same make, the steam pressure, revolutions and other conditions to remain the same. Change it to a compound by adding a low-pressure cylinder of the proper ratio. It will now develop with the same cutoff about 125 horsepower, not 200 as Mr. Harding would have us believe.

The last paragraph in Mr. Harding's article is all right, only he is mistaken as to the amount of power to be gained by compounding.

The initial cylinder condensation is less, the rotation is smoother, the strains are more evenly divided throughout the stroke, thereby permitting the use of lighter parts and lighter flywheels for the same degree of steadiness.

Charles E. Bigsworth.

Sprague, Wash.

I am afraid that Mr. Harding uses the terms rated horsepower, active horsepower, economy of a plant, economy of steam consumption, relative economy of two engines and what is considered good economy based on general practice, in a rather loose sense, and so [illegible] things are not what they seem.

A compound engine might be made to do twice the work of a simple engine and be much more economical, and at the same time the simple engine might be running in an uneconomical manner. Some times it is more economical to buy a [illegible] engine which may seem to be [illegible] uneconomical way than to buy a better engine which uses steam in a more economical way.

If the low-pressure cylinder is doing 100 horsepower and the high-pressure cylinder is doing 100 horsepower there is then a 200-horsepower engine, regardless of the builder's rating. If the low-pressure cylinder is taken away, we will still have a 200-horsepower engine, and it will develop 200 horsepower, but the fireman will sweat more, for it will use more steam as a 200-horsepower simple than as a 200-horsepower compound engine.

Mr. Harding says, in summing up: "I have learned that in order to increase the power of an engine one should raise the boiler pressure, speed the engine up, enlarge the cylinder or compound by adding a low-pressure cylinder."

I know a compound engine whose load is changed about 50 horsepower at a time. It is rated at 150 horsepower. When the full load is thrown on, it is changed from 150 horsepower (rated) to a 290-horsepower engine. The boiler pressure is not raised, the engine is not speeded up, the cylinders are not enlarged, and it is not compound, but on the contrary the speed is actually lowered trhee or four revolutions per minute. When the engine runs slower, the governor balls run in a lower phase and the cutoff is lengthened. The engine not only takes more steam, but more steam per horsepower and is therefore less economical.

Let us take a simple engine already overloaded, but developing 150 horsepower. It is actually a 150-horsepower engine. It is eating all the steam it can, but the power must be increased, therefore we will add a low-pressure cylinder which will use steam, but not the steam the high-pressure cylinder used or would use in developing 150 horsepower, but the steam it wasted by condensing it on its walls. For this reason the compound engine will develop, say, 200 horsepower, or the horsepower of the engine will be increased.

In order to make it run smoothly each cylinder is made to do an equal amount of work. The low-pressure cylinder is added not to increase the horsepower by using the same steam over again or to get more work out of the steam actually used by the high-pressure cylinder, but to increase the horsepower by using the steam which the original high-pressure cylinder condensed on its walls and wasted.

If Mr Harding will plot the two diagrams to the same spring scale and combine them into one, he will see that a compound engine does not consist of two separate engines using steam at two pressures but of one engine with two parts using steam at one pressure. The compounding does not make a second use of the steam but uses the steam that would be wasted. He must learn to look at a steam engine not as a machine which uses steam or changes the steam pressure into motion, but as a machine which changes the heat in the steam into work.

Angel Island, Cal.

Why Won't the Engine Carry the Load?

The accompanying indicator diagrams were taken from an Armington & Sims cross-compound engine, size 10½ and 16½ x 12 inches, speed 278 revolutions per minute, indicator spring, 60, steam pressure, 122 pounds, vacuum power, 30 pounds. This engine is connected to a two-phase induction alternator by a belt and was delivering 83.6 kilowatts to the switchboard when the diagrams were taken. During the time the indicator was being changed from the high-pressure cylinder to the low-pressure cylinder the load did

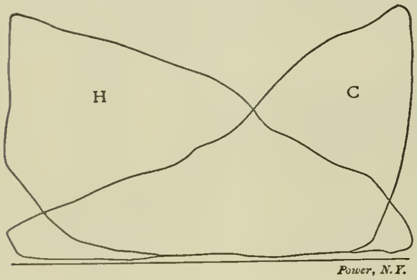

FIG. 1

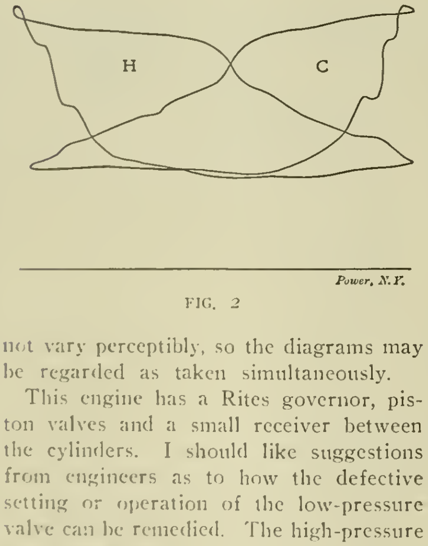

FIG. 2

not vary perceptibly, so the diagrams may be regarded as taken simultaneously.

This engine has a Rites governor, piston valves and a small receiver between the cylinders. I should like suggestions from engineers as to how the defective setting or operation of the low-pressure valve can be remedied. The high-pressure valve takes steam at the outside edges and exhausts at the center, while the low-pressure valve takes steam at the center and exhausts at the outside edges.

Another fault of this engine is its inability to carry a load one time that it will carry another time. For instance, in the evening the lighting load builds up gradually to 92 kilowatts which is this engine's limit. We put in another engine to help over the peak load, and when the load builds up to, say, 100 kilowatts, if we take out the other engine when the load goes down to 92 kilowatts, the Armington & Sims will not carry it, the steam pressure being the same. Why is this?

At what position should the governor be blocked while setting the valve?

Boiler Inspection and License Laws Desirable

The editorial in the April 27 number, "Boiler Inspection and License Laws Desirable," leads me to the belief that the situation in Maine is not fully understood, nor why the license law failed to pass at the last session of the State legislature. The bill that was proposed was so wretchedly drawn that no self-respecting engineer could possibly approve of it. It should have been called: "A Law to Corner the Market in Stationary Engineers and Firemen." The writer is a stationary engineer of more than fifty years' active experience and believes in a thorough inspection of all steam boilers, and any practical law that will prevent or reduce in number the loss of life by boiler explosions; and he so stated to the committee on legal affairs at the last session of the legislature.

The lawyer who appeared for Portland No. 1, N. A. S. E., stated that he did not draw up the bill and had passed a very unpleasant afternoon while advocating it. With other engineers from some of the largest and best-managed corporations in the State, the writer attended the hearing to protest against the proposed bill and at the same time to recommend the passing of a rigid inspection law for steam boilers. The lap seam and the factor of safety were explained to the committee, and legislation upon these was strongly recommended.

I do not believe there were any measures taken by any person or corporation to check the discussion in the newspapers of the State. The most intelligent and the best-equipped engineers of the State were opposed to this bill as presented, and so stated at the hearing. No one except the lawyer spoke in its favor. There was no minority report.

At the last session of the Massachusetts legislature there was a bill praying for relief from the hardships imposed on the manufacturers by the present license law. A recent visit to several of the large power plants and manufacturing concerns in that State and interviews with their chief engineers convinced me that they had abundant reason for complaint. If the Massachusetts law has proved to be a hardship, the bill offered in Maine would have proved a much greater one.

I do not think that the recent explosion at Farmingdale should be quoted against Maine any more than the disaster at Brockton should be cited against the Massachusetts license law.

Use Cylindrical Flywheels for Safety

There are several important points in Mr. Hodges' article in the May 4 number, page 798, that do not look at all like good reasoning.

The energy delivered by a flywheel is, as stated, proportional to the moment of inertia, but in reducing the mass, M contains the variables R = radius and b = the breadth, and hence should be simplified. Equating the moments of inertia for two wheels we shall get an expression as follows:

$$M_1 R_1^2 = M_2 R_2^2;\ I_1 = M_1 K_1^2;\ I_2 = M_2 K_2^2$$

where

M = Mass,

K = Radius of gyration, which can be taken equal to R for this discussion.

Reducing M to its components we have:

$$M = k\ b\ t\ R,$$

where

k = Density,

b = Width,

t = Thickness,

R = Radius.

Substituting in the first equation we have:

$$k\ b_1\ t_1\ R_1^3 = k\ b_2\ t_2\ R_2^3;$$

t and k can be taken as constant; $t_1 = t_2$, $k = k$. Then

$$b_1 R_1^3 = b_2 R_2^3,$$

or

$$\frac{b_1}{b_2} = \frac{R_2^3}{R_1^3},$$

from which it follows that the widths of two wheels of the same moment of inertia are to each other inversely as the cubes of the radii. As the weight varies as the width × the radius, the foregoing formula may be written as follows:

$$\frac{b_1 R_1}{b_2 R_2} = \frac{R_2^2}{R_1^2}.$$

In other words, the weights vary as inversely as the squares of the radii. Hence if a flywheel weighed, say, 2000 pounds, one of half the diameter would weigh 8000 pounds and one one-third the diameter 18,000 pounds. As ball bearings can be used only for light work, the inadvisability of putting in ball bearings to take care of this increased load can be easily seen.

The purpose of the article was also to show how the stress varies with a change in diameter. The same fallacy occurs here, also, as M is again a variable containing b and R, and should be reduced as low as possible. The force tending to burst a flywheel is, however,

$$F = \frac{M V^2}{4 R},$$

where

F = Force,

M = Mass of all rotating particles,

V = Velocity,

R = Radius.

Reducing V to $2 \pi R N$,

$$F = \frac{M (N\ 2 \pi R)^2}{4 R}.$$

N = Number of revolutions.

This force F is the total force at any one section, and dividing by $b \times t$, we get unit stress:

$$S = \frac{M (N\ 2 \pi R)^2}{4 R b t}.$$

Reducing M:

$$S = \frac{k\ b\ t\ R\ (N\ 2 \pi R)^2}{4\ b\ t\ R}$$

$$S = k\ \pi^2\ R^2\ N^2$$

Calling $k\ \pi^2 = C$,

$$S = C\ R^2\ N^2,$$

which is the formula given by Kent.

As to why this formula is incorrect, the reasoning is not at all clear. There are some four or five arguments, some directly opposed to others, which mean little and prove less. It is at once evident from the formula that the stress does not depend on either breadth or thickness, within the limits of the assumption, for the more material in the rim, the greater the cross-section to withstand the force. The mass, however, increases as the radius increases and the R^2 will stay in the discussion. In other words the stress varies as the square of the radius, which is even better for the purpose of the article.

To sum up conclusions then: To replace the present flywheel by one, say, one-third as large, we should have to increase the width twenty-seven times and the weight nine times, which would also decrease the liability of explosion by a factor of nine. The last may be secured, however, by increasing the spokes.

J. H. Snow.

Madison, Wis.

Boiler Efficiency

In the issue of May 4, page 811, W. Kent takes exception to my remarks appearing in the March 16 number, concerning the use of the term "efficiency" in connection with boilers, and states that I have used the term "boiler efficiency" in a different sense than it has been used for the past forty years by all authorities on steam boilers, and in a sense that is not in harmony with the meaning of the word "efficiency" as applied to other things in boilers.

There is no difference of opinion between us regarding the definition of "efficiency," which he gives as "output divided by input," but this is not the point. He states that the efficiency of a boiler is not a constant quantity, but necessarily variable due to rate of driving and other things. This is surprising. The difference, for example, between the early boilers in the form of kettles heated on the outside, with but a relatively small portion of the heat finding its way into steam, and those made later with tubes within them and passages arranged around the outside so that a much greater portion of the heat was absorbed, was one of mechanism and necessarily a constant; therefore the efficiency must be a constant and not a variable. Thus it is clear that the latter type is more efficient due to the fact that there were tubes through it and passages around it, and it is the recognition of this fact which I urge. Therefore the only difference between the two boilers being that of design and construction, serving them with a good or poor fire can in no way change their characteristics. Of course, if a good fire is made under a poor boiler and a poor fire under a good boiler, the result, which is the efficiency of operation, might be the same in each case.

Mr. Kent confuses the efficiency of operation with the efficiency of the boiler, and it is surprising to me that arguments of this kind should be presented, because a little thoughtful consideration will make it perfectly clear that the efficiency of a boiler itself should be recognized, and the efficiency of operation, which has masqueraded in some cases as the efficiency of the boiler, is inadequate to give definite information relative to the boiler itself.

Cause of an Engine Wreck

On page 892 of the May 18 number Leroy H. Wheat asks, "If the load is all thrown off of a Corliss engine would there not be a checking of the speed before the governor would drop from its highest place to the point where the intake valve would again open to admit steam?" And he suggests the setting of the collar on the governor stem so that the cutoff shall never be less than the valve opening, or 1/16 inch. This might not be too much, and yet with a good vacuum and no load I should be afraid to risk it, and I speak from long experience in rolling-mill work.

This was not the point I was looking at when writing the article alluded to. The question was, "What would be the result of lengthening the long rod and shortening the short rod on the governor of a Corliss engine?" This question had nothing to do with the limit to which this might be carried.

To show what can be done in this direction, a man had a large Corliss engine fitted with one condenser and the latest cutoff being too early for his work, he changed the rods as indicated until the shortest cutoff was at one-fifth stroke. This was all right as long as the entire empty mill was attached, but one day the main belt broke and there was an empty engine whose shortest cutoff was at one-fifth.

Lengthening the long rod and shortening the short rod may bring the shortest distance of cutting off at any place, and the result appears in the papers: "The load was suddenly thrown off and the engine ran away."

W. E. CRANE.

Broadalbin, N. Y.

State Supervision of Boilers

In answer to Mr. Sheehan's inquiry I will say that the State requires all stop valves 2 inches and over in diameter to be of the outside screw-and-yoke type, on new construction; that is, on boilers installed since May 1, 1908. This rule, however, does not affect valves on boilers installed prior to this date. That is why the inspector required the valve on the new boiler to be changed and allowed the others to remain.

Evidently Mr. Sheehan has not made use of the opportunity to get a copy of the State "Boiler Rules," which are published in pamphlet form and contain much valuable information for engineers. These rules can be had free of charge by applying to any member of the boiler-inspection department.

RALPH F. BLANCHARD.

Fitchburg, Mass.

Economy of Different Sized Engines

In relation to statements contained in James L. Guile's letter on page 891 of the May 18 number, I think Mr. Guile is making a mistake in presuming that the 8x8 engine will be more economical in the use of steam than the 8x10. It seems to me that he is basing his calculations on a 10x8 instead of an 8x10; that is, he considers the 10-inch dimension as the diameter of the cylinder instead of the stroke, which it really is, it being usual to name the diameter first and the stroke second, and in that case the 8x8 engine would not be the better under the other assumed conditions.

Suppose the initial steam pressure, absolute, to be 150 pounds, the back pressure 17 pounds, the revolutions per minute 250, and the indicated horsepower 50 for both engines.

Let x equal the mean effective pressure for the 8x8 engine; then by transposing the terms of the horsepower formula and substituting the given values, we have

$$x = \frac{33{,}000 \times 50}{\frac{8}{12} \times 50 \times 500} = 99$$

pounds. For the 8x10 engine the mean effective pressure will be

$$x = \frac{33{,}000 \times 50}{\frac{10}{12} \times 50 \times 500} = 79.2$$

pounds. I have used the round number 50 for the area of the 8-inch pistons in both cases in order to simplify matters, and further will consider that there is not any clearance. We want to find out at what points of cutoff, respectively, 99 and 79.2 pounds mean effective pressure can be obtained, bearing in mind the assumed data. The formula for finding the mean effective pressure is:

$$p = P \times \frac{1 + hyp\ log\ R}{R} - back\ pressure,$$

where

p = Required mean effective pressure,
P = Absolute initial pressure,
R = Ratio of expansion.

Back pressure is also expressed in terms absolute.

From the formula we can solve for the value of R, from which we can find where cutoff takes place, and then determine the difference in the quantity of steam used in the engines. First, to simplify, let

$$a = \frac{p + back\ pressure}{P};$$

then

$$a \times R - hyp\ log\ R = 1.$$

Assume a value for R and see how near to 1 we can get. For the 8x8 engine,

$$a = \frac{99 + 17}{150} = 0.773 +,$$

and,

$$0.773 \times R - hyp\ log\ R = 1.$$

Try $R = 2.5$; the hyperbolic logarithm of $2.5 = 0.9163$; so that the statement becomes

$$0.773 \times 2.5 - 0.9163 = 1.01.$$

This is sufficiently close to 1 for the purpose, to permit the use of 2.5 as the ratio of expansion in the 8x8 engine.

For the 8x10 engine assume the value of R to be 3.5. Then, as before,

$$a = \frac{79.2 + 17}{150} = 0.641;$$

and

$$0.641 \times R - hyp\ log\ R = hyp\ log\ of\ 3.5 = 1.2528.$$

Therefore,

$$0.641 \times 3.5 - 1.2528 = 0.99.$$

This also is sufficiently close to 1 to permit the use of 3.5 in the 8x10 engine.

From the foregoing, the point of cutoff in the 8x8 engine will be at or about 3.2 inches from the beginning of the stroke, to produce a mean effective pressure of 99 pounds, with the assumed conditions. For the 8x10 engine the cutoff will occur at or about 2.86 inches from the beginning of the stroke to produce a mean effective pressure of 79.2 pounds.

The difference is

$$3.2 - 2.86 = 0.34$$

inch, and

$$0.34 \times 50 = 17$$

cubic inches in favor of the 8x10 engine, or

$$17 \times 500 = 8500$$

cubic inches per minute, or 4.8 cubic feet of steam per minute, difference in favor of the 8x10 engine.

Of course the foregoing figures are not absolutely correct arithmetically, but they show the trend. I think there is hardly any doubt that the 8x10 will be the more economical engine and that William E. Snow, in the March 30 number, page 602, is correct in his findings.

CHARLES J. MASON.

Scranton, Penn.

"Notice to Visitors"

The ten notices to visitors in the April 27 number, suggest the following:

(1) Visitors are always welcome.

(2) Please clean your shoes.

(3) The engineer's time is limited, but he will be glad to answer sensible questions.

(4) The engineer-in-charge delights in keeping this engine room clean; please do not spit on the floor.

(5) Danger! Do not go near the engines, you are liable to get injured.

(6) The engineer does not know it all; sensible suggestions are always considered.

(7) If you do not know the engineer, make his acquaintance, you might find him interesting.

(8) Do not touch any of the apparatus in this room; it is liable to cause the engineer much trouble, and may prove fatal to you.

(9) The engineer's duties are many; if he has no time to entertain you, don't think he's "stuck up."

(10) Call again.

L. EARLE BROWN.

Ensley, Ala.

Kerosene Oil in Boilers

In Charles H. Taylor's article, page 807, May 4 number, concerning the use of kerosene oil in boilers, he states that if a boiler is excessively scaled there is danger in using kerosene oil, as it will undoubtedly find the weak places in the shell and tubes and is liable, in removing the scale, to start a leak.

I believe that if a boiler is made tight with excessive scale it is about time that something were done to remove the scale and show up the leaks so that they can be repaired. I cannot see where the danger lies, as the condition of the boiler certainly will not improve if the scale is allowed to remain.

Mr. Taylor gives the vaporizing point of kerosene oil at from 118 to 122 degrees, while Mr. Durand, in the same issue, on page 806, gives it at 338 degrees, and at the same time criticizes Mr. Mellon for stating that it vaporizes at 150 degrees. Now who is right? Kent gives the temperature of distillation at 338 degrees and the flashing point from 100 to 122 degrees.

LOUIS B. CARL.

Marshfield, Wis.

Some Useful Lessons of Limewater

What Causes the Limelike Deposit on Boiler Tubes; How to Get Rid of It; Softening Permanent-Hardness Water; Interesting Tests

BY CHARLES S. PALMER

As we begin this chapter on the uses of sulphuric acid, our attention is also called to the abuse of the acid and its salts; and this brings us square up against some of the problems and troubles of the fireman in the first lesson. We recall that there are two kinds of hard water, and that one kind, the temporary hardness, is caused by calcium bicarbonate or extra carbonate, in the water, which can be removed by simple heating when the plain carbonate of lime or calcium comes down, while the other kind of hardness, permanent hardness, is caused by calcium sulphate, which is not removed from the water by simple heating, but stays in the water.

The reason why this hard limelike layer gathers on the boiler tubes is that most of the water which goes into the boiler is evaporated off into steam, and the sulphate of lime or calcium, which makes the water permanently hard, naturally goes out of solution, settling on the tubes as a hard and dense layer, which in many cases has to be literally chiseled off. We noted that this special kind of trouble can be removed in part by treating the water with some soluble carbonate, like soda carbonate, which throws down the lime as insoluble calcium carbonate, leaving the sulphuric-acid part still in the water, as soda sulphate, for example.

Chemicals to Soften Permanent-hardness Water

Another way to get rid of this permanent hardness, in part, is to treat the water with something like sodium oxalate, or sodium [illegible], each of which will precipitate the lime or calcium part of the hardness, leaving the sulphate part still in solution in the water, as salt of sodium. These salts of sodium are soluble, and hence do not precipitate as crusts or layers on the boiler tubes.

The statement is frequently made that these soluble salts of sodium left in the boiler water do not hurt the boiler nor hinder the making of steam; and while this may be true in part, yet they can hardly be of any help in steaming, although the overcoming of the greater trouble of the hard sulphate of lime scale may more than offset the lesser trouble of still leaving the boiler water heavily charged with soluble salts of sodium. However, if the cost of the chemicals used to soften the permanent-hardness waters is not too great, no doubt there is great advantage in using them, for it merely means, in some cases, that the boiler must be blown off often enough to get rid of the salts accumulating in the water. You can see what this means by treating some of your hydrant water with a little dilute soda carbonate (washing soda, or the like), that is, if the water happens to be of the permanent-hardness kind.

After the lime part has settled out (or you can filter the calcium carbonate off, leaving the water perfectly clear), you can evaporate the solution down to dryness. Be sure not to use too strong a solution of soda carbonate, only just enough to leave the water barely alkaline; that is, so that it barely turns litmus paper blue. You will be interested to learn how little residue there is from the evaporation of the softened water; the residue is, of course, sodium sulphate, if you used sodium carbonate to soften the water.

But just stop and figure out what it means to handle the tons of water which goes through the boiler every week. Suppose that you treated only a pint of water in your experiment; that is about a pound roughly. Now suppose that you are firing the boiler for a fifty-horsepower steam engine. It is good practice to get a horsepower-hour with twenty pounds of dry steam. That makes one thousand pounds of dry steam every hour for your fifty-horsepower engine, or ten thousand pounds (five tons of water) every working day of ten hours. Now multiply the residue from your little pint of softened water by ten thousand and you will begin to get an idea of what it means to handle large quantities of hard water. Also, multiply the soda carbonate used to soften the pint of hard water by ten thousand, and you will get some notion of what it means to pay for the softening of water for a fifty-horsepower engine for one day.

But the steam is not always dry, and there is much waste, and perhaps you are using rather more than twenty pounds of dry steam per horsepower-hour; and hence the question of the advisability of using this or that water softener, or indeed, of using any water softener at all, comes up for consideration.

Other Questions to be Considered

But there are several other questions which will come up for study in connection with this subject of hard water. One is: What will one do if he has both permanent hardness and temporary hardness to handle at the same time? Another is: What will one do if he has not alone the salts of lime or calcium to handle, but also the salts of magnesium with those of calcium? These conditions are by no means uncommon, and something may have to be done when often it seems almost impossible to do anything. But the right way to look at troubles is that there is always some method of doing the trick, if one will stay with the game and never give up until he has found out what is best under the circumstances. We will first take up the question of the presence of both calcium carbonate and sulphate in the same water.

We will suppose that you have made such a water as that just described. This can be made by making some of the solution of extra, or double or bicarbonate of lime or calcium; as by blowing into limewater until the plain carbonate first thrown down by the breath is redissolved, at least in part. Let this stand; or, better, filter it to have it clear. It will be well to test a little of this water, which is temporary-hardness water, by heating to see if you really have what will throw down the plain carbonate. Then make some permanent-hardness water by shaking up some plaster of paris, calcium sulphate, with water. Then stand and decant off the clear liquid; or you can filter it to be sure.

Now mix the two, the solution of calcium bicarbonate or temporary-hardness water, and the solution of calcium sulphate or permanent-hardness water. If there is any precipitate on mixing, let the mixture stand until it is clear; or you can filter it. Perhaps you do not have to make any such mixture. Perhaps you are unlucky enough to have an abundant supply of this mixture right at hand in the city hydrant water. Never mind; take hold of the trouble and let us see what can be done with it all. Of course, the first thing to be done with this mixture of temporary-hardness and permanent-hardness water is now to get rid of the temporary-hardness part. This can be done either by heating in the heater and settling out, or by Clark's process as described in one of the earlier lessons.

Having got rid of the carbonate part of the lime, go right on to the sulphate part, using soda carbonate, as shown in the following reaction:

$$\left.\begin{matrix} CaSO_4 \\ \text{Calcium Sulphate} \\ \text{Soluble} \end{matrix}\right\} - \left\{\begin{matrix} Na_2CO_3 \\ \text{Soda Carbonate} \\ \text{Soluble} \end{matrix}\right\} = \left\{\begin{matrix} CaCO_3 \\ \text{Calcium Carbonate} \\ \text{Insoluble} \end{matrix}\right\} - \left\{\begin{matrix} Na_2SO_4 \\ \text{Sodium Sulphate} \\ \text{Soluble} \end{matrix}\right.$$

This soda carbonate will not only precipitate the calcium from its sulphate, but it will also precipitate any other soluble salts of calcium which may happen to be present in the water; such as the chloride. The same solution of soda carbonate will also thrown down the magnesium salts which may happen to be in the water along with the calcium. Some of these magnesium salts may go down with the scale on the boiler tubes, and some of them may do a worse thing still, eat out the iron tubes themselves. You will see in a moment how it is that some of the salts of magnesium can eat out the iron of the tubes; but note that you have actually removed the chief evil of having any of the lime settle on the boiler tubes from the mixture of both temporary- and permanent-hardness water in one, and that is something to be thankful for.

Sulphuric Acid is Very Strong

Now for the magnesium, and that brings us back to sulphuric acid. Sulphuric acid is a very strong acid, but it is not by any means the strongest acid. Thus, if you mix some soda with both sulphuric and muriatic (hydrochloric) acids, and evaporate the whole down to dryness, you will find that the sulphuric acid has driven off the hydrochloric acid, and thus the sulphuric acid seems to be the stronger; but this is not so, for the hydrochloric acid goes off simply because it is more volatile than the heavy and nonvolatile sulphuric acid, which takes a heat of nearly that of molten solder to drive it off. You will see what is meant if you stop to think that when two boxers meet in the ring, the stronger is not the one who can easily jump the ropes and quit the ring, but the man who stays in the field and does the most work for the same weight in the same time. So though the hydrochloric acid is really the stronger, if kept in the ring, yet his volatility gets away with his courage when he meets the heavier and more sluggish sulphuric acid; and so the sulphuric acid seems the stronger.

I shall later show something of the ways which are used in testing the comparative strengths of acids; but meanwhile we will look at the case of magnesium. If you take a bit of common salt and dissolve it in water, you can evaporate it down to dryness and still have the salt, sodium chloride, just as it was at the start. If you dissolve some limestone in hydrochloric acid, just enough acid barely to dissolve it, you can evaporate this down to dryness, and you will still have most of the calcium chloride with which you started, but not all; for, although all of the calcium part of the calcium chloride is there in the saucer, yet a small part of the calcium is in the form of lime, calcium oxide, as you can prove by letting it stand in the air for some time, when it will slowly gain in weight, as the five or ten per cent. of the lime in the seeming calcium chloride takes on some carbonic-acid gas from the air.

Magnesium Chloride

If you get some common magnesia and barely dissolve it in hydrochloric acid, you will have magesium chloride; and if you evaporate this solution down to dryness, you will not have pure magnesium chloride in the saucer, but largely magnesium oxide, or magnesia, just what you started with. This experiment is worth some trial and study, for it has much to do with the special question of waters which are hard with salts of magnesium. On the other hand, if you evaporate a solution of magnesium sulphate, epsom salts, down to dryness, you will still have magnesium sulphate in the saucer; but if you evaporate a solution of magnesium chloride down to dryness you have some plain oxide of magnesia, MgO, in the saucer.

You can prove that something of this sort is happening as you evaporate the solution of magnesium chloride down to dryness, both by holding a bit of blue litmus paper in the steam from the evaporating solution, when the paper will turn red, showing that the volatile hydrochloric acid is coming off. You can also readily smell the acid fumes from the evaporating solution. This is one of the facts to get clearly in mind about the chemistry of water hard with magnesium salts. We do not have many of these kinds of water in the eastern part of the country, but in the far West such waters do occur; and it is often a serious matter as to whether they can be treated economically in any way. Of course, there is always some way which is best under the circumstances. The point is that solutions of magnesium chloride (and magnesium bromide comes in the same list), when evaporated, act as though they were dilute solutions of hydrochloric acid, not very strong of course, but plenty strong enough to make trouble in time. Now the two great medicines for the treatment of such waters, as just shown, are lime and cheap soda carbonate; and both of these should be added, not at once, but in turn, and before the water is admitted to the boiler.

Tests for Sulphuric and Hydrochloric Acids

I shall have more to say about this question later; but meanwhile it will be convenient to have some simple tests with which to be on the lookout for both sulphuric acid and hydrochloric acid. The best test for hydrochloric acid is silver nitrate. This you can make by dissolving a silver dime in nitric acid. Of course, there are several other metals in the dime, put in to harden the silver, which would be otherwise much too soft to stand the wear and tear of daily handling. You can get around this by putting a piece of common sheet copper into the solution of silver nitrate, when you will see the silver come down on the copper in a beautiful crystalline form. This will take some hours to be thoroughly done; when all the silver is down on the copper, take out the copper, wash off the silver, say back into the tumbler, rinse off the silver several times with clean water to get rid of the copper solution, and then redissolve the pure silver in a fresh supply of nitric acid. *One thing you will want to note is that the dissolving of metals in nitric acid should be done in the open air; or before the furnace door, where there is a good draft to carry away the poisonous brown "nitric fumes" from the action of the metal on the nitric acid. Do not breath these fumes.* You can see that the metals are all chemically equivalent to hydrogen in some form; and as the metal acts on the acid, it reduces the acid if it can be easily reduced, as can nitric acid; and hence in this case we have the production of the fumes, which will be explained further as we come to nitric acid and the compounds of nitrogen.

This solution, from one dime, will last you a long time with careful use. It takes only a drop or two to test water; and though you can add enough to get the thick curd-like silver chloride, yet a single drop of the colorless solution of silver nitrate will give a distinct cloudiness in most common hydrant water. This white silver chloride will settle to the bottom of your test tube, and it will turn purplish gray in a few minutes, depending on the amount of light that strikes it; for you are close to photography when you use this test of silver nitrate with the chlorides.

This white silver nitrate is readily soluble in ammonia, and it is readily brought back by reacidifying with nitric acid. Silver nitrate is also a test for soluble bromides, salts of hydrobromic acid, and for iodides, salts of hydriodic acid; but in the case of the bromides, silver bromide is yellowish, and is soluble with difficulty in ammonia; while in the case of the iodides, silver iodide is distinctly yellow, and it is not soluble in ammonia.

I shall consider the tests for sulphuric acid and soluble sulphates next time.

Obituary

James Bennett Forsyth, president and general manager of the Boston Belting Company, died at his home in Boston June 11.

Discussion on "Small Steam Turbines"

Following is an abstract of a discussion presented by Charles B. Burleigh at the local Boston meeting of the A. S. M. E., on Friday, June 11, on George A. Orrok's paper on "Small Steam Turbines," presented at the Washington meeting of the society in May. Mr. Burleigh said:

While this paper is extremely interesting as presenting comparative data on the different small turbines at present available, the details as given (with the exception of the efficiency curves) are more general than specific.

A careful examination and comparison of the water-rate curves presented in this paper is extremely interesting, particularly in view of the fact that the author states that these curves "have in most cases been obtained from the manufacturers."

It is unfortunate that the curves vary so widely in capacities and speeds that a complete comparison of all is not possible, and it is also to be regretted that the paper does not state the normal rating given to the machines to which the different curves apply or which of the speeds is their commercial standard; but nevertheless, I have attempted to compare such as are closely similar with a view to determining as closely as possible the relative efficiencies of the different types.

For instance, the Terry curve (Fig. 25) gives a water rate of 57 pounds per brake horsepower at 2330 revolutions per minute, at 150 pounds gage pressure when developing 25 horsepower.

The Sturtevant curve (Fig. 26) shows a water rate of 61 pounds at 2300 revolutions at 121 pounds pressure when developing the same output; therefore according to these figures the Sturtevant turbine is 7 per cent. less efficient than the Terry, but I am inclined to feel that this is rather unjust to the Terry machine, for I should infer from the Sturtevant curve that 25 horsepower represented maximum load or its most efficient point, while the same inference would lead one to infer that the 25 horsepower point on the Terry curve represented less than half load, or practically its most inefficient point, and as the Sturtevant curve shows this machine to be some 16 per cent. less efficient at half load than at full load, and the Terry curve shows this machine to be some 22 per cent. more efficient at full load than at half load, it is safe to infer that the Terry machine on general principles is much more efficient than the Sturtevant.

The same Terry curve shows that when developing 60 horsepower the water rate is 44 pounds. The Bliss curve (Fig. 27) at the same output, 1900 revolutions, is 55 pounds. The Kerr curve (Fig. 31) at 2800 revolutions and 175 pounds pressure and 60 horsepower output shows a water rate of 52 pounds. The Curtis curve (Fig. 28) at 2400 revolutions, 150 pounds pressure and 60 horsepower shows a water rate of 40 pounds; therefore, according to these figures the efficiencies rank: Curtis, 40; Terry, 44; Kerr, 52; Bliss, 55; and this allowing Kerr 15 pounds higher pressure and 400 revolutions higher speed.

On the same basis, allowing the Curtis turbine its standard designed speed of 3600 revolutions, the water rate on its curve is shown to be 31 pounds. The Terry turbine is more than 18 per cent. more efficient than the Kerr and 25 per cent. more efficient than the Bliss. The Curtis at the same speed is 10 per cent. more efficient than the Terry and more than 25 per cent. more efficient than the average of the three and, at standard designed speed, 42 per cent. more efficient than the Terry and 62 per cent. more efficient than the average of the three at 60 horsepower output.

Comparing the Bliss curve (Fig. 27) at 120 horsepower, 2600 revolutions, the Kerr curve (Fig. 31) at 175 pounds, 150 horsepower, 2000 revolutions, and the Curtis curve (Fig. 29) at 150 pounds, 2000 revolutions and 150 horsepower, we note the water rates as follows: Bliss, 40 pounds; Kerr, 41 pounds; Curtis, 29 pounds.

These figures tend to show that the Bliss and Kerr are not widely different, but that the Curtis is some 40 per cent. more efficient at 150 horsepower output. These curves, therefore, would tend to show that the efficiencies of the Terry, Kerr and Bliss turbines were not widely different, and that the small Curtis turbine is in a class by itself, some 40 per cent. more efficient than any of the other types.

It is to be regretted that the author was unable to present efficiency curves of the other turbines described.

The paper credits the De Laval and Curtis types each with 70,000 horsepower of turbines in "successful commercial operation," and also states that the first De Laval turbines were "introduced into this country about 1898." The small Curtis turbine was not introduced until some 10 years later.

As this capacity includes the small Curtis units used for all purposes, it is reasonable to assume that it also covers all applications of the De Laval machine, and this latter machine has been extensively used for driving pumps, blowers or other high-speed rotary machinery, while at least 90 per cent. of the small Curtis units in service are operating generators for lighting or driving industrial establishments, for which reason they have all been sold in competition with the highest-grade and most efficient reciprocating units.

While the Curtis turbine is eminently well adapted for driving centrifugal pumps, air compressors and exhausters and other high-speed rotary machinery, it has not as yet invaded this field to any great extent, due largely to the fact that its manufacturers are more familiar with and have better facilities for making their initial bow to the commercial electrical field than to the mechanical, and it must be admitted that 70,000 horsepower in less than five years is a very profound bow.

Further than this (with apologies to the public who find it necessary to operate pumps and blowers), it is the exception rather than the rule, where refinements are considered as warranting any increase in investment or efficiency is seriously considered in the purchase of this class of machinery.

It is interesting to note from the paper that the buckets used in the De Laval, Terry, Dake, Bliss, Sturtevant and Kerr turbines are of steel, some cast and others milled. Originally the Curtis buckets were milled in the wheel periphery, but experience has demonstrated the fact that steel buckets are far from ideal where any perceptible moisture is present in the steam, for wet steam will wear steel turbine buckets.

The liability of operation under wet-steam conditions is much more common in connection with the use of small steam units than with large ones, as superheaters are seldom, if ever, installed in small plants, pipes are seldom covered and long steam mains are usual. For this reason the use of steel buckets in the Curtis turbine was abandoned some years ago, and all turbines from the smallest to the largest are fitted with composition buckets, upon which many years of use with wet steam has no appreciable effect.

The paper states that the Sturtevant, Bliss and Curtis machines are provided with an emergency governor. It would be rather interesting to learn if the Terry, Dake and Kerr turbines are not similarly equipped. I should be rather surprised to learn that they were not, and if not should feel it to be a serious handicap against their successful introduction.

The author emphasizes the reliability of this type of prime mover, which to my mind is its principal reason for existence, which is greatly increased by its simplicity. These characteristics of the impulse steam turbine are practically admitted by its worst enemy, as in these particulars it is almost identical with the hydraulic turbine which, previous to the commercial development of the steam turbine, stood alone as the simplest power-producing prime mover.

I want to call attention to the statement to the effect that "in none of these machines is clearance an important factor."

This is characteristic of the steady-running impulse turbine regardless of size, and is due to the fact that in this type of machine all steam admitted through and expanded by the nozzle or nozzles, on entering the machine or any stage of it, is of a pressure corresponding to that of the stage into which it is admitted; therefore, the atmosphere surrounding the buckets is of a given density at all points, and consequently there is no tendency for the admitted steam which has been given direction by the expanding nozzle to change its course and escape into an atmosphere of its own density.

This calls to mind another feature of the small-turbine situation, which is brought prominently to notice by this paper, and that is the entire absence of any development of the so-called reaction type of turbine in the small sizes. There are good and sufficient reasons for this, but as this type of turbine is not mentioned in the paper they cannot properly be made a part of this discussion.

In closing, I wish to comment in a friendly way on the author's implication that the small turbine is less efficient than the high-speed steam engine, where he says, "The field of the small steam turbine is somewhat narrow when compared with the high-speed steam engine. The small turbine has its place, however, and with the development of a more economical machine at lower speed ranges, will have a much wider field."

I will readily admit that its present speed characteristics limit its field in comparison with the high-speed engine to the extent of the mechanical application of its output; but will not admit that the present efficiency of the Curtis type in any way limits its field in comparison with the high-speed engine, nor do I think the author intended to be so understood; but to obviate any possibility of error I will call your attention to a paper presented by Messrs. Dean and Wood before this society last June, at the Detroit meeting, and the discussion which followed by Messrs. Young and Treat, detailing the results obtained from water-rate tests of some fourteen high-grade, high-speed engines of different design and manufacture, which had been in service three months or longer.

As these water rates were given on the indicated horsepower and on the kilowatt basis, I have allowed 5 per cent. for friction in each case, to facilitate a comparison on a brake-horsepower basis, in accordance with the curves forming a part of the paper.

Mr. Dean's figures are as follows:

Engine	No. 1	No. 2	No. 3	No. 4
Capacity	[illegible]	[illegible]	110 h.p.	160 h.p.
Water rate	30.45	37.7	33.6	39.5

Mr. Wood's figures are as follows:

Engine	A	B	C
Capacity	[illegible] h.p.	[illegible] h.p.	160 h.p.
Water rate	31	35.2	35.8

Mr. Young's figures are as follows:

Engine	No. 1	No. 2	No. 3	No. 4	No. 5	No. 6
Capacity	70 h.p.	30 h.p.	28 h.p.	130 h.p.	123 h.p.	45 h.p.
Water rate	48.3	39.9	37.8	36.3	33.2	31.9

Mr. Treat's figures were as follows:

Engine	No. 1
Capacity	30 h.p.
Water rate	43

Compare the foregoing water rates per horsepower with the curves of standard Curtis turbines, as shown by the curves in Figs. 28 and 29 of this paper.

To assist in this comparison I have tabulated the results, placing the turbine water rate under the water rate of the corresponding capacity of engine and we have:

Horsepower	28	30	30	45	70	100	123	130	130	140	150	150	160	250
Engine water rate	37.8	39.9	43	31.9	48.3	35.8	33.2	36.3	35.2	33.6	30.45	37.7	39.5	31
Curtis water rate	41	41	41	32	31	30	30	30	30	29	29	29	29	29

It will be noted from the foregoing that on the smallest sizes it has been necessary to compare the half-load water rates of the turbine with the full-load water rate of the engine, for the reason that the smallest Curtis curve in the paper is 65-horsepower, but even under these conditions the average of the four smaller engines at full load is only 0.85 of a pound better than the half-load water rate of the turbine.

From this point up we have an exact comparison and at no point does the engine water rate begin to compare with that of the turbine. The nearest approach is at 150 horsepower, and here the turbine is 5 per cent. better and the widest margin at 160 horsepower, where the turbine is 36 per cent. better, while the average from 70 to 250 horsepower shows the turbine to be 22 per cent. more efficient than the engine.

But it may be said that these curves were obtained from the manufacturers and apply to new machines, while the engines were tested in service and had been in use for some time. This enables me to bring to notice the fact that the engine deteriorates with wear while the turbine does not, and it is the day-in-and-day-out water rate in which we are interested and not the builder's guarantee on the new machine.

The Curtis turbine does not fall off in efficiency due to long service, nor is its efficiency affected by adjustments, and in this connection I will refer to a statement made by Prof. R. C. Carpenter in discussing this paper at the time it was presented before the association at Washington, in which he said that he had tested a 75-kilowatt Curtis turbine which had been in service some 7000 hours and the results were not materially different from the results obtained on a new machine of the same capacity and design.

It is extremely rare that an opportunity is offered for procuring reliable data on different types of apparatus operated under identically similar conditions. I may, therefore, be pardoned for quoting from a letter recently received from a gentleman who had this opportunity and availed himself of it to profit thereby. He says in part:

"We have a 50-horsepower automatic engine, operated at 200 revolutions per minute, driving a 35-kilowatt compound-wound generator, which we use in connection with our 35-kilowatt turbine. We have made tests running the turbine and engine on alternate nights, off the same boiler and under the same conditions of load, steam pressure and exhaust, and find that for the same run and load the engine set requires 1500 pounds of coal, against 900 pounds for the Curtis turbine, or a saving in coal in favor of the turbine of about 40 per cent."

From the foregoing I am inclined to feel I may be excused for not admitting that the present efficiency of the small Curtis turbine in any way limits its field in comparison with the high-speed engine or other types of turbine.

Convention of the American Water Works Association

Occupying the entire week between June 7 and 12, the sessions of this, the twenty-ninth annual convention of the American Water Works Association, embraced every phase of the problem of supplying water to cities. Scientists, mechanical engineers and men skilled in every department of such work were present, and read papers of educational and technical value, making this one of the most successful meetings of the association. The convention, which was held at Milwaukee, Wis., was opened in the Plankington house Monday afternoon. Mayor D. S. Rose had been scheduled for the address of welcome, but he was called out of town, so Assistant City Attorney Clinton G. Price extended the keys of the city to the visitors. President French then read his annual address, after which the session adjourned until the following day.

Business was transacted promptly, and strictly according to schedule, this being made necessary by the large number of papers that had been prepared. The character and scope of them may be judged by the following list of titles and authors:

"Valuation of Water Power and Diversion Damages," by Robert C. Horten.

"Hypochloride of Lime on Mechanical and Slow Sand Filters," by A. E. Walden.

"Test and Notes on Gas Producer Pumping Plant," by J. R. Fitzpatrick.

"Fire Losses," by H. W. Wilson.

"Growth in Water Mains," by Erastus G. Smith.

"Sterilization of Water at Boonton Reservoir," by George W. Fuller.

"Sterilization of Jersey City Water," by Dr. J. L. Leal.

"Notes on 'Sterilization and Cost of Treatment,'" by George A. Johnson.

"An Attempt to Annul a Perpetual Charter," by James R. Fitzpatrick.

"Liability of Water Companies for Fire Losses," by Chester R. McFarland.

"The Wisconsin Utility Bill," by C. B. Salmon.

"Notes on Going Value and Methods by which It may be Completed," by John W. Alvord.

"Development of Water Supply at Superior, Wis., by William C. Lounsbury.

vision were: "Coal for Hand-fired Steam Plants," by D. T. Randall; "The Use and Abuse of Fuels," by H. M. Wilson; "Smoke and Smoke Prevention," by Profs. L. P. Breckenridge and K. G. Smith; "Buying Fuel by Test," by E. W. Bemis and C. F. Schultz; "The Purchase of Coal upon Heat Value Contract," by Edward H. Taylor; "Chemical Data as Related to the Power Plant," by Prof. S. W. Parr.

These papers discussed questions relating to the fuel which enters into the cost of operation of water-works systems as one of the first and most important expense items, one which may, with proper management, be reduced considerably in the majority of plants.

of boiler for different pressures, conditions, etc., was outlined. "Superheating for Duty," by Ernest H. Foster, and "Test of Pumping Engines with and without Superheating Steam," by John Primrose, the two latter being treated together by Mr. Primrose.

Much detailed information on the practical operation of plants and the cost of pumping water was contained in George G. Kennedy's contribution, "Boiler Equipment, Practice and Results at the Pumping Station of Harrisburg, Penn." "Boiler Room Symposium," by J. M. Whitham, in the absence of the author, was read by Secretary Diven, and in a paper entitled "Practical Coal Handling for Pumping Stations," by S. Bent Russell, this neces-

DELEGATES AND VISITORS AT AMERICAN WATER WORKS ASSOCIATION CONVENTION, MILWAUKEE, WIS., JUNE 7-12, 1909

"The Maidstone Epidemic," by William P. Mason.

"A Typhoid Epidemic Due to Milk," by Erastus G. Smith.

"The Sanitary Condition of the Southern End of Lake Michigan," by J. Herbert Brewster.

"The Acquisition by New York City, of the Larger Two Water Systems of Staten Island," by Leslie L. Tribus.

"Municipal Ownership of Public Utilities," by E. MacLean.

"Concrete in Water Works Construction," by William Curtis Mayley.

Thursday was devoted to papers on boiler-room economics and allied subjects. These papers were of special interest to engineers, as the questions were those directly affecting the operation of the plant from a dollars-and-cents standpoint. Among the papers presented in this di-

Another group of papers took up boiler feed water under the headings: "Boiler Water Treatment and Its Saving," by Marshall Miller; "Water Supply and Treatment for Power Plant Purposes," by William Miller Booth; "The Boiler Water," by Edward Barrow. Much of interest and value was developed from the reading and discussion of these papers.

"Milwaukee Pumping Engines" was the subject of a paper by Cornelius T. Myers, outlining the history of the city water-works pumping equipment and containing a large amount of valuable test data on the remarkably efficient results being obtained there.

Other papers of interest were: "Modern Boiler Practice," by John W. Hill, in which the construction of boilers for use in water-works pumping stations was taken up and the determining of different types

sary part of the power-house equipment was analyzed.

Officers for the ensuing year are: Dr. W. P. Mason, Troy, N. Y., president; Alexander Milne, St. Catharines, Ont., first vice-president; John W. Alvord, Chicago, Ill., second vice-president; Dow R. Gwinn, Terre Haute, Ind., third vice-president; R. J. Thomas, Lowell, Mass., fourth vice-president; J. A. Affleck, Harrisburg, Penn., fifth vice-president; J. M. Diven, Charleston, S. C., secretary-treasurer.

Of the Water Works Manufacturers' Association, the officers for 1909 are: Dennis F. O'Brien, Newark, N. J., president; Fred A. Smith, New York, N. Y., vice-president; Robert K. Mulligan, New York, N. Y., secretary-treasurer.

New Orleans was chosen as the next place of meeting.

POWER AND THE ENGINEER

DEVOTED TO THE GENERATION AND TRANSMISSION OF POWER

Issued Weekly by the

Hill Publishing Company

JOHN A. HILL, Pres. and Treas. ROBERT MCKEAN, Sec'y.

505 Pearl Street, New York.
355 Dearborn Street, Chicago.
6 Bouverie Street, London, E. C.

Correspondence suitable for the columns of POWER solicited and paid for. Name and address of correspondents must be given—not necessarily for publication.

Subscription price $2 per year, in advance, to any post office in the United States or the possessions of the United States and Mexico. $3 to Canada. $4 to any other foreign country.

Pay no money to solicitors or agents unless they can show letters of authorization from this office.

Subscribers in Great Britain, Europe and the British Colonies in the Eastern Hemisphere may send their subscriptions to the London Office. Price 16 shillings.

Entered as second class matter, April 2, 1908, at the post office at New York, N. Y., under the Act of Congress of March 3, 1879.

Cable address, "POWPUB," N. Y. Business Telegraph Code.

CIRCULATION STATEMENT

During 1908 we printed and circulated 1,836,000 copies of POWER.

Our circulation for May, 1909, was (weekly and monthly) 152,000.

June 1	42,000
June 8	36,000
June 15	36,000
June 22	36,000
June 29	36,000

None sent free regularly, no returns from news companies, no back numbers. Figures are live, net circulation.

What is the Maximum Bearing Pressure in Compound Engines?

The following question is exercising the drafting-room corps of a prominent engine factory: "Assuming a certain initial pressure of, say, one hundred and fifty pounds as applied to a simple engine, the diameter of cylinder and the dimensions of bearings, pins, etc., being designed for this pressure, what area of cylinder would be permissible in a tandem or cross-compound engine using the same bearing and pin dimensions?"

That is to say, if the engine were simple, the pins, bearings, etc., would have to be designed to sustain a pressure upon the piston of one hundred and fifty pounds per square inch, but if it were a compound, this initial pressure would be neutralized in part by the receiver pressure; but again there is the receiver pressure acting upon the whole area of the low-pressure cylinder. It is a pretty subject for discussion, and we shall be glad to have our correspondents take it up.

As to Books

A book that would tell the reader how to locate a thump in an engine, determine the efficiency of a tungsten lamp, rewind an obsolete type of arc light dynamo, analyze boiler feed water, learn all about alternating currents and locate trouble in a balky gas engine would "fill a long-felt want." We receive almost daily requests for a small manual of some such modest range, written in plain English, without any mathematics; and we wish somebody would publish one or send us the manuscript and let us publish it. Of course, there are many handbooks covering a wide range, such as Kent, Suplee, Tulley, etc., but these don't quite reach. If the price isn't too high or the treatment too scientific, the range is too low or the information is not given in sufficient detail. What is needed is a book that will tell a man anything he wants to know about any engineering subject, in a plain, practical way.

Of course, dear readers, you recognize that this is more or less of a joke, but we assure you in dead earnest that we really are asked to recommend books just as impossible as the imaginary one described in the preceding paragraph. Now, we don't mind in the least receiving and answering letters like that; the only thing about it that worries us is that we can't do what we are asked to do. Books on engineering are necessarily of two kinds: one treating a single branch or subject very fully and the other covering a wide range of subjects in very condensed style. A book written in elementary style, without any formulas, cannot deal thoroughly with a dozen branches of engineering; it would take several volumes about the size of the Century Dictionary to do that. Consequently, a general handbook covering a wide range must be limited to stating fundamental facts, without attempting complete explanations of principles or practical working instructions, and formulas must be used to save space.

Every engineer, no matter how small a job he is filling now, should have a little library of books dealing with all the subjects that relate in any way to his work. The library should include one or two good handbooks, for quick reference, but there should be at least half a dozen other books, each devoted to one branch or subject and covering that branch or subject very thoroughly. If you are shaky on simple mathematics, a good arithmetic and a very elementary algebra should occupy prominent places on the bookshelf. If you get stuck, write to us and we'll help you over the stump if we can, but don't turn up your nose at formulas or get discouraged as soon as you meet one; the road to success is a whole lot rockier without them than if you can use them. And don't forget that you can't learn much about a great many subjects from any single book.

Proper Distribution of Draft

If a boiler plant consisting of six boilers, of the same capacity, and with each boiler equipped with an individual stack, all the stacks being of the same diameter and of suitable area, but varying in hight from one hundred and fifty feet for the highest down to twenty-five feet, any engineer would at once condemn the layout and think it absurd that a design of this kind should exist. However, we believe we are safe in saying that there are hundreds of plants being operated under similar conditions, without the engineer in charge giving the matter the slightest thought.

It is rare that a plant consisting of a number of boilers has an individual stack for each boiler, but conditions approximating those just stated are frequently obtained in plants where several boilers are supplied by a single stack. Movement of flue gas is obtained by very small differences in pressure, and it is greatly affected by the slightest variations in size, shape or direction of the flue passages and the method of discharging currents from individual boilers into the main connection, or any condition tending to form eddies or pockets in the flue. On account of this sensitiveness, it is practically impossible to design a breeching or connections that will give each boiler exactly the same amount of draft. Individual dampers are generally supplied with each boiler, so that those which have the freest draft may be choked down, while the others are opened up and in this way the draft at the grate may be made the same on all the boilers.

A simple means of determining when the draft is equalized, is to note if the same amount of coal can be burned per square foot of grate under each boiler, and when this condition is obtained the position of the individual dampers can be marked, so that they may be kept set at these points while the boilers are in operation; the drafts in the furnaces can also be measured by the use of an ordinary draft gage, and the proper damper adjustments made.

Often a supposed lack of boiler capacity is merely the improper distribution of the load between existing boilers, and if you need more steam, be sure that none of your boilers are "soldiering" on account of poor draft distribution.

Engine Room Ignorance

If you were told the truth about yourself, the probabilities are that it would not be gratifying. No one sees himself as others see him, hence the jolt when brought face to face with the real facts of the individual case. There is no use beating about the bush, but rather come out into the open and make observations of your own condition as well as that of others.

The question of technical versus practical knowledge has been discussed again and again, but assuming that the engineer is fortunate enough to have acquired knowledge in both schools, one is compelled to admit that there are many things about the engine room of which he is even then ignorant. When either the technical or practical experience is lacking, this ignorance must be greatly increased in either one or the other branch of engineering science.

This ignorance in the engine room is the result of several conditions, none of which is unsurmountable.

The most common excuses for not knowing things are: "I don't have time to read." "I never had an opportunity to obtain an education." "When I have worked twelve hours in a hot, dirty, ill-ventilated engine room, I don't feel that I owe my employer any more of my time—time spent for his benefit that he will never pay me for," and so on.

Such excuses are entirely in error. You *do* have time to read, you *have* had an opportunity to obtain an education, for you have it now, and your employer will pay you for the time you spend in digging into the whys and wherefores of things; but even suppose he refuses to do so, there are others who will one.

Most engineers know that the information regarding engineering matters, as understood by the average engineer, is a long way from being complete. If this were not so, the educational work in the various organizations not only would not be continued, but would never have been instituted. In a large number of instances the leaders of such organizations are more watchful of the engineer's condition than he is himself, because of the thousands of stationary engineers in the United States but a small percentage of them are visibly interested in either the betterment of themselves or their fellow workmen.

There are no two ways about it, the engineer is either forging ahead or falling behind. The following aptly illustrates this fact: In a certain steam plant the engineer in charge somehow or other labored under the delusion that he knew enough to hold his position with his company without any more knowledge than he then possessed. Result—something happened of a nature which showed that he was not of sufficient caliber to handle the job, and he was assigned to a place in the fire room, whither he went, not with the best possible grace, perhaps, but he went nevertheless. This was a case of going backward, but who was to blame? Just one instance of lost opportunity with none to blame but "self."

In the same plant was another man, employed as electrician, who knew he did not know a good many things about engineering but wanted to know. Result—he read and studied engineering subjects, and when the regular engineer "fell down" he was placed in charge of the plant, with his former chief in the fire room. Just an instance of being ready for the opportunity, with credit to no one but himself.

Which man do you believe pursued the right course, which man was the one to pattern after, which man forced his employer to recognize his ability, and how would you have liked to have been in the engineer's place?

Easy to answer, easy to understand, easy to see the benefit of knowledge, and an easy matter to decide as to your own attitude.

Peat in the United States

The following has recently been issued by the United States Geological Survey:

A number of cities and towns in the United States may obtain their light, heat and power direct from peat bogs in the near future. The statement is made by Federal experts that millions of dollars worth of fuel lies undeveloped in the swamps and bogs of the country, awaiting only the genius and business ability of the American before it drives the wheels of progress. Its value, as a basis of its use roughly guessed at by experts of the Geological Survey, who have been studying the peat deposits for some time, is more than thirty-eight billion dollars—more money than is represented in all the property, stock, implements and buildings owned by the farmers of the United States.

With the coal supply being used at a tremendous rate peat is expected to become a most important auxiliary fuel and one that will prolong the life of the coal itself. An important fact which leads the experts to believe that peat will soon come into quite general use in certain parts of the country is that it is as a rule found in quantities in regions far removed from the coal fields, so far that the cost of transporting the coal amounts to several times the cost of the fuel itself at the mines.

The States containing the greatest amount of peat are the eastern Dakotas, Minnesota, Wisconsin, Michigan, northern Iowa, Illinois, Indiana, Ohio, New York, the New England States, New Jersey, portions of Virginia, North and South Carolina, Georgia and Florida.

A thorough investigation of the peat resources is now being undertaken by the Geological Survey, not only as to the amount of peat and its location, but also its use. Prof. Charles A. Davis of the technologic branch, has general charge of the investigations.

Professor Davis, who has just issued jointly with Edson S. Bastin a bulletin on peat, is optimistic on the future of peat, yet he believes the development of the industry should be accompanied by great caution.

"The operation of a gas engine at the experiment plant on peat in one or two tests has shown that this fuel is but little inferior to many grades of soft coal now on the market and superior to some in the quantity of power gas produced," says Professor Davis. "I believe the day is coming soon when cities located near the peat bogs and away from the coal fields will obtain their power and light from peat. I understand that Florida is to have a power plant soon that will use peat as fuel and will transmit the electricity to Jacksonville.

"In the development of this industry, however, it must be remembered that peat contains from 85 to 90 per cent. water as it comes from the bogs. All but 15 or 20 per cent. can be dried out by exposure of the peat to the air. In burning peat in gas producers to make power gas, this peat will burn successfully with 50 per cent. moisture, which is impossible in a furnace.

"The burning of peat for power, heat, or light is but one of its many uses. The byproducts of great value include coke, illuminating oils, lubricating oils, paraffin wax, phenol, asphalt, wood alcohol, acetic acid, ammonium sulphate and combustible gases of good fuel value. If used for fuel gas there is enough nitrogen stored in the peat resources of the country to supply six hundred and forty-four million tons with a value of thirty-six billion dollars in addition to the gas.

The Marion Flue Blower

The blower illustrated herewith is a permanent fixture in the rear wall of the boiler setting and blows the soot in the direction of the draft, out through the chimney, cleaning the boiler while in commission, without reducing the steam pressure.

The feature of the device is the rotating nozzle which has three, sometimes four, openings, according to the size of the boiler; these openings all pointing to a different section of the tube sheet. On the base of the nozzle casting is a flat valve seat on which a disk with one opening is held by the steam pressure. The disk may be rotated by a valve stem attached to the indicator on the handwheel, as shown in Fig. 1, and thus each nozzle opening may be blown in turn. As the nozzle is rotated while each opening is being blown, all of the boiler tubes are cleaned.

Fig. 1 shows the heavy cast-iron cap which protects the nozzle from the fire, Fig. 2 shows the parts, and Fig. 3 shows the blower installed. It is located opposite the center of the tube space, but not in the center of the boiler, and each one is constructed especially to fit the existing conditions of combustion space, firewall, etc., in the different boiler settings, a nozzle being furnished which will insure the steam reaching all tubes. This blower is manufactured by the Marion Machine, Foundry and Supply Company, Marion, Ind.

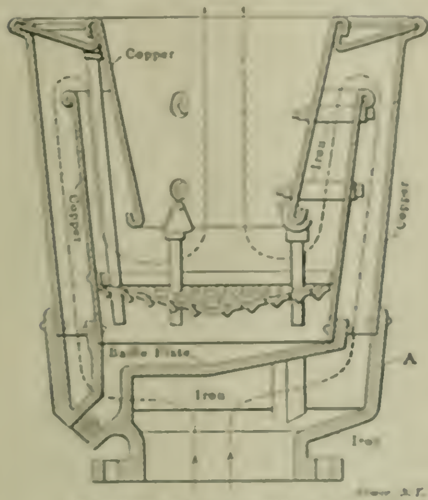
The "Neverust" Exhaust Head

The "Neverust" exhaust head, which is manufactured by Franklin Williams, 39 Cortlandt street, New York City, is novel as regards its manner of construction and the materials used. It is made entirely of copper and cast iron, which permits of making it of large size, due to the fact that owing to its lightness, it can be made of heavy gage copper and still combine strength and efficiency.

The base is composed of a cast-iron casting to which the copper shell is riveted. It will be seen from the illustration that directly over the opening at the bottom of the head is a cast-iron baffle plate, cast solid with the base of the head. To this baffle plate is riveted an inner shell, which in turn supports the outlet shell of the exhaust head, which having a turned edge at the top laps over the turned edge of the piece forming the top of the exhaust head proper. This in turn fits into the turned edge of the outer shell, thus forming the top of the exhaust head.

A drain runs from the top of the exhaust head to the upper side of the baffle plate, which is connected to the atmosphere by means of the drain as shown, thus thoroughly draining the head from all accumulation of condensed steam. The construction of the head is most rigid and thorough. The passage of the steam as it goes to the head takes the course indicated by the dotted lines. Owing to the fact that the base of the head is extended upward at *A*, the steam current



"[illegible]" EXHAUST HEAD

will not cut it away at this point, and as the steam expands at the top of the head, there is no tendency to cut at that point.

The "Success" Boiler Compound Feeder

The "Success" boiler compound feeder is manufactured by the Cunningham Boiler Specialty Company, Detroit, Mich. Three views of this device are shown herewith. As the name implies, this feeder is for the purpose of feeding boiler compound to a boiler. It feeds the exact amount required and does it with every stroke of the feed pump. The "Success" feeder is actuated by the boiler-feed pump and consequently when less water is being pumped to the boilers less compound is used, and the proportions of the neutralizing agent and feed water remain the same.

It is fitted with a glass measuring receptacle which permits the attendant to see and regulate the amount of boiler compound admitted and delivered to the boiler. No valves are employed, save one, which is a three-way plug. A duplex ratchet is used to actuate the plug which is designed to insure a slow and positive movement.

Boston A. S. M. E. Meeting Successful

On Friday, June 11, there was a very successful meeting of the Boston branch of the A. S. M. E., at the Lowell building of the Massachusetts Institute of Technology, Professor Hollis presiding and E. L. Moulthrop acting as secretary.

The meeting opened at eight o'clock with a few preliminary remarks by Professor Hollis with regard to the object of the meeting, and he invited all interested in mechanics to attend the meeting. He introduced Calvin W. Rice, who assured those present that this was not a branch meeting but a bona-fide meeting of the association, and he hoped they would so consider it.

The subject of the evening was then taken up, the discussion of Mr. Orrok's paper, which discussion was opened by Dr. Lowenstein of Lynn, followed by a representative of the Terry Turbine Company, and he by a representative of the Sturtevant people, and the local representative of the De Laval people. He was followed by a representative of the Kerr people and the paper was also discussed by Capt. Manning of the Amoskeag Mills, C. F. Crissy and Richard H. Rice of Lynn.

Professor Miller, of the Massachusetts Institute of Technology, had tabulated the efficiencies from the different curves on the board and offered a few remarks in connection with these. Charles B. Burleigh also discussed the paper, and an abstract of his remarks appears on another page of this number.

There were about 150 present.

Carborundum in Wireless Telegraphy

By J. G. Smith

Carborundum as an abrasive is undoubtedly a pretty well-known article among the readers of POWER, but it is doubtful if many are aware that it is now used by the big American wireless telegraph company, the United, as a detector in receiving instruments. In fact it has almost entirely supplanted other substances, such as silicon, molybdenite, etc., in this particular work, because of its greater reliability for all-around service, it being affected to a hardly noticeable degree by the heavy discharges of the sending apparatus, as is common with other substances, and thus not requiring new adjustment after each period of sending.

Carborundum comes from the electric furnaces at Niagara Falls in cakes about an inch or two in thickness, and in color ranges from a silver-gray to plain black, sometimes with all the colors of the spectrum interspersed, including the inimitable green of Niagara. This color scheme does not mix in one bundle, but runs in sections, and the dark blue, solid portion of a cake is the part the wireless man is after. Carborundum seems to be the hardest when the color is dark blue, and when a piece of this kind is used the oscillations give a sharp, clear tone in the receiving telephones, which quality seems to be lacking in the other colors; for when it is of any other color it seems to be softer and the sounds are inclined to be muddy.

The writer has made a careful study of this question and can properly say no carborundum of any color than can approach in any way the dark blue for sensitiveness and general results. Carborundum has a positive and negative side and careful adjustment must be made with this in view in wireless work. It also has a high resistance to direct current, but is susceptible to alternating-current oscillations, one of the reasons why it is found so useful in wireless telegraphy.

Disastrous Boiler Explosion at Denver

At 6 o'clock on the evening of June 15, a boiler explosion, serious in the loss of life it produced, occurred in the west side plant of the Denver Gas and Electric Company, which is controlled and operated by Henry L. Doherty, of New York City. The plant in question is the largest of the three stations in Denver operated by this company, and has a capacity of about 9000 boiler horsepower. It is really the main distributing station, as the other two are smaller and are tied in with the main station.

Some three years ago an addition was made to the station, and in this new part were installed two 400-horsepower Wickes vertical boilers, also a 2000-kilowatt Curtis turbine and two 1500-kilowatt direct-connected alternators. These units were supplied as much as possible with steam from the Wickes boilers, and the balance of the steam beyond their capacity was drawn from the remainder of the boiler installa[illegible], consisting of Heine water-tube [illegible]ers, the piping being so arranged that it was an easy matter to switch from the new installation to the older boilers, or draw from both as desired.

The explosion occurred in one of the Wickes boilers, which was carrying 150 pounds steam pressure. The tubes all broke away from the lower drum and the upper part of the boiler went straight up into the air for a distance of 300 feet, then dropped down through the roof of the old part of the station at a point 175 feet distant, landing directly on top of two generators, one a 500-kilowatt, 500-volt, direct-current belted machine and the other a 600-kilowatt, 2300-volt, alternating-current belted generator. Part of the gallery and railing in front of the switchboard were torn away, but the switchboard was not injured. None of the prime movers in the station was harmed in the slightest degree, and what is more strange the piping of the Heine boilers was all left intact, so that the station was put in operation in a very short time after the accident. Only the piping in the new part of the station was twisted out of place, and the second Wickes boiler was toppled over but did not explode, although it was carrying full steam pressure.

Three firemen who were working around the Wickes boilers were reported killed, among them being Chief Engineer Harry L[illegible]ner, and a child one-half a mile distant met a similar fate from flying débris. Six others in the plant were seriously injured and others in the immediate vicinity received injuries of a more or less serious character. The damage to property is estimated at $75,000, and from this standpoint the owners of the plant were most fortunate, as the general destruction of the plant might easily have been expected.

It has been rumored that low water was the cause of the explosion, the fireman pumping in a fresh supply instead of pulling the fires and observing the usual precautionary measures. Within a week previous to the explosion, William Lawless, deputy boiler inspector for the city, had made an interior inspection and W. H. Odett, chief inspector for the London Guarantee and Accident Company, had made an exterior inspection about the same time and had inspected the interior in February. Neither could account for the explosion.

It is reported that this is the first explosion of a Wickes boiler, and it will be of interest to learn from the manufacturer or perhaps from the London Guarantee and Accident Company, in which the boilers were insured, the exact cause of the explosion. Photographs of the accident and a fuller description will be published in an early issue.

Cleveland Industrial Exposition

The Cleveland (Ohio) Industrial Exposition, which was held from June 7 to 19, inclusive, was an unqualified success and unique in that it was participated in by Cleveland industries only. The project of thus exploiting Cleveland-made products was conceived in December, 1908, and it received such hearty support by the local manufacturing interests that it was soon seen that the available public halls would not accommodate the prospective exhibitors. Therefore, an exposition building having a larger ground-floor exhibit area than any other exposition structure in the country was erected. The total area was 72,030 square feet. It was nearly opposite the Central armory, the use of which for exhibition purposes was also secured, giving a total area of 114,565 square feet, including the bridge connecting the exposition building and the armory.

The walls of the new building, which was on the site of the proposed city hall, were of wood covered with staff, and it had a fire- and waterproof canvas roof supported by three huge masts mounted on structural-iron supports anchored to 30-ton blocks of iron-weighted concrete.

F. F. Prentiss, of the Chamber of Commerce, chairman of the executive committee, suggested the exposition.

Business Items

There are now in operation thirteen sets of Neemes shaking grates in the Fulton Mills of the American Woolen Company, Fulton, N. Y. The Woolen company has just ordered from Neemes Bros., of Troy, N. Y., ten more sets six feet six inches square. This will make 23 sets of these grates in use in these mills.

The Farmers' Coöperative Brick and Tile Company, of Mason City, Iowa, has ordered a 14x30-inch heavy-duty Twin City Corliss engine from the Minneapolis Steel and Machinery Company, together with transmission machinery and piping for the plant. This is the second Twin City Corliss engine that they have installed within a year.

Further improvement in trade conditions is reported by the Wisconsin Engine Company, of Corliss, Wis., which has recently shipped two more of its "higher-speed" Corliss engines, one for the Chicago, Milwaukee & St. Paul Railroad Company and the other to the Carbon brick yards, at Carbon, Penn. The above company reports a large number of inquiries, not only for its standard and "higher" speed Corliss engines, but for its complete-expansion gas engines, most of the inquiries being from well-known concerns to which operating economies are of great importance.

A new folder issued by the International Acheson Graphite Company is known as 273-B. It is descriptive of the company's graphited greases, products which are designed for gear, cup and ball-bearing use. In the manufacture of its graphited grease, the company states that it uses the purest and best graphite, which is a perfect lubricant in itself. The graphite and grease are carefully blended, and it is claimed that the resultant product will do far more work than any other grease product on the market, great value being given the combination by the superior lubricating qualities of the graphite.

The Chapman Valve Manufacturing Company recently issued $300,000 worth of preferred stock. This was done because the board of directors, in conjunction with the stockholders, believe that a better product, if such a thing be possible, must be put on the market to keep up with competition. They advise us that the Chapman valve has been the standard for high class for years. It would, therefore, appear that this company has no intention of allowing its product to remain at a standstill on past reputation, but intends to make an even greater fame for Chapman valves. Under these conditions it is not at all strange that this preferred stock has been over-subscribed three or four times, as we are given to understand from reliable sources.
